**Experimental.** Mixed metal oxides containing Cu(I), such as $CuAlO_2$, $CuFeO_2$, $CuGaO_2$, $CuNbO_3$, $Cu_5Ta_{11}O_{30}$, and $Cu_{6.78}V_6O_{18.78}$ were synthesized by SSR method according to the literatures[2-4)]. As references, $CuAl_2O_4$ and 0.7wt% Cu-loaded $Al_2O_3$ were also synthesized by SSR and impregnation method, respectively. The hydrogenation of styrene oxides using various Cu-based mixed metal (catalyst: were carried out in an autoclave toluene 2 30 mg, substrate: 2.7 mmol, solvent: mL, $H_2$ pressure: 1.0 MPa, reaction temperature: 80°C, reaction time: 18 h).

**Fig. 1. Catalytic activities for styrene hydrogenation.**

**Results and discussion.** The XRD patterns showed that the target Cu(I)-based mixed metal oxides containing Cu(I) were synthesized. **Fig. 1** shows the styrene hydrogenation performance of the catalysts at 80°C. Among the Cu(I)-based mixed metal oxides, $CuAlO_2$ exhibited the highest activity, followed by $CuFeO_2$. Two-coordinate Cu(I) oxides, $Cu_5Ta_{11}O_{30}$, $CuGaO_2$, and $CuNbO_3$ showed the activity at 100°C, while $Cu_{6.78}V_6O_{18.78}$ hardly worked for hydrogenation reaction. Cu(II) mixed metal oxide, $CuAl_2O_4$ showed lower activity than $CuAlO_2$. In addition, the low activities were obtained by using $\gamma$-$Al_2O_3$, $Cu_2O$, CuO, Cu, and $Cu/Al_2O_3$ as catalysts. XRD patterns suggested that $CuAlO_2$ retained its bulk structure at 80°C. Temperature programmed reduction profile using $H_2$ suggested that obvious $H_2$ consumption peaks appeared at higher than 200°C, while there was no reduction peak below 200°C. Cu 2p XPS and Cu $L_3$-edge XANES spectra of $CuAlO_2$ showed the surface formed Cu(II) species almost disappeared to form Cu(I) species after hydrogenation at 80°C. Thus, we consider that Cu(II) species that partially formed on the surface of $CuAlO_2$ were reduced to active Cu(I) species during the reaction. In conclusion, we found that Cu(I) species on the surface of delafossite $CuAlO_2$ are active species for $H_2$ activation at low temperature.

**Keywords:** $NH_3$ synthesis, Ru catalyst, rare-earth oxide

**Introduction**

Ammonia ($NH_3$) is one of the most preferred hydrogen carriers because it can be easily liquefied under mild conditions and its hydrogen density is larger than that of liquid hydrogen [1]. From the viewpoint of using hydrogen derived from renewable energy, the development of an $NH_3$ synthesis system and catalysts with higher activity than the current Haber–Bosch process under mild conditions is required. Ru/CeLaO$_x$ catalysts exhibit high $NH_3$ synthesis activity under mild conditions [2]. In our previous study, the substitution of La with Ti in Ru/CeLaO$_x$ catalyst increased the pore volumes, which is the principal factor enhancing catalytic activity [3]. In this study, the effect of Si addition to the Ru/CeLaO$_x$ catalyst to increase the pore volumes and improve the $NH_3$ synthesis activity was investigated.

**Results and discussion**

Figure 1 shows the relationship between the rates of $NH_3$ synthesis and Si addition Y (Y(mol%) = Si/(Ce+La+Si)) to Ru(3wt%)/CeLaO$_x$ catalyst at 350 °C. The rate of $NH_3$ synthesis exhibited a volcanic-type trend with respect to that of Si addition Y and was the highest at Y = 10. Scannig electrom microscope observations were performed to analyze the morphology of the catalysts (Figure 2). At Y = 10 the catalyst was mesoporous with no observed aggregation of $SiO_2$ particles. However, at Y = 30, $SiO_2$ particles were found in the catalyst. The observation suggests that the rate of $NH_3$ synthesis decreased as the rate of Si addition increased because the Ru on $SiO_2$ was inactive (Figure 1). The factors for improving the catalytic activity at Y = 10 in terms of the states of Ru and CeLaSiO$_x$ will be discussed.

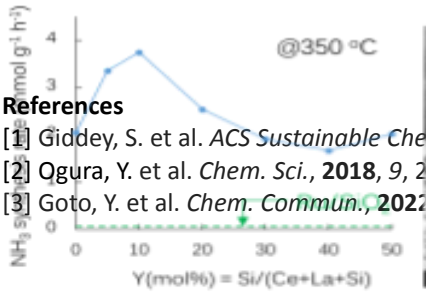

**Figure 1.** $NH_3$ synthesis rate of Si-doped Ru(3wt%)/CeLaO$_x$ catalysts at 0.1MPa and 350 °C.

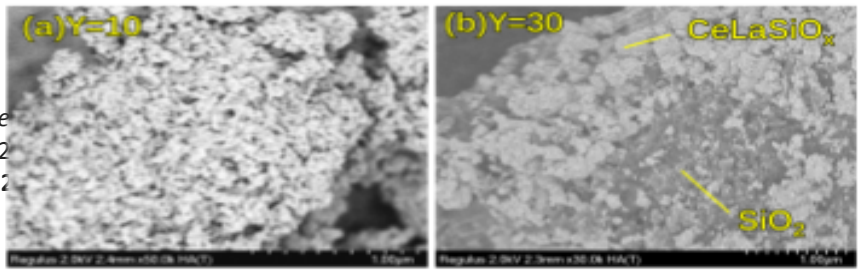

**Figure 2.** SEM images of Si-doped Ru(3wt%)/CeLaO$_x$ catalysts (a) Y = 10, (b) Y =30.

# Hydrogenation of aromatic LOHC compound over $Ru/CeO_2$ catalysts with dual functions of heterolytic $H_2$ adsorption and $H_2$ spillover

Dongun Kim, Tae Wan Kim, Young-Woong Suh*

*Department of Chemical Engineering, Hanyang University, Seoul 04763, Republic of Korea*

**Keywords:** Liquid organic hydrogen carrier, Hydrogenation, Ru–$CeO_2$ interface, Heterolytic $H_2$ adsorption, $H_2$ spillover

**Introduction.** Liquid organic hydrogen carrier (LOHC) systems, a kind of chemical $H_2$ storage technology, are based on reversible hydrogenation of $H_2$-lean molecule and dehydrogenation of $H_2$-rich one. Benzyltoluene ($H_0$-BT) is a promising LOHC material with excellent thermophysical properties [1]. Catalytic hydrogenation performance is typically dependent on the ability of $H_2$ adsorption on the catalyst surface. Heterolytic $H_2$ adsorption and $H_2$ spillover can enhance $H_2$ adsorption capacity [2]. In this respect, $CeO_2$ containing both basicity and oxygen vacancy is expected to contribute to bringing about both phenomena simultaneously [3,4]. Thus, we herein prepared $Ru/CeO_2$ catalysts with different basicity and oxygen vacancy, followed by evaluation of their hydrogenation activity and demonstration of both phenomena.

**Experimental/methodology.** $CeO_2$ samples were synthesized by precipitation using $Ce(NO_3)_3{\cdot}6H_2O$, followed by aging at 40 to 100 °C, washing, and drying at 105 °C, which are labeled as $CeO_2(x)$, where $x$ indicates the aging temperature. $Ru/CeO_2$ catalysts were prepared by wet impregnation using $Ru_3(CO)_{12}$ (Ru content: 2 wt%), followed by drying at 105 °C and activation at 500 °C in a $H_2$ flow, which are denoted as $2Ru/CeO_2(x)$. The hydrogenation activity was measured in a Parr autoclave reactor [5]. Catalytic properties were analyzed by several analysis techniques.

**Results and discussion.** The first-order rate constants for the conversion of $H_0$-BT ($k_1$) and $H_6$-BT ($k_2$) of the Ru catalysts in the hydrogenation of $H_0$-BT became higher with increasing the aging temperature (Figure 1a). Notably, the activity increase was more pronounced between $2Ru/CeO_2(80)$ and $2Ru/CeO_2(100)$ than between $2Ru/CeO_2(40)$ and $2Ru/CeO_2(80)$. In this respect, we selected $2Ru/CeO_2(40, 70, 90, \text{and } 100)$ as representative Ru catalysts for further characterization. The $CO_2$-TPD profiles showed that the quantity of basic sites as well as the fraction of strong basic sites observed in the range 290 to 298 °C were gradually increased with the aging temperature (Figure 1b). The oxygen storage capacity (OSC), corresponding to oxygen vacancy determined by $O_2$ chemisorption, was also convergently inclined as the aging temperature increased (Figure 1c). The behaviors of heterolytic $H_2$ adsorption and $H_2$ spillover were closely associated with the obtained basicity and oxygen vacancy.

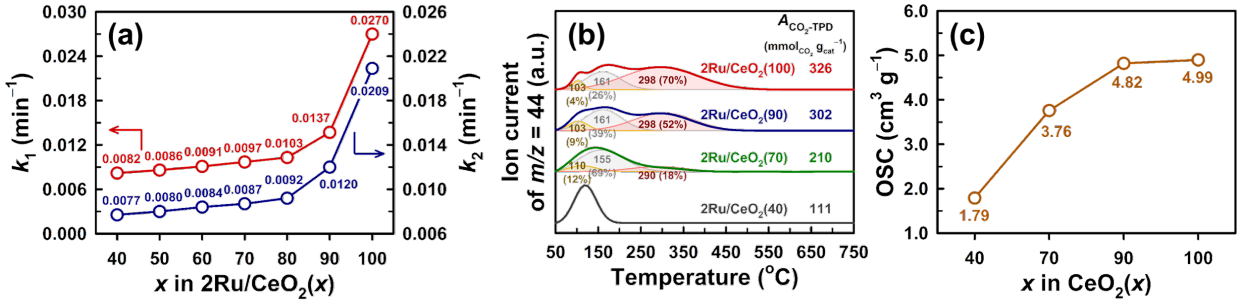

**Figure 1.** (a) Activites and (b) $CO_2$-TPD profiles of $2Ru/CeO_2(x)$ catalysts. (c) OSC results of $CeO_2(x)$ samples.

**Keywords:** Biodiesel, Heteropoly acid, Metal-organic framework, Transestrification, Acid catalyst

**Introduction.**

Renewable energy sources are now commonly used nowadays. One of them is biodiesel which has advantages like less air pollution by emission gas and non-conversion of conventional diesel engine. Biodiesel is made by plant, animal fat and waste oil. Biodiesel production includes esterification and trans-esterification reaction. Acid catalyst is known for simultainious reaction of esterification and transesterification process with addition of methanol.[1][2] Core-shell acid catalyst of ion-exchanged heteropoly acid(HPA) and metal-organic framework(MOF) is presented. HPA is known for its strong acidity but has high solubility, lack of surface area and low thermal stability. MOF has large surface area and lack of catalytic activity. By combinding two materials we made strong acid catalyst with large surface area and high thermal stability.[3] Catalysts are stabilized by strong chemical bond between HPA and MOF.[4]

**Experimental/methodology.**

To make core-shell acid catalyst, certain amout of heteropoly acids were used to coat the ZiF-8 particles under stirring condition and dried. The catalysts were used for biodiesel production using reactor. Collected fatty acid methyl ester(FAME) were analyzed using GC.

**Results and discussion.**

4 catalysts were made by different amount of HPA. To analyze the morphology of core-shell shape, Energy-Filtering Transmission Electron Microscopy (EF-TEM) and TEM Energy Dispersive X-ray Spectrometer (EDS) were used. Example of core-shell shape catalyst is shown in Figure 1. Catalyst of 1:1 weight ratio of HPA and MOF has highest conversion ratio of FAME.

# Highly Selective and Stable Zn promoted precipitated Iron Catalysts for the Production of Linear alpha olefin Via Fischer-Tropsch Synthesis

Kwang Young Kim, Gyoung Woo Lee, Geun Bae Rhim, Min Hye Youn, and Dong Hyun Chun*

*Korea Institute of Energy Research, 152 Gajeong-Ro, Yuseong-Gu, Daejeon 34129, Republic of Korea*
**cdhsl@kier.re.kr*

**Introduction.**

Fischer-Tropsch synthesis (FTS: $nCO + \{2n(+1)\}H_2 \rightarrow C_nH_{2n(+2)} + nH_2O$) is an attractive technology for the production of eco-friendly chemicals from waste biomass/plastics or carbon dioxide via syngas ($CO + H_2$) [1]. High temperature-FTS (HT-FTS) is preferred to synthesize olefinic hydrocarbon selectivity with high productivity. However, one of the main drawbacks of HT-FTS is the low stability of catalyst, which requires fused iron-based catalyst with fludized reactor. One feasible approach to overcome this drawback is using precipitated catalysts consisting of Low Temperature-FTS catalysts, such as precipitated iron-based catalysts, with various promoter. In the precipitated catalysts, the activity, selectivity and stability of the desired products is highly dependant on the active phase of iron carbide which mainly controlled by the electronic and structral promoter [2]. Therefore, it is worth drawing a clear correlation between promoter and iron carbide phase for the precision design of HT-FTS catalystsIt is important. One of structural promoter Zn, enhanced catalytic performance by improving dispersion of Fe partcile during the reaction. However, few study has yet reported a clear correlation between iron carbide phase and stability of catalyst, probably due to difficulties in elucidating Fe carbide phase and unexpected interactions between promoter and Fe catalyst. Furthermore, some conclusions are still controversial.

**Experimental/methodology.**

The Zn promoted catalysts were prepared by precipitation method with different Zn loading (~). We controlled the Zn promotional effect by adding various amount of Zn nitrate precursor. The structural and chemical properties evolution after the reaction of Zn promoted precipitated iron was characterized by Mössbauer and X-ray diffraction analysis. The FTS was performed in a fixed-bed reactor at 305 °C and 1.5 MPa using syngas ($H_2/CO$ = 5.6 NL/$g_{(cat)}$·h) for 114 h after activating the catalysts with syngas ($H_2/CO$ = 1/1, 5.6 NL/$g_{(cat)}$·h) at 280 °C and ambient pressure for 5 h.

**Results and discussion.**

The addition of Zn promoter improve the catalytic activity and stability of P-Fe (Fig. 1). The stability of Zn promoted catalysts increased as the amount of Zn promoter increased. Especially, when the Zn addition at 9 atomic %, the catalytic LAO in $C_6$-$C_8$ weight fraction is maximized (~11%). Further analysis was investigated to confirm the composition of iron carbide phase as the addition amount of Zn. The composition of $Fe_7C_3$ phase decreased dramatically with increased Zn atomic %. The increase of stability and activity of Zn promoted catalyst highly depend on the composition of iron carbide during the reaction.

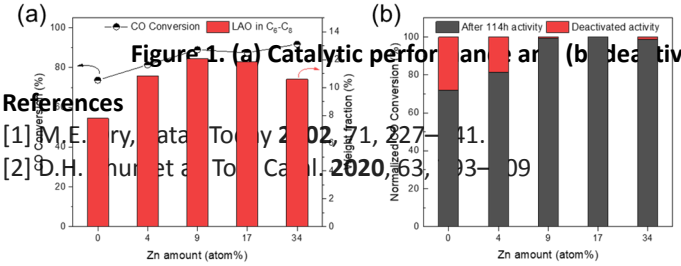

**Figure 1. (a) Catalytic perfor an e ar (b dea tivated activity of Zn promoted P-Fe catalysts.**

# Doping effect of $Ru/La_2Ce_2O_7$ catalyst in Ammonia Synthesis

Na Young Kim[1], Seok-Ho Lee[1], Seong Ho Lee[1], Kwan-Young Lee[1*]

[1]*Department of Chemical and Biological Engineering, Korea University,*

**Introduction.** Ammonia is increasingly important material as a hydrogen carrier due to its advantages such as ease of transportation, high hydrogen content, and high energy [1]. The currently commercialized ammonia synthesis method is Haber-Bosch method, which synthesizes ammonia under high-temperature and high-pressure reaction conditions to overcome high dissociation energy of $N_2$ molecules. Since it consumes a lot of energy, catalyst research is needed to synthesize ammonia at mild conditions.
The study was conducted by introducing $La_2Ce_2O_7$, which is known to have high thermal stability and good performance among oxide-based supporters [2-3]. This research aims to enhance the ammonia synthesis activity through oxygen vacancy by doping dissimilar metals to La or Ce ion site of $La_2Ce_2O_7$. Oxygen vacancy is known to be able to accelerate the rate determining step of ammonia synthesis- $N_2$ dissociation & N-H formation reactions- and has an effect of relieving hydrogen poisoning [4]. In this research, the synthesized catalyst showed good activity in ammonia synthesis reactions, and its structure and characteristics were revealed through various characterization analysis.
**Experimental/methodology.** $La(NO_3)_3{\cdot}6H_2O$, $Ce(NO_3)_3{\cdot}6H_2O$, $X(NO_3)_n{\cdot}mH_2O$, citric acid, $Ru_3(CO)_{12}$, and tetrahydrofuran (THF) were purchased from Sigma-Aldrich. Supporter and catalyst were synthesized by impregnation method. For supporter preparation, La, Ce, X precursors and citric acid were stirred in DI water at least 1h, and then solvent was removed by rotary evaporator at 80 °C. After the powder is calcined at 700 °C, 4h (5 °C/min), X-doped $La_2Ce_2O_7$ was synthesized. Then, supporter and Ru metal precursor were stirred in THF at least 1h and solvent was removed by rotary evaporator at 80 °C. After heat treatment at 500 °C to remove CO ligands, X-doped $Ru/La_2Ce_2O_7$ was synthesized.
Reaction tests were performed in fixed bed reactor under 400 °C, 0.1 MPa, $H_2/N_2$=3, GHSV=72,000 $mL{\cdot}g_{cat}^{-1}h^{-1}$. Generated ammonia was captured in $H_2SO_4$ trap and its concentration was measured by ammonia detector. Catalyst characterization was done by XRD, CO-chemisorption, TEM, XPS, and etc.
**Results and discussion.** Catalysts were synthesized differently depending on the amount of X material. No other peaks were observed in XRD data (Fig 1), it can be confirmed that aggregation does not occur and all catalysts were well synthesized.

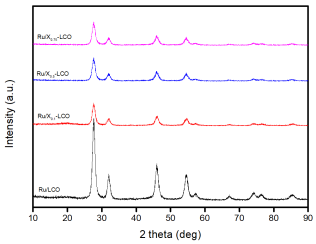

**Fig 1. XRD data**

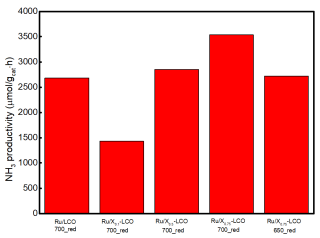

**Fig 2. $NH_3$ synthesis productivity**

Before the test, catalysts were reduced under 650 or 700 °C, $H_2$ 60 ml/min. From the result (Fig 2), $Ru/X_{0.75}$-LCO showed the highest catalyst activity in $NH_3$ synthesis reaction (3,535 $\mu mol{\cdot}g_{cat}^{-1}h^{-1}$). Also, all X-doped Ru catalysts showed more productivity than benchmarking catalyst (Ru/LCO) except $Ru/X_{0.1}$-LCO. According to these results, we can expect that certain amount of X doping enhances catalyst activity in $NH_3$ synthesis and reduces the reduction temperature of catalyst.

# The catalytic performance of Pd-M/TUD-1 catalysts (where M= Fe, Co, Cu and Ni) in cyclohexene hydrogenation

Manal M. Alshahrani[1*], Mohamed S. Hamdy[1]

[1]*Department of Chemistry, College of Science, King Khalid University, Abha, Saudi Arabia*
[*]*mm.alshahrani@kku.edu.sa*

**Keywords:** Heterogeneous catalysts; bimetallic catalysts; cyclohexene hydrogenation; Sol-gel method.

**Introduction.**

Catalytic hydrogenation of cyclohexene has attracted great attention in petrochemical industry to produce cyclohexane which used as starting materials in many processes such as nylon production, pesticides, medicines and fuels [1,2]. The multiple active sites catalysts provide catalytic performance better than single active sites catalysts due to the synergic effect of multiple active sites that provide the following important phenomena's: (i) Increasing species migration on larger surface area to prevent deactivation, (ii) Increasing of the stability of the intermediate on the catalyst surface and then leads to more conversion of these intermediates to products rapidly [3]. Herein, we report a series of supported bimetallic Pd-M/TUD-1 (M = Fe, Ni, Cu, Co) catalysts prepared by sol-gel method for cyclohexene hydrogenation.

**Experimental**

The sol/gel synthesis technique has been applied to prepare a series of supported bimetallic Pd-M/TUD-1 (M = Fe, Ni, Cu, Co) catalysts. The metal salts (normally nitrate source) have been mixed with the silica source with triethanolamine to prepare homogeneous mixture. This mixture has been treated hydrothermally and calcined to remove all the organic molecules. The prepared catalysts were characterized by several characterization techniques such as FTIR, XRD, SEM, HR-TEM, EDX, UV-Vis, Raman spectroscopy and $N_2$ physisorption to understand the structure and the properties of the prepared catalysts. The hydrogenation reaction has been carried out in Parr high pressure reactor at 1 bar pressure and 25°C for one hour. Analysis was performed by using GC which equipped with FID detector.

**Results and discussion**

The characterization results confirmed the formation of mixed nanoparticles of Pd and M (M = Co, Cu, Fe, and Ni) supposed on TUD-1 mesoporous silica. The cyclohexene hydrogenation reaction has been achieved over the bimetallic catalysts Pd-M/TUD-1 as shown in figure 1. Amongst the investigated catalysts the highest conversion of cyclohexane was obtained over Pd-Fe/TUD-1 catalyst in which 13.8% conversion was obtained with 100% selectivity towards cyclohexane. Pd-Ni/TUD-1 exhibited 10.2% conversion, while Pd-Co/TUD-1 catalyzed 6% cyclohexene conversion. The reason for such activity can be related to the higher electronegativity of iron (1.96) compared to Ni (1.88), Cu (1.85) and Co (1.84) while the Pd (1.58) has the lowest electronegativity. The difference between Pd electronegativity and metal promotors enhance the electron getting from Pd species to these metal promotors (Fe, Ni, Cu and Co) in different degrees. The increasing in electron-deficiency $Pd^{\delta}$ $^{\delta+}$ sites lead to strong interaction with electron-rich $\pi$ $\pi$ electrons of double bond in cyclohexene and the metal promotors increase the adsorption of cyclohexene on the catalyst surface and a high hydrogenation rate has been achieved. The detailed characterization results as well as the optimization of the catalysts will be discussed during the presentation.

# Effect of Alkyl Chain Length on the Structures of Dendritic Silica Supported Palladium Catalysts for Hydrogenation of Furfural

Ye Eun Kim[1,2], Panseong Kim[1], Gangmin Kim[1], Man Sig Lee[1*]

[1]*Korea Institute of Industrial Technology, Ulsan, Republic of Korea*
[2]*Korea University, Seoul, Republic of Korea*
[*]*lms5440@kitech.re.kr*

**Keywords:** Dendritic silica, Alkyl chain, Furfural hydrogenation, $Pd/SiO_2$

**Introduction.** In general, it is widely accepted that the catalytic activity can be significantly affected by the support properties, such as pore size, porous structures, and acid-base properties [1-3]. Dendritic silica with three-dimentional porous structures can lead to higher mass transfer and catalytic activity compared to traditional mesoporous silicas (MCM-41, SBA-15, KIT-16). Herein, we prepared the dendritic silicas with different structures and investigated the effect of supports on the catalytic activity.

**Experimental/methodology.** The dendritic silicas were hydrothermally treated at 120 ℃ for 6 h with varying the different kinds of alcohols as co-solvents. The synthesized powder was filtered, washed with acetone and distilled water, and dried overnight. The dried samples were calcined at 550 ℃ for 6 h to remove the surfactants. The dendritic silica supported Pd catalysts were prepared by chemical reduction method and the catalytic activity was conducted via furfural hydrogenation.

**Results and discussion.** Dendritic silicas with different dendritic structures could be successfully prepared by using various alkyl chain-containing alcohols as co-solvents. The dendritic silicas exhibited distinct morphologies, revealing a correlation between catalyst surface area and activity. When the longer alkyl chain-containing alcohols were used, the larger wall distance was observed, leading to the increase in the specific surface area and Pd dispersion. This result exhibited that the wall distance was affected by the hydrophobicity of oils and the affinity of cationic surfactant and cyclohexane. The longer alkyl chain alcohol has a tendency with hydrophobicity which interacts with cyclohexane (a hydrophobic solvent). Various dendritic silicas were used as catalyst supports, and the effect of supports on the furfural hydrogenation was observed. The larger specific surface area and wall distance showed the increase in the initial reaction rate in 1 h as well as an improvement in selectivity toward tetrahydrofurfuryl alcohol. The larger specific surface area and wall distance resulted in an increase in the initial reaction rate within 1 hour, as well as an improvement in selectivity. This improvement was attributed to the enhanced specific surface area, providing a uniform Pd dispersion area for better interaction with reactants. In conclusion, the dendritic silica-based catalyst with a larger wall distance improved catalytic activity due to its larger specific surface area and higher mass transfer efficiency.

# Ba-Si Oxynitride-Hydride as a Transition Metal-Free Catalyst for Ammonia Synthesis

M. Kitano*, Z. Zhang, M. Miyazaki, H. Hosono

[1] *MDX Research Center for Element Strategy, International Research Frontiers Initiative, Tokyo Institute of Technology, Yokohama, Japan*

**Keywords:** Oxynitride-hydride, ammonia synthesis, anion vacancy

**Introduction.** Catalytic ammonia synthesis is vital for production of fertilizer, which is needed to produce food for the world's expanding population. Dissociation of $N_2$ and $H_2$ to form ammonia generally occurs on the surface of supported transition metal (TM) particles such as Fe and Ru. The ammonia formation reaction can be promoted by electron donating support. Recently, combination of TM and hydride materials has been demonstrated to function as efficient catalysts for ammonia synthesis under mild reaction conditions.[1,2] TMs, however, are still irreplaceable as active centers for $N_2$ dissociation in most cases. In the present study, we fabricate a novel Ba-Si oxynitride-hydride with high concentration of $H^-$ and $N^{3-}$ ions via low-temperature solid-state reaction, and demonstrate its excellent ability for TM-free $N_2$ activation to produce $NH_3$ continuously under mild conditions.

**Experimental/methodology.** $Ba_3SiO_{5-x}H_yN_z$ powder was prepared by a solid-state reaction of $SiO_2$ with $Ba(NH_2)_2$ at 400-700°C for 12 h under $NH_3$ atmosphere. XRD, FT-IR, HAADF-STEM, XPS, XAFS, FT-IR, TPD, $N_2$ adsorption-desorption were used to characterize the catalysts. Ammonia synthesis reactions were conducted in a fixed bed flow system and the produced ammonia was trapped in 5 mM sulfuric acid solution and the amount of $NH_4^+$ generated in the solution was determined using ion chromatography.

**Results and discussion.** $Ba_3SiO_{5-x}N_yH_z$ without any TM site shows continuous ammonia production at ca. 0.37 mmol $g_{cat}^{-1}$ $h^{-1}$ without degradation in activity during the 150 h test at 400°C and 0.9 MPa. The total amount of ammonia was estimated to be ca. 5.25 mmol (per 0.1 g of catalyst), which is much higher than that of the amount of $N^{3-}$ (0.16 mmol) and $H^-$ (0.37 mmol) in the lattice, and indicates the ammonia produced originates from the activation of molecular $N_2$ and $H_2$ but not from the decomposition of $Ba_3SiO_{5-x}N_yH_z$. Neither $Ba_3SiO_5$, $Ba(NH_2)_2$ nor $SiO_2$ powder exhibits activity for ammonia synthesis, even at temperatures up to 540°C, while the $Ba_3SiO_{5-x}N_yH_z$ powder can effectively activate $N_2$ to produce ammonia at temperatures down to 300°C (0.04 mmol $g^{-1}$ $h^{-1}$, Fig. 1). The lattice heteroanions of $H^-$ and $N^{3-}$ are easily desorbed to form a high concentration of $V_a$ sites with confined electrons, where $N_2$ can be captured and directly activated to ammonia in the absence of any TM site. FTIR experiment revealed that $Ba_3SiO_{5-x}N_yH_z$ exhibits an $N_2$ adsorption peak centered at around 2016 $cm^{-1}$, which is much lower than that of conventional Ru catalysts and the reported electride-based catalyst (Ru/C12A7:$e^-$, 2176 $cm^{-1}$). This result indicates that electrons trapped at the surface anion vacancy sites directly interact with $N_2$ and facilitate π-back donation into the antibonding orbital of the $N_2$ molecule, which leads to a shift of the $N_2$ adsorption band.

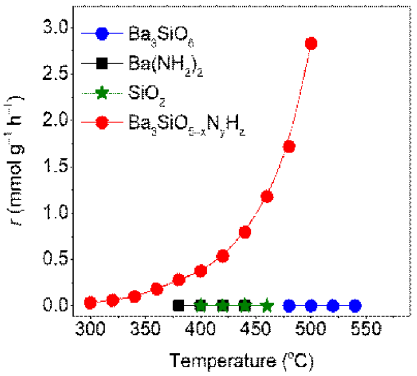

**Fig. 1** Temperature dependence of the ammonia synthesis rate over various materials without TMs.

# Plasma-Supported Catalytic Synthesis of Light Hydrocarbons

J. Titus[1,2] , T. Lorenz[2], M. Drößiger[2], O. Kuschel[1], C. Koch[2*]

[1]*Institute of Chemical Technology, Universität Leipzig, Leipzig, Germany*

**Keywords:** plasma catalysis, light hydrocarbons, $CO_2$ conversion

**Introduction.** Methane and carbon dioxide count as two main contributors to the greenhouse effect. Hence, their emission needs to be reduced. While $CO_2$ as thermodynamically highly stable molecule is widely inactive, recent research focuses on its hydrogenation. A promising, but thermodynamically challenging route is the dry reforming of methane in which $CO_2$ and $CH_4$ are converted at elevated temperatures to form synthesis gas. An alternative pathway to thermal catalysis is the excitation of the reactants in a plasma [1]. Here, we report the catalytic synthesis of light hydrocarbons and oxygenates from $CO_2$ and $CH_4$ in a dielectric barrier-discharge (DBD) reactor. Besides a variation of the catalyst, the effect on plasma parameters and product gas composition is investigated.

**Experimental/methodology.** An equimolar stream of $CO_2$ and $CH_4$ is lead through a self-build V-DBD reactor in which plasma is generated at temperatures up to 573 K. The plasma is ignited using a novel electrode material. The reaction products are studied via GC. To enhance the selectivity toward defined reaction products, the catalyst powder is introduced within the plasma according to in-plasma catalysis. Since the reaction is conducted within the plasma, its effect on catalysts is studied by investigating varying active metal loaded alumina-supports. These were prepared eighter by sol-gel method [2] or via incipient wetness-impregnation, to distinguish additionally the effect of preparation method and catalyst characteristics on the resulting plasma.

**Results and discussion.** The novel electrode material allows the generation of a plasma, which is indicated to be a highly diffusive plasma-mode (Fig. 1). Further, the determination of energy input needed to ignite the plasma, even in presence of $CH_4$ and $CO_2$ suggest, that the excitation of reactants follows the so called ladder climbing pathway. Hence, the dissociative pathway is expected to be suppressed. Besides the reduction of energy input into the plasma, the reaction product distribution is limited favoring, e.g. C-C coupling.

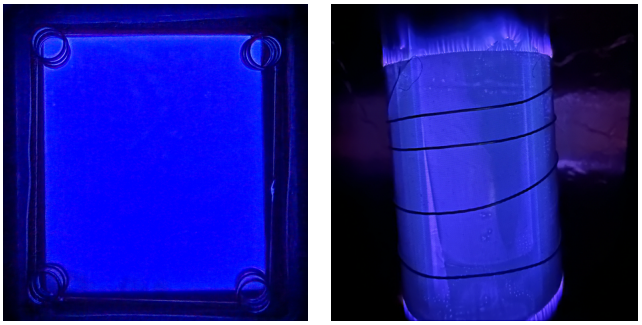

**Figure 1: Image of the plasma generated using the novel electrodes in presence of a catalyst, or planar (left) and tubular (right) catalyst studies.**

By exciting $CO_2$ and $CH_4$ within the plasma, resulting reaction products were found to be short chained ($\leq C_4$) hydrocarbons. Hence the formed, excited species follow a C-C coupling mechanism. The presence of alcohols leads to the conclusion, that not only $CH_4$ participates in the reaction, but also the $CO_2$ is inserted within the reaction products.

**Keywords:** metal organic frameworks, supported catalysts, dry reforming of methane, strong metal-support interactions.

**Introduction.** Dry reforming of methane (DRM) using carbon dioxide ($CO_2$) is an inimitable approach for eliminating both greenhouse gases, methane and $CO_2$, emissions while producing synthesis gas which further can be converted to useful fuels.[1] However, the industrialization of DRM has been limited due to sintering and carbon accumulation (coking) issues related to the catalysts under the harsh reaction conditions.[2] Here, we developed a new methodology for producing supported nickel-based catalysts with tunable metal-support interface for DRM using metal organic frameworks (MOFs) as precursors of the catalyst components (both metal and support).

**Experimental/methodology.** The MOFs derived catalysts were obtained by calcining coalesced (through sonication) Ni-BDC and La-BDC MOFs at different temperatures. The obtained catalysts were characterized using XRD, SEM, TEM, temperature programmed physisorption and chemisorption. Finally, the catalytc activity was tested towards DRM at extreme environments of 800 °C and high gas hourly space velocities.

**Results and discussion.** In this work, we produced tunable supported Ni-based catalysts consists of strong metal-support interactions (SMSIs) for dry reforming of methane using MOFs as precursors for synthesizing Ni/NiO nanoparticles supported on different lanthanum phases ($La_2O_3$, $La_2O_2CO_3$, and $La(OH)_3$).

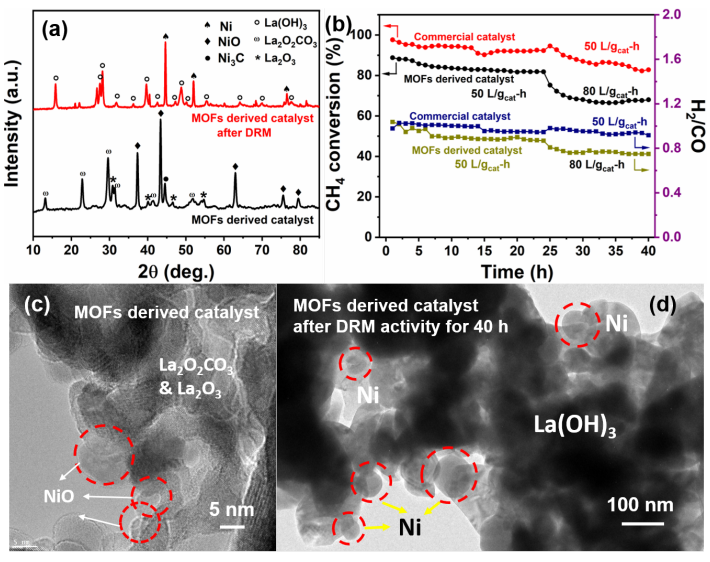

**Figure 1: (a)** XRD patterns of as synthesized and spent MOFs derived catalyst, **(b)** comparison of DRM activity of MOFs derived catalyst with commercial catalyst; TEM images of **(c)** as-synthesized and **(d)** after DRM activity of MOFs derived catalyst, respectively.

**Figure 1a** shows the phases formed before and after DRM activity of the MOFs derived catalyst. The DRM activity in **Figure 1b** demonstrate that the MOFs derived catalyst exhibited stable and high $CH_4$ conversion rates even at high gas hourly space velocities. Although the commercial catlayst has shown high $CH_4$ conversion rate at initial hours, a continuous decrease in conversion rate was observed at lower GHSV, which lacks the stable catalytic activity. The TEM images shown in **Figure 1c** and **1d** reveals that the MOFs derived catalyst exhibit SMSIs with no coking and minimal sintering (bottleneck of industrializing the DRM reaction). Since the supported catalysts with these qualities are highly desirable for the industries, the present synthesis can open up avenues to produce supported catalysts for the energy production sector.

**Keywords:** nitrogen-doped carbon, zeolite-templated carbon, metal clusters, catalyst support, hydrogenation reactions

The electronic properties of metal catalysts are modulated by the interaction of the metal clusters with a catalyst support. Due to the chemical intertness of the carbon surface basal plane, the electronic interaction between carbon supports and the noble metal is weak. To provide stronger interaction, this study exploited functionalization of 3D graphene-like zeolite-templated carbon materials with nitrogen heteroatoms to create nitrogen-containing surface functional groups and defective centers. Catalytic activity, selectivity and stability can be adjusted by modulation of the metal–metal coordination in 3D graphene-like zeolite-templated carbon materials.

3D graphene-like microporous carbons (β-(N)carbon and Y-(N)carbon) were prepared using the beta (*BEA) and faujasite (FAU) zeolites in the $H^+$ form of the molecular Si/Al ratios 4 – 12 as hard templates. Chemical vapour deposition was performed to execute the carbonization process with the appropriate carbon and nitrogen precursors. Pyrrole as a nitrogen precursor was used for incorporation of the pyridinic and pyrrolic groups. The use of acetonitrile as a carbon and nitrogen precursor led to the formation of graphitic nitrogen. Typical procedure for carbonization consists of a carbon deposition with diluted stream of the carbon and nitrogen precursor at 700 - 850 °C and sample heat treatment in a stream of nitrogen at 900 °C. The zeolite/carbon composite was leached in aqueous solutions of hydrofluoric and hydrochloric acids to remove zeolite template. The impregnation with organic solutions of corresponding element salt in hexane or acetylacetone as solvents allowed the introduction of metal clusters (Pt and Pd) into carbon materials.

Hydrogenation of 1,3-butadiene, 1-hexyne and benzene (as model compounds) allowed the evaluation of the effects of increased interaction with the support and reduced metal–metal coordination on activity, selectivity and stability. The conventional metal supported catalysts were used to compare activity and stability. The method enabled an adaption of the electronic properties and the dispersity of active metal clusters on the (N)carbon catalysts to increase the reaction rates and to tailor the activity, selectivity and stability of the catalyst.

**Keywords:** carbon dioxide utilisation, exsolution, dry reforming, greenhouse gases, efficient catalysts

**Introduction.** Innovating technologies to efficiently reduce carbon dioxide ($CO_2$) emissions or covert it into useful products has never been more crucial in light of the urgent need to transition to a net-zero economy by 2050. The design of efficient catalysts that can make the above a viable solution is of essence. Many noble metal catalysts already display high activity, but are usually expensive. Thus alternative methods for their production are necessary to ensure more efficient use of noble metals. Exsolution has been shown to be an approach to produce strained nanoparticles, stable against agglomeration while displaying enhanced activity[1]. Here we explore the effect of a low level of substitution of Ni into a Rh based A-site deficient titanate aiming to investigate the formation of efficient, low loading noble metal catalysts. We show that this design principle not only fulfils a major research need in the conversion of $CO_2$ but also provides a step-change advancement in the design of tandem catalysts.

**Experimental/methodology.** The perovskite oxide powders were synthesized by a modified solid-state synthesis. In order to exsolve particles, the samples were reduced at temperature in a controlled atmosphere furnace, under continuous flow of $H_2$ with heating/cooling rates of 5 °C/min. To measure the effect of reduction temperature on the exsolution of Rh particles, 800 °C and 1000 °C with a dwell of 10 h were used. The crystalline phase components of all freshly prepared and reduced samples were investigated using X-ray diffraction, scanning and transmission electron microscopy were used to study the nano and microstructure of the materials and an Image processing program (ImageJ) was used to carry out the particle morphological analysis. Thermogravimetric analysis and temperature programmed oxidation were carried out to measure extent of reduction and carbon deposition. Catalytic testing was done under a reactant gas mixture of (12.5% $CH_4$: 12.5% $CO_2$: 75% $N_2$) from 600 to 800 °C.

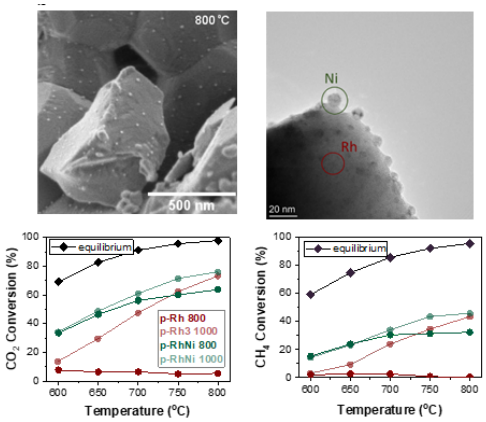

Figure 1: a. SEM and TEM images of the exsolved samples b. Catalytic testing

**Results and discussion.** The results here (fig1) demonstrate that doping of Ni could indeed enhance its exsolution capabilities driving more Rh particles towards the surface of the perovskite, also demonstrating significantly improved catalytic activity in DRM reaction compared with its undoped counterparts reduced

at the same temperature. However, temperature still seems to be a greater driving force for exsolution of cations from a perovskite lattice. Nevertheless, we demonstrate that there might be a way to produce catalysts with distinct active sites that could be employed for what we normally call tandem catalysis. These materials are produced in a single step and could avoid any deactivation mechanisms usually caused by the degradation of two or more catalysts put together in an assembly method.

# Pt-, Ru- modified H-Beta, H-Y zeolites and H-MCM-41 mesoporous material extrudate catalysts for synthesis of menthol from citronellal: Influence of structures, acid sites Pt- and Ru- metal nanoparticles size distributions

*[1]N. Kumar, [1]Z. Vajglova, [1]P. Mäki-Arvela, [1]K. Eränen, [2]M. Peurla, [1]D. Yu. Murzin, [1]Åbo Akademi University, Laboratory of Industrial Chemistry and Reaction Engineering, Faculty of Science and Engineering, Henriksgatan 2, FI-20500 Turku/Åbo, Finland, [2]Turku University, Institution of Biomedicin, FI-20140, Turku, Finland*

Increased demand of menthol for applications in the pharmaceutical, medicinal, food and fragrance industry requires enhancing the current synthetic route of production. Utilization of different catalytic formulations and optimization of reaction conditions are important for enhancing the production of synthetic menthol. In the present research the main aims were synthesis and physico-chemical characterizations of Pt-, Ru- modified H-Beta, H-Y zeolites and H-MCM-41 mesoporous material extrudate catalysts. Further aim was application of these acidic, Pt- and Ru- modified extrudates for the production of menthol from citronellal. Pristine H-Beta, H-Y extrudates were synthesized using bentonite binder with varying compositions. H-MCM-41 mesoporous material extrudate was synthesized using colloidal silica bindzil binder. Pt-, Ru- modifications were carried out using *in-situ* and post synthesis modifications. Physico-chemical characterization of pristine H-Beta, H-Y, Pt-H-Y, Pt-H-Beta (Fig 1), Ru-H-Beta, Ru-H-Y (Fig 2) and Ru-MCM-41 revealed that method of introduction of Pt-, Ru- in the extrudates influenced metal nanoparticle size distribution, location and dispersion. The physico-chemical characterizations were carried out using several instruments such as XRD for phase purity and $N_2$-physisorptions for textural properties, surface area, pore volume and pore size distributions. Pt-, Ru- metal nanoparticles size distributions were measured using TEM and SEM was utilized for determination of morphological features of the extrudates. Evaluations of the catalytic properties of the Pt-, Ru- modified extrudates in the transformation of citronellal to menthol were carried out in trickle bed reactor at pressure 10 bar, temperature 70 $^{o}$C. The catalysts were pretreated in flow of hydrogen at 350 $^{0}$C prior to catalyst evaluations. The zeolite structure, amounts of Brønsted and Lewis acid sites of pristine H-Beta, H-Y, Pt and Ru modified H-Y, H-Beta extrudates were observed to influence the conversion of citronellal and selectivity to menthol. Furthermore, Pt- and Ru- metal nanoparticle size distributions, locations and dispersion were also observed to influence the conversion of citronellal and selectivity to menthol.

# CuFe@zeolite catalysts selectively hydrogenate C≡C triple to C=C double bond

A. Kurbanova*, J. Přech, S. Kurucová, M. Mazur, D. Zákutná

*Dept. of Physical and Macromolecular Chemistry, Faculty of Science, Charles University, Albertov 6, Prague 2, Czech Republic*

**Keywords:** Reductive demetallation, zeolite, hydrogenation, hydrogenolysis, triple bond, ester

**Introduction.**

Selective reduction of C≡C triple to C=C double bond, avoiding full saturation of the hydrocarbon, is an important reaction in many petrochemical as well as fine chemistry processes. Typical catalysts for this reaction are based on palladium, sometimes partially poisoned with lead (Lindlar catalyst). Nevertheless, application of noble metals as well as heavy metals raises environmental and cost issues since the production of noble metals is costly and energy-intensive while, e.g., lead compounds are poisonous. Thus, replacing these metals with other inexpensive transition metals such as Fe, Cu, and Zn without sacrificing the selectivity, would necessarily reduce their production costs as well as the ecological footprint. Encapsulating the metallic particles in a zeolite carrier could then provide and stabilize fine dispersion of the metallic particles.

In this contribution, we present preparation and catalytic performance of CuFe and CuZn bimetallic nanoparticles encapsulated into zeolite channels in the partial hydrogenation of C≡C bond. We also demonstrate potential of these catalysts in ester hydrogenolysis.

**Experimental/methodology.**

The CuFe@zeolite and CuZn@zeolite composite catalysts are produced by reductive demetallation of Fe-MFI or Zn-VET zeolites followed by ion-exchange into $Cu^{2+}$ forms. Reductive demetallation means a transformation of framework $Fe^{3+}$ and $Zn^{2+}$ metal ions into metallic nanoparticles, where the metal has oxidation state 0, under $H_2$ atmosphere at high temperatures [1,2]. The reductive demetallation is accompanied by the formation of defects in the zeolite structure nevertheless, the zeolite structure does not collapse. Catalytic hydrogenation of ethynyl anisol to vinylanisol was carried out in heptane at 5 bar $H_2$ pressure and 50°C. Hydrogenolysis of methyl laurate was performed at 100 bar $H_2$ at 250°C.

**Results and discussion.**

The CuFe@MFI (3% wt. Cu, 2% wt. Fe) and CuZn@VET (3% wt. Cu, 7% wt. Zn) gave 21% and 16% conversion after 3 h, respectively, in 3-ethynylanisole hydrogenation. The Lindlar catalyst (5% et. Pd, poisoned with Pd) gave 100% and a 2% $Pd/SiO_2.Al_2O_3$ reference provided 85% conversion. Nevertheless, at 20% conversion, CuZn@VET provided 84% selectivity towards 3-vinylanisole and CuFe@MFI 80% selectivity. These selectivity values are comparable with the selectivity of the Lidlar catalyst (94 % at 22% conversion) under the same conditions while $Pd/SiO_2.Al_2O_3$ exhibited 85% selectivity. Taking into account the above cost and environmental issues, the CuFe and CuZn composite catalysts represent a promissing alternative to the state-of-the-art Pd based catalysts.

CuZn mixed oxides are also established catalysts of ester hydrogenolysis. Similarly, the CuFe@MFI catalyze methyl laurate hydrogenolysis to lauryl alcohol and methanol. In contrast to the CuZn mixed oxides, it also exhibits significant transesterification activity (yielding lauryl laurate with 60% selectivity at 50% conversion) whose origin is likely from remaining share of acid sites in the catalyst. Thus, tuning the demetallation conditions should control the transesterification activity.

**Keywords:** catalytic combustion of volatile organic compounds, transition metal oxide catalysts, ceramic monoliths, 3D printing, MFI zeolite washcoat

**Introduction.** The emission of volatile organic compounds (VOCs) into the atmosphere remains a serious problem that poses both an environmental threat and a negative impact on human health [1]. Extensive scientific research has led to the development of several effective methods for the VOCs elimination. Among them, the catalytic combustion has appeared to have the greatest potential for the removal of organic pollutants from a very dilute air stream. However, passing the polluted air through a catalytic converter at a high volumetric flow rate may result in an observed pressure drop in the bed constructed of powder catalyst. This disadvantage disappears when monolithic reactors are used. In the presented work, the application of technique of manufacturing ceramic monoliths supported by 3D printing was proposed. As the active phase, transition metal oxides were used, which are less expensive and more resistant to the presence of heteroatoms than noble catalysts.

**Experimental.** The ceramic monoliths were obtained by the templating technique using 3D printed resin-based matrices. The prepared resin templates were modified using a paste consisting of α-$Al_2O_3$ powder dispersed in a sodium silicate solution and calcined at 850 °C [2,3]. Afterward, the surface of the monolith was coated with a MFI zeolite layer to increase porosity and thus develop the specific surface of support. Finally, different amounts of precursors of the active phase (i.e. single Co, Cu, and Mn oxides, as well as their mixtures) were introduced by the wet impregnation and coprecipitation methods. The calcined materials were characterized in terms of morphology (SEM), chemical composition (XRF), structure (XRD), texture parameters ($N_2$ adsorption), surface composition (XPS), reducibility ($H_2$-TPR), as well as were tested as catalysts in the total oxidation of toluene under various conditions.

**Results and discussion.** Preliminary catalytic tests revealed that a major difficulty in maintaining stable operation of the catalytic system working in the total oxidation of toluene is a large amount of heat released during the exothermic reaction. To avoid this negative effect, we proposed the use of a catalytic bed consisting of a cascade of variously modified short monoliths instead of one long monolith. In the developed system, the heat released in the first part of the catalytic bed (active at lower temperature) is used to heat the reacting mixture to the temperature required for activity in the next part of the same bed (active at higher temperature). Various arrangements of short monoliths, differing in composition, were tested. The best catalytic results were achieved over properply arranged the monolith systems consisting of individual CuO or $Co_3O_4$ oxides, as well as mixed Cu-Mn-O. Furthermore, it was proven that the catalytic activity in the studied catalytic system is correlated with the mobility of lattice oxygen involved in the oxidation process according to the Mars–van Krevelen mechanism.

# Fe-modified $SrTiO_3$ and Mn-modified $SrTiO_3$ as materials for environmental catalysis

A. Łącz*, P. Gwóźdź, N. Moskała, S. Komarek, E. Drożdż

*AGH University of Science and Technology in Krakow, Faculty of Materials Science and Ceramics, Poland*
**alacz@agh.edu.pl*

**Keywords:** Mn-doped $SrTiO_3$, Fe-doped $SrTiO_3$, catalyst, NOx reduction

**Introduction.** There has been a growing interest in the use of perovskite-based materials in environmental catalysis in recent years. One of the concepts is the application of strontium titanate ($SrTiO_3$) doped with *d*-metals for NOx reduction by ammonia ($NH_3$-SCR). The possibility of incorporation of manganese or iron into the Ti-sublattices in the $SrTiO_3$ perovskite structure can be controlled by introducing non-stoichiometry into Sr-sublattice. Thus, the materials with various levels of non-stoichiometry and various Fe/Mn content were obtained and studied to evaluate the impact of strontium deficiency on the structure and catalytic properties of Mn-doped $SrTiO_3$ and Fe-doped $SrTiO_3$.

**Experimental/methodology.** The strontium titanate-based materials modified with Mn/Fe were synthesized by the sol-gel method. The powders with the nominal compositions: $SrTi_{0.98}Me_{0.02}O_3$, $Sr_{0.95}Ti_{0.98}Me_{0.02}O_3$, and $Sr_{0.90}Ti_{0.90}Me_{0.10}O_3$ (where Me = Fe or Mn) were obtained by the proper thermal treatment with the calcination at 900°C for 3 hours performed in the flow of air as a final step. The materials were characterized in terms of their structure (XRD analysis) and microstructure (SEM observations, the specific surface area measurements (BET), and dynamic light scattering (DLS) analysis). Additionally, to evaluate the material's redox properties temperature-programmed reduction (TPR) and temperature-programmed oxidation (TPOx) measurements were performed. To assess the possibility of using the obtained materials in environmental catalysis the catalytic tests were performed - selective catalytic reduction of NOx with ammonia ($NH_3$-SCR) and selective catalytic oxidation of ammonia ($NH_3$-SCO) were chosen as the test reactions.

**Results and discussion.** The analysis of XRD results showed that all Fe-modified materials were single-phase since only strontium titanate with the cubic structure was identified. For Mn-modified materials, strontium titanate was also observed however for the samples with the highest amount of introduced manganese a small amount of additional phase - $Mn_3O_4$ was also observed. Nevertheless, these results clearly showed that the introduction of non-stoichiometry in the Sr-sublattice has a positive impact on the incorporation of dopant into the perovskite structure. The performed catalytical test implied that Mn-modified $SrTiO_3$-based materials have better catalytic performance compared to Fe-modified $SrTiO_3$. The conversion of NO in $NH_3$-SCR reaction calculated for a temperature range of 100 – 600°C for materials doped with Mn is presented in Figure 1. It should be underlined that the change of the reaction from $NH_3$-SCR to $NH_3$-SCO is clearly seen for all materials regardless of the amount of introduced dopant and the assumed Sr non-stoichiometry.

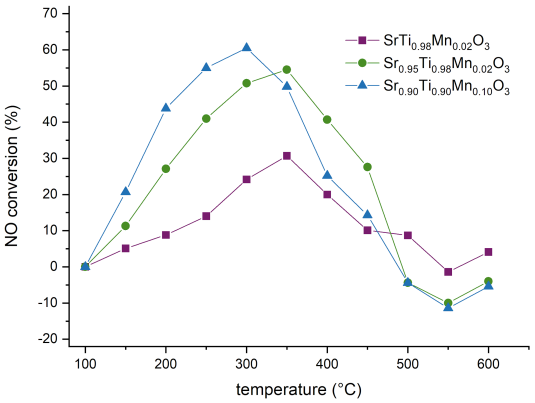

Figure 1. Conversion of NO in $NH_3$-SCR reaction as a function of temperature for Mn-modified $SrTiO_3$ materials.

# The cluster model for ZN catalysis: Understanding catalyst activation and deactivation pathways

Giuseppe Antinucci*, Felicia D. Cannavacciuolo, Christian Ehm, Roberta Cipullo, Vincenzo Busico

*Department of Chemical Sciences, University of Naples Federico II, Naples, Italy*
**giuseppe.antinucci@unina.it*

**Keywords:** Ziegler-Natta catalysts, DFT, activation mechanism, active sites model.

**Introduction.** Detailed mechanistic understanding of industrially relevant heterogeneous catalysts is rare; as a matter of fact, discovery and even optimization are mostly driven by empiricism. Ziegler-Natta catalysts (ZNCs) for the production of isotactic polypropylene are no exception in this respect. Modern ZNCs are complex multicomponent formulations.[1-3] Nanostructured $MgCl_2$ is used as support, on which a titanium compound (generally $TiCl_4$) and a Lewis base called "Internal Donor" (ID) are co-adsorbed (where ID is an organic donor such as an aromatic or aliphatic mono- or diester, or a 1,3 diether). Activation of the precatalyst is carried out by an $AlR_3$ species (typically $AlEt_3$), usually mixed with another organic Lewis base, generally an alkoxysilane, called "External Donor" (ED).[2,3] Among the several models that have been proposed to explain donors (and possibly Al-alkyls) effects on the active Ti sites of ZNCs, the most recent and widely accepted one is the so-called "three-site model" (Figure 1).[4] According to this model, the first coordination sphere of Ti, assumed to be in the Ti(III) oxidation state, is always octahedral and $C_2$-symmetric (like in crystalline $TiCl_3$)[4]; steric hindrance in the second coordination sphere, on the other hand, can vary depending on whether or not the first-neighbour surface Mg or Ti atom on either side exhibits a coordination vacancy.

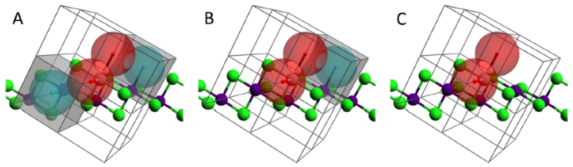

***Figure 1.*** *Three-site model for ZN active sites.* [4,5]

**Experimental/methodology.** In the present work, we extended the DFT-D 'flexible-cluster' approach[6] to the computational modeling of activation and deactivation pathway in ZN catalysis. The approach offers a good compromise between speed and accuracy, and has great potential for realistic simulations of the catalytic species in industrially relevant formulations. All geometries were optmized at TPSS/cc-pVDZ level of theory, followed by a single point energy calculations at M06-2X/cc-pVTZ level.

**Results and discussion.** Here we provide experimental and computational evidence that $TiCl_4$ and the other components of the formulation (*i.e.*, donor and $AlR_3$ species) are more intimate than has been assumed so far, to the point that these systems resemble immobilized molecular catalysts more than conventional heterogeneous ones. Invoking such (metastable) species can explain some long-standing 'mysteries' regarding activation and deactivation pathways in ZN catalysis. As a matter of fact, state-of-the-art DFT-D modeling reveals how the formation of metastable $TiCl_4$-$\mu$-$AlR_3$ surface species allows for low-energy activation and reduction pathways of $TiCl_4$. Similarly, direct coordination of the external donor to the Ti can explain how catalyst deactivation mechanisms, *e.g.* Cl/OR (R = Me, Et, etc.) metathesis, can occur.

Last but not least, consequences on active site models for the stereoselectivity in the chain propagation step will also be highlighted.

[*] *E-mail: lamac@jh-inst.cas.cz*

**Keywords:** Lewis acid, borane cluster, hydrosilylation, deoxygenation, heterogeneous catalysis

**Introduction.** Reactions catalysed by acid-based catalysts are of general importance in industrial chemistry. Heterogeneous catalysts are typically preferred based on many advantages they possess in practical applications. On the other hand, molecular borane derivatives, such as the ubiquitous $B(C_6F_5)_3$ (BCF),[1, 2] have been demonstrated to act as strong Lewis acid homogenous catalysts in many reactions, including those featuring uncommon mechanisms (e.g., Frustrated Lewis pair chemistry). Recently, “Activated borane” (**ActB**)- a solid porous amorphous polymer prepared by co-thermolysis of decaborane(14) (*nido*-$B_{10}H_{14}$) and organic hydrocarbons was reported.[3] This material emerged as a promissing candidate for heterogeneous catalysis, because it features Lewis acid centres, likely of a tricoordinated borane character, suitable for similar transformations as known for BCF.

**Experimental/methodology.** In this contribution we would like to present screening of catalytic properties of three different newly prepared **ActB** materials prepared from toluene, cyclohexane and *n*-hexane in hydrosilylation/deoxygenation reactions of various carbonyl substrates (ketones, aldehydes) with $Et_3SiH$ as the reductant of choice. Testing was performed as batch reactions in various solvents and different conditions (temperature, stoichiometry, etc.) were studied. Selected reactions were tested also under flow conditions using an XCube microfluidics-based system.

**Results and discussion.** It has been confirmed that **ActB** materials are capable heterogeneous Lewis acid catalysts for the above type of transformation. The activity and selectivity toward different products (deoxygenation vs silylation) changes with the nature of the material and consequently with the strength of the Lewis acid centers.

| catalyst | product distribution | | |
|---|---|---|---|
| | 1 | 2 | 3 |
| ActB-Tol | 0 | >99 (88) | 0 |
| ActB-cyHx | 0 | >99 | 0 |
| ActB-nHx | 83 | 12 | 5 |

# Designing innovation catalyst for the synthesis of plasticizers based on hybrid material deep eutectic solvent and metal oxide

P. Latos[1*], J. Gabzdyl[1], A. Chrobok[1]

[1] *Silesian University of Technology, Gliwice, Poland*
[*] *Piotr.latos@polsl.pl*

**Keywords:** Deep eutectic solvent, esterification,

**Introduction.** Deep eutectic solvents (DESs) are an emerging class of materials promising for applications as inexpensive "designer" solvents with tunable physicochemical properties. A detailed review of the current literature reveals the lack of predictive understanding of the microscopic mechanisms that govern the structure−property relationships in this class of solvents. Metal oxide are used as substrates for the synthesis of various task-specific materials. Their phase, morphology, particle size and purity, often, are of significant importance for applications, such as catalysis, photovoltaics, and batteries. It is essential to obtain metal oxide particles with defined specific characteristics, which give control over optical and electronic properties. On the other hand the use of solid metal oxides in catalysis causes isolation problems. Metal oxide particles can be suspended in the reaction mixture and a series of unit operations are necessary to separate the catalyst. To overcome this issue metal oxide can be dissolved in DES.

**Experimental/methodology.** In this work, dissolution experiments were performed in the popular DES choline chloride-urea (molar ratio 1:2) by suspending the ZnO (0,8 wt%) at temperature below 100 °C in order to avoid the decomposition of urea. The driving force of dissolution is the coordination of urea to the metal atom. The amount of zinc oxide was determined by ICP-OES and XRF analysis.

**Results and discussion.** A hybrid system based on DES and ZnO was tested as catalyst in transesterification reaction of dimethyl terephthalate with butanol resulted in the synthesis of alternative non-phthalate plasticizer. Butyl terephthalate was obtained in high yield (92%) and full conversion dimethyl terephtalate, under mild reaction conditions at 100–120 °C and using a 10:1 molar ratio of alcohol to ester and 3.2 wt% of catalyst.

During the reaction course, the formation of the second ester phase was observed what facilitates the reaction progress, shifting the equilibrium towards the ester formation. Lower phase was consisted with catalyst and methanol and the upper phase contained product and unreacted butanol.

Another important parameter for industrial application is the stability of the catalyst and the possibility of its further reuse in following processes. To demonstrate the stability of a hybrid system based on DES and ZnO the post reaction two-phase mixture was separated and the lower phase (containing mainly catalyst) was dried using rotary evaporator and used for the next cycle. The studied catalyst was stable in ten consecutive cycles and could be used without any loss of activity.

In summary, a new catalyst for the synthesis of butyl terephthalate in the presence of hybrid system based on DES and ZnO has been developed. This work contributes to the development of sustainable and environmentally-friendly processes for the production of green plasticizers.

**Keywords:** Bi-functional catalyst, Oxidative dehydrogenation, Nanoscale intimacy, $CO_2$, Soft oxidant

**Introduction.**

The use of $CO_2$ as a soft oxidant, in the dehydrogenation of alkane, can increase the thermodynamic yield of olefins by removal of $H_2$ *via* reverse water gas shift (rWGS) reaction and improve the catalyst lifetime by facilitating coke removal [1]. Classical $CO_2$-oxidative dehydrogenation catalysts are bi-functional, composed of (1) noble metal nanoparticles and (2) reducible metal oxide nanoparticles on a high surface area support. The metal nanoparticles are catalysts for the generation of olefins from paraffins by dehydrogenation while the reducible metal oxides activated $CO_2$ to facilitate the rWGS reaction. Recently, $Pt_1Sn_1$ intermetallic catalysts exhibited high catalytic activity during the dehydrogenation reaction [2]. We explored the combination of silica-supported $Pt_1Sn_1$ intermetallic nanoparticles (Pt-Sn@$SiO_2$) and $CeO_2$ as a bi-functional catalyst for $C_5$ oxidative dehydrogenation with $CO_2$ ($CO_2$-ODH). To prevent thermal cracking reaction, it is crucial to maintain the reaction temperature below 400 °C, where the activation of $CO_2$ is limited, necessitating an increase of the cerium content. However, an excess of cerium oxide can hinder the formation of intermetallic compounds between Pt and Sn, leading to significant loss of selectivity towards olefins. To address this challenge, we examined the $CO_2$-ODH activity concerning the intimacy between Pt-Sn alloy and $CeO_2$.

**Experimental/methodology.**

The Pt-Sn@$SiO_2$ catalyst was prepared using the incipient wetness impregnation method while $CeO_2$@$SiO_2$ was synthesized by the co-precipitation method. The Pt-Sn@$SiO_2$ and $CeO_2$@$SiO_2$ were physically mixed with the weight ratio of 1 to 1. On the other hand, co-impregnated catalyst was prepared by loading the Pt and Sn precursors onto $CeO_2$@$SiO_2$ by incipient wetness impregnation and calcined in air for 2 h at 350 °C.

**Results and discussion.**

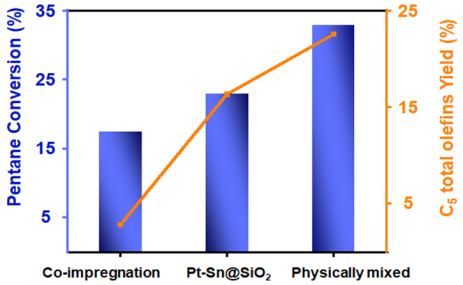

***Figure 1. Pentane conversion and olefins yield obtained using different integration methods. Reaction conditions: temperature = 500 °C, molar flow ratio of $CO_2$:Ar:$C_5$ = 4:4:1, catalyst amount = 0.2 g.***

For the co-impregnated catalyst, the XPS and CO-FTIR results confirmed that the strong interaction between Pt and Ce hindered the formation of Pt-Sn intermetallic nanoparticles (NPs). In contrast, for the physically mixed catalyst, Pt-Sn intermetallic NPs were not disturbed due to the nanoscale positioning of the

Pt-Sn alloy and $CeO_2$ sites. As a result, the physically mixed catalyst demonstrated a significantly higher olefin selectivity (68.7%) compared to the co-impregnated catalyst (20.9%). Furthermore, the presence of $CeO_2$@$SiO_2$ can facilitate the rWGS reaction, leading to an enhancement in pentane conversion (32.8%) when compared to the Pt-Sn@$SiO_2$ catalyst (22.9%).

**Keywords:** Single Atom Catalysts, OER

**Introduction.** The use of single metal atoms has been considered as an efficient way to improve catalytic activity. The strategy of single-atom (SA) recombination with MXenes has been successfully applied in electrocatalyst research [1,2]. More importantly, with the development of single-atom catalysts (SAC), it is relatively easy to establish intrinsic reaction mechanisms by pointing out the nature of catalytically active sites. A strong interaction between the individual atoms and the support is the key factor for the stabilization of the SACs, affecting their electronic structures and catalytic performance. The development of a low-cost and high-efficiency catalyst for the oxygen evolution reaction (OER) is essential to meet the future industrial demand for hydrogen production through electrochemical water splitting. Most MXene surfaces with oxygen (O) end groups are reported to be more stable than the -OH and -F terminated surfaces [3]. The electron energy loss spectroscopy (EELS) experiment shows the absence of the F group on MXene [4.] Furthermore, the OH group would be converted to the O group on high-temperature annealing [5] and it is possible to synthesize O-terminated MXene in Attempt. Cobalt (Co) has emerged as an interesting base metal due to its catalytic power to split water. In this work we have focused on oxygen (O) terminated Ti and Mo-based MXenes, $Ti_3CO_2$, $Mo_2CO_2$ and $Mo_2Ti_2C_3O_2$. We systematically investigate OER performance for single Co-atom adsorbed in O-vacancy MXene surface. We find that the OER activity of the SAC can be tuned using the vacancy of the surface termination in the substrate. The charge transfer between the SAC and the substrate, in particular, can be tailored to improve catalytic activity. The magnetic moment at the SAC site is also important. We demonstrate these findings using overpotential calculations.

# Packed bed of 3D printed catalysts for $CO_2$ methanation

J. Lefevere[1*], B. Michielsen[1]

[1]*Flemish Institute for Technological Research - VITO, Sustainable Materials Department, Boeretang 200, 2400 Mol, Belgium*

**Keywords:** 3D printing, $CO_2$ methanation, upscaling

**Introduction.** 3D printing offers a wide range of opportunities for the future, although still some challenges need to be overcome before a widespread industrial implementation can happen. In the chemical industry, 3D printing can be used for producing lab ware, reactors or inert supports for catalysts. Another possibility is the direct printing of catalytic material. Several examples of 3D printed catalysts can already be found in literature [1,2], showing benefits in terms of pressure drop as well as minimizing mass transfer limitation compared to traditional shaped pellets. However, the benefits of 3D printed catalysts need to be balanced versus the extra cost of production. For industry, questions still remain concerning the quantification of these benefits, implementation of 3D printed catalyst in industrial reactors and cost of production on large scale. In this work, steps have been taken to get closer to an answer on these questions.

**Experimental.** 3D printed alumina structures were prepared using direct ink writing (DIW). After printing of 4 different designs, the structures were calcined and impregnated with nickel for testing in $CO_2$ methanation reaction. For the first time ever, a packed bed of 3D printed structures was tested and compared with catalyst pellets. Both catalytic properties as well as pressure drop of the different shapes were evaluated. Additionally, a pilot production process for 3D printed catalysts has been set-up to study the feasibility and related costs of producing 3D printed catalysts on large scale.

**Results and discussion.** Pressure drop measurements revealed a significantly lower pressure drop over the packed beds of 3D printed structures compared to traditional pellets. The measurements also prove that the gas flow effectively flows through the structures and not solely around them as pressure drop over the bed decreases with higher porosity in the 3D printed samples with the same dimensions. In $CO_2$ methanation 3D printed catalysts show increased activity at lower temperatures compared with the pellets. The upscaling efforts indicate that it is possible to produce 3D printed catalysts on a multi-ton scale. Running this equipment gives insights in the cost of production and feasibility of large-scale production of 3D printed catalysts. The key steps in the process were detected and requirements for further upscaling to industrial levels identified.

This work shows the potential of large-scale production and implementation in industrial reactors of 3D printed catalysts. This opens a new window towards further tuning of catalysts in function of desired properties. The pilot production set-up gives the information needed for the next step: full industrial scale production and an indication of cost price on case-per-case base.

# Partial hydrogenation of biofuel from Waste Cooking Oil by Steel Slags based catalyst

M. S. Leone,[1] P. Mastrorilli,[1] M. M. Dell'Anna[1]
[1]*DICATECh department of Politecnico di Bari, Bari, Italy*

[*]*mariastella.leone@poliba.it*

**Keywords:** Hydrogenation, FAMEs, steel slags

**Introduction.** Growing environmental pressure to reduce waste and contamination leads to consider recycling solutions. Wastes offer an opportunity in terms of catalysis. The growing interest in their direct application as active materials is mainly driven by a combination of economic and environmental reasons. In this context, steel slags[1] can play a significant role in catalysis because of its unique chemical composition and physical qualities. Their use is of great economic importance and could contribute to the reduction of solid waste. Herein, we report on the synthesis and characterization of a new catalyst based on steel slags with magnetic properties able to facilitate its recovery and reuse after the catalytic cycle. This new material was constituted of a nanocomposite of nickel nanoparticles and iron oxides deposited onto steel slags as support with basic features, and it was used as catalyst for the partial hydrogenation of FAMEs (Fatty Acid Methyl Esters)[2] coming from waste cooking oil. The partial hydrogenation reaction aimed at selectively converting all C18 polyunsaturated esters into C18:1 monounsaturated product, thus turning a waste into a feedstock for valuable biofuel.

**Experimental/methodology.**

*Catalyst synthesis*

$FeCl_3 \cdot 6H_2O$ (6 mmol) and of $FeSO_4$ (3 mmol) were dissolved in deionized water (130 mL) and subsequently added of steel slags (2.08 g). The mixture thus obtained was kept under stirring for 6 hours at 35°C, and then centrifuged and removed of the surnatant solution. The obtained solid was washed 3 times (5 mL) with deionized water and left overnight at 85°C to get a brown solid (2.28 g, Fe/SS). Subsequently, 0.82 g of Fe/SS were added to a solution obtained by dissolving $NiCl_2 \cdot 6H_2O$ (0.73 g) in 20 mL of deionized water.The mixture was kept under stirring at 65°C overnight, and then it was dried at 85°C for 16 hours. The obtained brown material was calcined at 300°C under dihydrogen (5 bar) for 30 minutes, turning into the final red solid employed as the catalyst (1.15 g, Fe-Ni/SS).

*Catalytic run*

FAMEs (125 mg) from WCO, Fe-Ni/SS (50.0 mg) and 5 mL of methanol were put in stainless steel autoclave under dihydrogen atmosphere at an initial pressure of 5 bar for 3 h at 70°C. The reaction products were characterized by GC-MS.

**Results and discussion.** The novel catalyst based on iron oxides/nickel nanocomposites supported onto steel slags resulted active and selective in the partial hydrogenation reaction of FAMEs obtained by WCO. In fact, after hydrogenation reaction the main component of the mixture resulted the monounsaturated C18:1 methyl ester, which represents a good compromise between oxidation stability and cold flow properties of the whole blend. In addition, the catalytic system was recyclable up to five subsequent runs without losing its activity and selectivity. Further analyses are still in progress to better characterize the new synthetized material.

# Pinning of transition metal nanoparticles onto silanol-rich 2D zeolitic materials

Ang Li, Daniel N. Rainer, Martin Kubů, Jiři Čejka, and Michal Mazur

*Department of Physical and Macromolecular Chemistry, Charles University, Hlavova 8, 128 43 Prague 2, Czech Republic*

**Keywords:** Zeolites; Transition Metal nanoparticles; metal-zeolite nanocomposites; metal-silanol interactions; sintering resistance.

**Introduction.**

Transition metal-zeolite composites have emerged as catalysts for various industrial and laboratory-scale processes, such as hydrogenations. [1] Nevertheless, efficient synthesis of metal-zeolite composites with anti-sintering, thermally stable metal nanoparticles and reducible metal oxide nanoparticles still remains a challenge. Encapsulating of the metal species into zeolite frameworks can improve the stability of metal by the spatial confinement effect. Significant advancements in the fabrication of well-defined metal species confined within zeolites opened routes for preparation of variety of potential catalysts. Yet, it is still challenging to effectively confine some of the transition metals or reducible metal oxide nanoparticles into zeolites because of the inherent nature of these species, high surface energies with various valences, low melting points, and sensitivity at acidic and base conditions.

Recently, we have successfully encapsulated Rh nanoparticle into non-porous layered zeolitic precursor, IPC-1P. [2] The zeolitic layers have a defined silanol nests with quadruple geometry. This generates the pinning effect between the Rh species and silanol nests. Final materials show excellent sintering resistance of reducible metal oxide nanoparticles even at harsh conditions (750 °C for 6 h). Herein, we show the effective incorporation of various transition metals (Ag, Zn, Co, and Cu) into the silanol-rich layered zeolite support. Resulting materials were composites of reducible metal oxide nanoparticles supported and stabilized by zeolite.

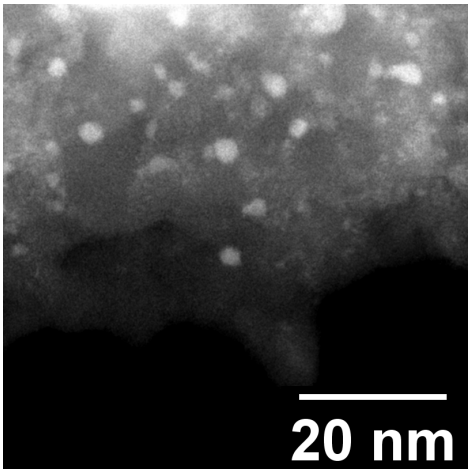

***Figure 1.*** *Representative ADF-STEM image of Zn@IPC layered material after calcination.*

**Experimental/methodology.**

Silanol-rich zeolitic support with transition metal oxide nanoparticles (denoted as metal@IPCs) were prepared by introduction of metal precursors during a swelling process of IPC-1P. Layered IPC-1P was synthesized by the hydrolysis of UTL germanosilicate. Swelling of layered precursor was performed by introduction of a long surfactant (docosyltrimethylammonium hydroxide) into the interlayer space. Transition metal precursors were stabilized with protective ligands and then encapsulated simultaneously with the swelling. The final metal@IPCs were obtained after a calcination at 550 °C in air.

**Results and discussion.**

The produced metal@IPCs composite catalysts were investigated by PXRD, sorption of Ar, SEM, STEM, and STEM-EDS. PXRD and Ar sorption results confirmed the disorder stacking of the zeolitic layers. ADF-STEM images of calcined materials (e.g. Zn@IPC, Fig. 1.) showed that the transition metal oxide nanoparticles

were uniformly dispersed on the zeolite support. This shows the efficient stabilization of reducible metal oxide nanoparticles. Materials have shown the stability over thermal treatment, including in-situ heating in electron microscope. STEM imaging of in-situ heated materials shown the sintering behavior of the metal species at elevated temperatures.

**Introduction.** Platinum group metals (PGMs) are known for catalysing a wide range of chemical reactions involved in biomass conversion with high activity and selectivity. However, PGMs are scarce, expensive, and are susceptible to deactivation by the impurities present in the reaction systems [1]. Therefore, focus has been shifted on finding viable alternatives such as $Mo_2C$ and $W_2C$ transition metal carbides (TMC) [2]. While catalytic activity of TMC is to some degree known, it is still not clear what the structure-activity relationships are. In this work, we used an efficient descriptor-based approach [3] to gain insights into structure-activity relationships for $Mo_2C$ catalyst, and then further tuned the activity of $Mo_2C$ by heteroatom doping.

**Experimental/methodology.** All the DFT calculations were performed using VASP package. Electron-ion interactions were described using PAW method and PW basis set. Microkinetic modelling (MKM) was performed using MKMCXX package. The most stable β-$Mo_2C$ (101) facet for hydrodeoxygenation (HDO) of butyric acid was chosen as a prototype for investigation of the structure-activity relationships.

**Results and discussion.** First, the full HDO reaction pathway over β-$Mo_2C$ (101) surface was identified by DFT mechanistic study, Fig.1 (A). Subsequently, microscopic parameters (elementary steps and activation barriers) obtained using DFT were plugged into an MKM model to derive experimentally measurable macroscopic parameters such as surface coverages and degree of rate control (DRC) coefficients. DRC analysis (Fig.1 (B)) shows that butanol dissociation is the rate-determining step. To facilitate this reaction step, we doped the metal active site with a range of transition metals (*M*), as in Fig.1 (C). Upon electronic structure analysis, Fig.1 (D), we discovered that *M* (*d*-band filling) and *M* (radius) are decent descriptors correlating the activity of β-$Mo_2C$ (101) surface and doping active metal site with **Zr** *and* **Nb** can remarkably improve butanol dissociation and thereof enhance the overall activity. These fundamental understandings provide a practical strategy for tailor-made TMCs development towards HDO reactions.

**Keywords:** zeolite, aluminum distribution, paired acid sites, isolated acid sites, Al-zoning, hollow zeolite, methanol-to-aromatics (MTA)

**Introduction.** Zeolites are the catalytic workhorses of various relevant reactions, primarily because of their acidic properties. There is general agreement that modulating the organization of aluminum and its associated acid site can further exploit the potential of zeolites [1,2]. However, to date, there have been few studies on unravelling the influence of Al distribution on acid-catalyzed reactions at the mesoscopic and microscopic levels.

**Experimental/methodology.** HZSM-5 zeolites with different Al distribution, i.e., intraparticle distribution and Al proximity at the nanoscale, were prepared first and characterized in detail (**Figure**). The catalysts were then evaluated in methanol-to-aromatics and olefins-to-aromatics reactions. Both static and Molecular Dynamics calculations were performed to disclouse the mechanisms [3].

**Results and discussion.** Our results demonstrate that Al enrichment at positions closer to the external surface results in more paired acid sites that exhibit enhanced activity than the isolated ones. As suggested by theoretical calculation, paired acid sites promote proceedings of hydride-transfer, oligomerization and cyclization reactions because of their higher protonation ability and enhanced stabilization effect. Secondly, such Al organization accelerates progression of cascade reactions to yield aromatics and alleviate their diffusion out. Exploiting the Al-zoning feature, we further fabricated hollow zeolites by desilication. Combining the optimized active sites with the improved diffusion and void-confinement properties of hollow crystals results in the highest capacity to produce aromatics (19.4 $g_{carbon}$ $g_{zeolite}^{-1}$).

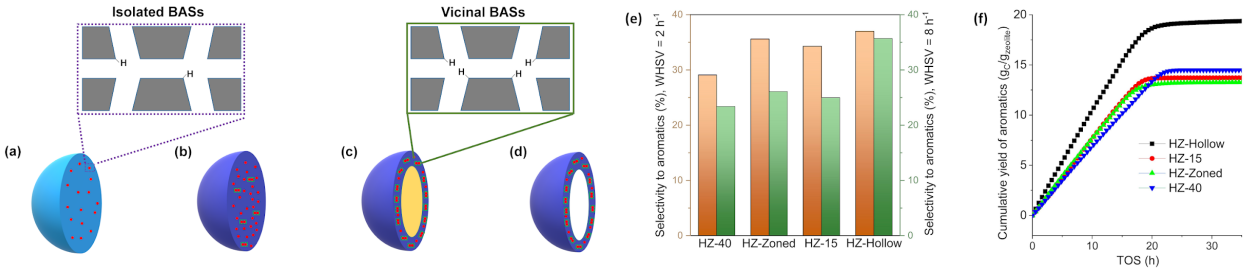

**Figure.** Schematic representation of the HZSM-5 catalysts used for comparsion and their catalytic performance at 400 °C. (a) HZ-40 (Si/Al=40, homogeneous Al distirbution). (b) HZ-15 (Si/Al=15, homogeneous Al distribution). (c) HZ-Zoned (Si/Al=40, Al-zoned). (d) HZ-Hollow (Si/Al=18, hollow zeolite). (e) The averaged selectivity to aromatics over 5 h time-on-stream at WHSV = 2 $h^{-1}$ and WHSV = 8 $h^{-1}$. (f) Cumulative yield of aromatics with TOS over different zeolite samples at WHSV = 8 $h^{-1}$. BASs: Brønsted acid sites. WHSV: weight hourly space velocity of methanol.

# Cluster-sized alloys on zeolite for robust ethylene removal at 0 °C

Mingyue Lin[1], Haifeng Wang[2], Tamao Ishida[2], Guangli Xiu[1*], Toru Murayama[2*]

[1]*East China University of Science and Technology, Shanghai, P.R. China*

**Keywords:** Ethylene removal, cluster-sized alloys, acetate intermediate, stability

**Introduction.** Fruits and vegetables and other edible agricultural products will continuously release ethylene gas as the ripening agent, which will accelerate the food aging and quality deterioration even in the cold chain transportation and storage. Catalytic oxidation has widely been considered as a desirable method for efficient removal of trace ethylene at low temperatures. However, all current reported catalysts are prone to poisoning and deactivation at around 0 °C, and the continuous operation time for ethylene removal is less than 2 hours[1,2], which is difficult to meet the requirements of long-time food preservation. Solving the poor catalyst stability is the key.

**Experimental/methodology.** Au-Pt alloy NPs/ZHM20 catalysts with different molar ratios of Au and Pt were prepared by sol immobilization method[3]. Physical and chemical properties were characterized by ICP-AES, HAADF-STEM, EDS, XANES, XRD, XPS, etc. $C_2H_4$ removal measurements were performed on a fixed-bed flow with U-shaped glass reactor. The catalyst was pretreated at 150 °C for 2 h under $N_2$ flow (50 mL $min^{-1}$) before the test. Reactant gas that contained 50 ppm $C_2H_4$/20% $O_2$/$N_2$ balance was fed to the catalyst bed with a total flow rate of 10 mL $min^{-1}$, and the inlet and outlet concentrations of $C_2H_4$ and $CO_2$ were measured by an online 490 Micro GC system (Agilent). The space velocity was 3000 mL $h^{-1}$ $g^{-1}$.

**Results and discussion.** We prepared gold-platinum (Au-Pt) alloy nanoparticles (NPs) catalysts ($Au_{54}Pt_{46}$/ZHM20) that showed robust $C_2H_4$ (of 50 ppm) removal capacity at 0 °C for 15 days (360 h) and that the performance of the used catalysts would be fully recovered by heat treatment for at least two times. This catalyst showed two stages of $C_2H_4$ removal: the first stage was attributed to the adsorption of $C_2H_4$ and the second could be due to the catalytic conversion of $C_2H_4$ to intermediates on $Au_{54}Pt_{46}$/ZHM20. Investigations by *in-situ* diffuse reflectance infrared Fourier transform (DRIFT) spectroscopy of $C_2H_4$ oxidation and online temperature programed desorption measurements of the spent catalyst suggested that the Au-Pt nanoalloys favor the formation of acetic acid (AcOH) from selective ethylene oxidation. And this on-site-formed acetate intermediate would partially cover the catalyst surface at 0 °C, thus exposing active sites to prolong the continuous and effective $C_2H_4$ removal .

# Structural and morphology studies of nanocomposites ZnO-$ZnAl_2O_4$ obtained by hydrothermal carbonization and thermal treatment

K. Antoniak-Jurak*, A. Mrozek, R. Bicki, P. Kowalik

*Łukasiewicz Research Network – New Chemical Syntheses Institute, Pulawy, Poland*
**katarzyna.antoniak@ins.lukasiewicz.gov.pl*

**Keywords:** hydrothermal carbonation raw ZnO and AlOOH, crystallization, morphology transformation, nonocomposites ZnO-$ZnAl_2O_4$

**Introduction.**
The combination of ZnO and aluminas to construct the ZnO-$ZnAl_2O_4$ nanocomposites are used in a number of applications as sensors, high temperature ceramic material, photocatalysts, supports and catalysts for various chemical reactions [1]. These materials show a number of unique surface properties providing high reactivity [2]. The present study examined the effect of different parameters of $CO_2$ saturation of raw ZnO and boehmite (AlOOH) in aqueous suspension on changes in morphology and structure of hydroxy-carbonate precursors and final oxide systems derivatives. The $CO_2$ saturation kinetics of aqueous ZnO-AlOOH suspensions are discussed. Moreover, the studies of the changes of morphology and structure of ZnO-$ZnAl_2O_4$ were also presented.

**Experimental.**
The preparation of ZnO-$ZnAl_2O_4$ (with a Zn/Al molar ratio of 0.7) was carried out by hydrothermal carbonation of a suspension of raw ZnO (ZnO pure, 99.5%wt., POCH) and boehmite (AlOOH, Versal-250) in a policlave lab pressure reactor (BÜCHI). The effects of temperature (ranging from 15 to 60 $^oC$), suspension concentration, pressure (up to 5 bar) on the kinetics of the process as well as on changes in morphology and phase composition were studied. The hydroxycarbonates obtained were subjected to subsequent thermal treatment (in the temperature range of 500-900 $^oC$). The materials after saturation were investigated by XRD, SEM, TG/DTG coupled with MS methods and their calcination products (ZnO-$ZnAl_2O_4$ nanocomposites) were additionally subjected to TPD_$CO_2$ and TPD_$NH_3$ studies. HR-TEM studies were also performed for selected samples.

**Results and discussion.**
It has been shown that irrespective of the concentration of the ZnO-AlOOH suspension, the conversion of ZnO to carbonate forms proceeds at a relatively high rate during the initial phase of carbonation, while in the later stages the process proceeds constantly at a significantly lower rate. The temperature is a factor that slows down the rate of ZnO to $ZnCO_3$ conversion which when taking into account Arhenius' law, shows that the carbonation reaction is not a limiting step. The rate of conversion of ZnO to $ZnCO_3$ is limited by the rate of dissolution of ZnO and/or the concentration of $CO_2$ in the reaction medium ($CO_2$ solubility in water decreases with temperature increase). A strong influence of hydrothermal carbonation parameters, especially temperature and pressure, was shown to have altered the surface morphology and phase composition of the carbonate precursors. As temperature and pressure increase, the carbonation products show a radically different phase composition. It was found that the calcination conditions of Zn-Al hydroxy-carbonate precursors strongly determine the surface-structural, acid-base properties and surface morpho-logy of ZnO-$ZnAl_2O_4$ nanocomposites.

**Keywords:** perovskite oxides, exsolution, nanoparticles, *in-situ* studies

**Introduction.** Exsolution from perovskite oxide catalysts has drawn increasing interest in the last decade. In this process, catalytically active metal nanoparticles decorating the material's surface are formed by selectively reducing metal elements within the perovskite structure, which consequently migrate to the surface [1]. Many recent studies are focusing on systems with one or two reducible elements [2]. In the latter case, often formation of alloyed particles has been observed. In this work, the perovskite NCF ($Nd_{0.6}Ca_{0.4}FeO_{3-\delta}$) has been doped with a combination of Co, Cu and/or Ni. Thus, up to three reducible elements (including the host metal Fe) are present, leading to even more complex exsolution behavior, as all of them can contribute to the resulting nanoparticle composition.

**Experimental/methodology.** Several single or dually doped variations of NCF have been synthesized and characterized utilizing a combination of complementary techniques. In particular, the reduction behavior – accompanied by exsolution – has been investigated, as well as the chemical composition and morphology of exsolved nanoparticles. Methods used include Temperature Programmed Reduction (TPR), (*in-situ*) X-Ray Diffraction (XRD), X-Ray Absorption Spectroscopy (XAS), and Scanning Electron Microscopy (SEM).

**Results and discussion.** Choosing the doping element(s) in combination with control of the reduction parameters (gas phase, temperature, time, etc.) opens up a variety of resulting surface morphologies. Depending on the exact conditions, it is possible to have a mixture of particles with different metallic phases (eg. Ni doping leads to Ni-rich fcc particles and Fe-rich bcc particles), or homogeneous particles with an alloy phase (eg. a FeCoCu alloy in the case of combined Co- and Cu-doping, cf. Figure 1).
These insights allow precise tuning of the material's surface for an intended application. For example, in catalysis particles with optimized catalytic activity can be achieved.

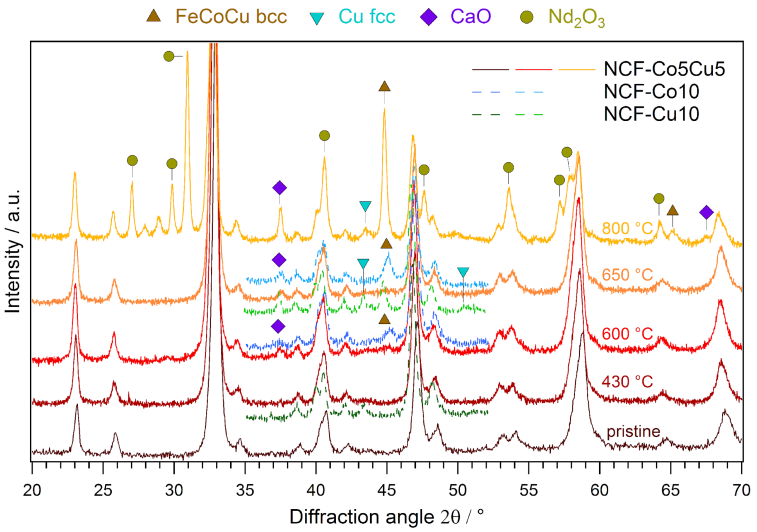

Figure SEQ Figure * ARABIC 1: XRD patterns of Co- and/or Cu-doped NCF after reduction at various temperatures, revealing exsolved phases.

# Influence of the starting biomass in the Pd-biochar catalyst properties

L. Longo*[1], M. Signoretto[1], F. Menegazzo[1], A. Di Michele[2]

[1]*Ca' Foscari University, Venezia, Italy*
[2]*University of Perugia, Perugia, Italy*
[*]*lilia.longo@unive.it*

**Keywords:** biochar, biomass, Pd catalyst, hydrogenation.

**Introduction.**

The transformation and use of biomass are fundamental steps for the circular economy transition. From the pyrolytic decomposition of biomass, it is possible to obtain three different fractions. The gas fraction can be treated to obtain syngas, the liquid fraction, bio-oil, is a source of chemicals and biofuels. The solid fraction, namely biochar, is mainly considered a byproduct of the production of bio-oil and biogas, however it is a sustainable material able to immobilize organic carbon in its structure, reducing the greenhouse effect. Biochar can be obtained by all type of biomass and in particular from wastes [1]. The thermal treatments and the activation can tune the morphology, porosity, and surface functionalization of the material, to adapt it to the desired scope. It can be employed as support for metal nanoparticles dispersion, used in different catalytic fields, such as contaminant degradation, synthesis of fine chemicals, hydrogenation/oxygenation reactions [2], reforming etc. In this work, four different types of biomasses were considered, due to their different nature and composition: a) hazelnut shells (HS), a lignocellulosic biomass b) broken rice grains (BR), mainly made of starch, c) rice husks (RH), a lignocellulosic biomass with a high amount of silica (30 wt.%) and c) chromium free leather tannery waste (L), a byproduct of the tannery industry, made of collagen and tanning agents. The biochars were characterized, activated, and employed as support for Pd NPs. The catalytic activity was evaluated in a model reaction, such as benzaldehyde hydrogenation, and the characteristic of the catalysts were related to the biochar features.

**Experimental/methodology.**

Biomasses were subjected to slow pyrolysis at 700°C and the obtained biochars were further activated by steam at 850°C. The activated biochars were washed by HCl 1M to eliminate residual ashes and then 0,6 wt.% of Pd was dispersed on the support by wetness impregnation method, and reduced by sodium formate at 80°C. All the materials were fully characterized by several techinques, such as CHNS elemental analysis, FT-IR, $N_2$ physisorption, Temperature Programmed Reduction, SEM, TEM, XRD etc. The catalysts were compared in the hydrogenation of benzaldehyde, performed at room temperature and atmospheric $H_2$ pressure, in ethanol as solvent.

**Results and discussion.**

The catalysts obtained showed different performances, that were related to the nature of the support. Pd on Activated Rice Husk biochar (Pd/ARH) showed the best results, followed by Pd/AHS. At very mild conditions, Pd/ARH was able to convert benzaldehyde to benzyl alcohol (82%) in 40 minutes, and to toluene (97%) in 200 minutes. On the other hand, ABR and AL showed lower activity of the final catalysts. Several was the reason were attributed to a better performance of ARH overall. Indeed, the starting biomass played a crucial role: the presence of lignin in the biomass was found to be crucial to obtain a hierarchical porous structure with micro and mesopores and inner channels both in ARH and AHS. Moreover, ARH showed a high oxygenated surface, and a hybrid organic/inorganic structure, and therefore it was able to better anchor Pd NPs on the surface and ensure a high dispersion of the metal, with a medium particle size of 3,8 nm.

# Pd-Fe catalysts boosting effect for the Selective Oxidation of Benzyl alcohol through in situ $H_2O_2$ production

A. Lopez-Martin*, Richard J. Lewis, Graham J. Hutchings

*School of Chemistry, Cardiff University, Cardiff CF10 3AT, United Kingdom*
**lopez-martina@cardiff.ac.uk*

**Keywords:** Alcohol oxidation, green chemistry, hydrogen peroxide.

**Introduction.**

Selective oxidation of benzyl alcohol to benzaldehyde is critical for laboratory and commercial processes. The low atom inefficiency of the current process and the large amounts of undesirable byproducts generated by it have pointed out the importance of the use of molecular oxygen or $H_2O_2$ as oxidants.[1] A group of bimetallic Pd-based catalysts has been studied in this work, with interesting results in the case of $PdFe/TiO_2$ presenting a high selectivity to benzaldehyde via the in situ production of $H_2O_2$ under low-temperature reactions conditions.[2]

**Experimental/methodology.**

Mono and bimetallic catalysts were prepared by an excess chloride impregnation procedure. The catalytic study covered the direct synthesis of $H_2O_2$, the degradation of $H_2O_2$, and the benzyl alcohol oxidation via in situ production of $H_2O_2$ at low temperature. Catalysts were characterized by TEM, EDX, XPS, BET and EPR experiments were also performed.

**Results and discussion.**

Previous studies showed that the gold incorporation into Pd catalysts had a positive effect on the production of $H_2O_2$ and the production of benzaldehyde.[3] The new series of catalysts were tested finding that $PdFe/TiO_2$ showed a small enhancement in the $H_2O_2$ synthesis, linked with a very low degradation of it. Regarding the benzyl alcohol oxidation reaction via in situ production of $H_2O_2$, the incorporation of Fe into the catalyst showed an incredible improvement, with productivity greater than that observed for $Pd/TiO_2$ and $PdAu/TiO_2$ (Figure 1).

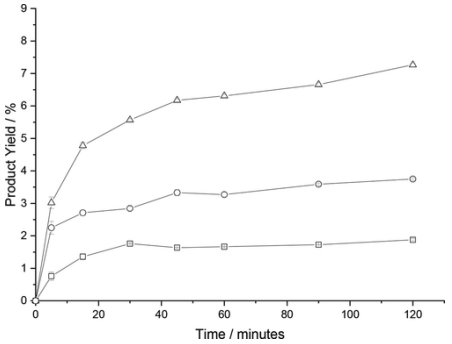

**Figure 1. Catalytic activity toward the selective oxidation of benzyl alcohol as a function of reaction time. Key: 1%$Pd/TiO_2$ (squares), 1% $PdAu/TiO_2$ (circles), 1% $PdFe/TiO_2$ (triangles).[2]**

The XPS results after reducing the samples showed a high proportion of $Pd^{2+}$ in the case of the $PdFe/TiO_2$ catalyst, being maintained longer than the rest of the catalysts. This is in agreement with previous studies that showed how the $Pd^0$-$Pd^{2+}$ domains have higher catalytic activity for both the synthesis of $H_2O_2$ and the selective oxidation of benzyl alcohol,[4] indicating some of the reasons for the higher activity of the 1%$PdFe/TiO_2$ catalyst at the presence of $Pd^0$-$Pd^{2+}$ domains and the continual low-level production of $H_2O_2$ over extended reaction times.

**Keywords:** 3D printing, $CO_2$ methanation, CO-PROX, ceria-based catalysts, monolith supports

**Introduction.** A new method to synthesize integral carbon monoliths with a controlled channel morphology was developed in this work by combining 3D-printing technology and sol-gel polymerization. Robust and consistent carbon monoliths were obtained with a perfect replica of the channel architecture

**Experimental/methodology.** As a proof of concept, carbon monoliths with tortuous channels that split and join successively along the monolith length were designed. The carbon monoliths were synthesized by polymerization of a mixture of resorcinol (R), formaldehyde (F) and water (W) following a modified Pekalas's method [1] followed by carbonisation. Different R/W molar ratios (1/13, 1/15 or 1/17 )were used in order to control the porosity of the resulting carbon gels. The obtained monoliths were tested as catalyst supports for the preferential oxidation of CO in the presence of $H_2$ (CO-PROX) [2] and in carbon dioxide hydrogenation to methane [3] after loading $Cu/CeO_2$ and $Ni/CeO_2$ active phases, respectively.

**Results and discussion.** The behavior of this novel carbon monolith catalyst outperforms the catalyst with a conventional honeycomb design in the tested reactions. Results show that the macroporosity of the carbon network favours the anchoring and dispersion of the active phase both in the channel surface and the carbon network. The channel architecture affects the gas diffusion both through the channel and the carbon network and in consequence, affects the active phase accessibility and activity. In $CO_2$ methanation (Fig. 2), the reaction rate was enhanced by 25% at 300 °C, which is attributed to an increased turbulent flow in the channel network of the advanced designs.

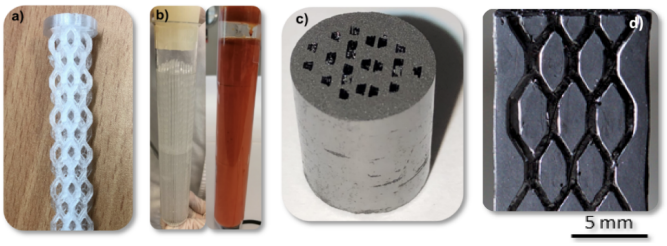

Figure 1. (a) 3D template, (b) RF formaldehyde mixture into glass tube before and after polymerization. (c) top view and (d) cross section of the obtained carbon monolith.

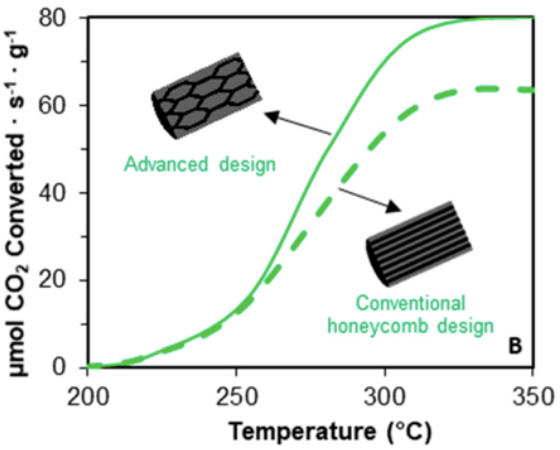

Figure 2. $CO_2$ methanation activity results of $Ni/CeO_2$ /carbon monoliths prepared in this work through 3D printing.

# Atomic Cu-N-P-C Active Complex with Integrated Oxidation and Chlorination for Improved Ethylene Oxychlorination

Hongfei Ma*, Wei Zhang, De Chen

Department of Chemical Engineering, Norwegian University of Science and Technology, Trondheim, (Norway)

*Presenting author, hongfei.ma@ntnu.no

**Introduction.** Fine constructing the chemical environment of the central metal is vital in developing efficient single-atom catalysts (SACs). Herein, the atomically dispersed Cu on the N-doped carbon is modulated by introducing Cu−P moiety to Cu-N-C SAC. Through fine-tuning with another heteroatom P, the Cu SAC shows the superior performance of ethylene oxychlorination. The Cu site activity of Cu-NPC is four times higher than the P-free Cu-NC catalyst. And 25 times higher than the Ce-promoted $CuCl_2/Al_2O_3$ catalyst in the long-term test (>200 h). The EDC selectivity can be splendidly kept at ~99%. Combined experimental and simulation studies provide a theoretical framework for the coordination of Cu, N, P in the complex active center and its role in effectively catalyzing ethylene oxychlorination. It integrates the oxidation and chlorination reactions with superior catalytic performance and unrivaled ability of corrosive-HCl resistance. The concept of fine constructing with another heteroatom is anticipated to provide us inspiration for rational catalyst design and expand the applications of carbon-based SACs in heterogeneous catalysis.

**Experimental/methodology.** The Cu single atom catalyst, co-doped with nitrogen and phosphorus, was prepared by an impregnation and pyrolysis method. Lignin (purchased from St1 Renewable Energy) was used as the carbon source and support.

**Results and discussion.** The Cu-NPC catalyst shows high activity and selectivity during the 200 hours on stream with the EDC selectivity of ~99%. It is affording a 4-times conversion than that of the Cu-NC catalyst. The production rate of Cu-NPC is much higher (~25 times) than the Ce-doped $CuCl_2/Al_2O_3$ catalyst, as shown in Figure 1b. Such a high intrinsic site activity made the catalyst highly active so that the production rate per catalyst mass was also higher compared to the $CeCu/Al_2O_3$ catalyst (~1.2 times), as shown in Figure 1b. However, the Cu-NC shows a much lower activity per gram catalyst compared to the $CeCuCl_2/Al_2O_3$ catalyst, but a much higher activity in terms of the Cu amount. Herein, doping P into the Cu-NC can greatly enhance the reactivity, in terms of per unit gram of catalyst and per unit amount of Cu. The results demonstrated that the Cu-NPC is more active, selective, and stable for ethylene oxychlorination compared to the Ce-doped $CuCl_2/Al_2O_3$-based catalysts.

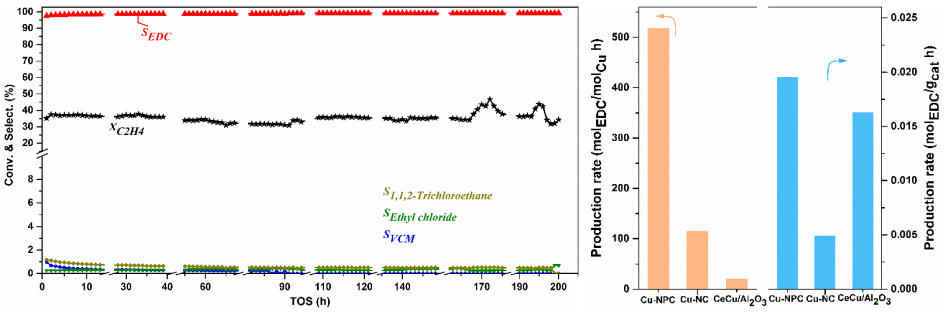

Figure 1. (a) $C_2H_4$ conversion and product selectivity of Cu-NPC catalyst, (b) Comparison of the production rates (calculated from the reaction at the 3rd hour).

*[*]ar@kemi.dtu.dk*

**Introduction.** Supported liquid-phase (SLP) catalysis is an industrially relevant approach to heterogenize homogeneous catalysts by immobilizing a liquid phase containing the catalyst complexes on the inner surface area of porous support material [1] (Figure 1). The MACBETH (Membranes And Catalysts Beyond Economic and Technological Hurdles) consortium is working towards applying a breakthrough technology consisting of a SLP catalyst with in-situ product separation in a catalytic membrane reactor (CMR) to the gas phase hydroformylation (HyFo) of $C_4$ olefins to yield n-pentanal [2]. This encompases optimization of the support material, the liquid-phase composition and the membrane which minimizes unwanted aldol formation by in-situ aldehyde removal. Upscaling aspects including construction of a pilot plant (TRL 7), solvent selection for in-situ liquid-phase addition and precious metal recovery are also in focus.

**Experimental/methodology.** Macroporous monoliths made of sintered α-SiC powder were wahscoated (1 or 2 times) with nanometer-sized silica particles (7 and 70 nm) [2] to add mesopores of various sizes and volumes for catalytic phase retention. Afterwards, SLP catalysts were obtained by impregnating the monoliths with a Rh-bpp-sebacate catalyst system (Rh/bpp/sebacate = 1/4/16 molar ratio) and tested for 1-butene HyFo at 120 °C and 10 bar (1-butene:CO:$H_2$ = 1.04:4.46:4.46 mmol/min).

**Results and discussion.** The SLP systems demonstrated stable performance for 140 h time on stream with low aldol formation. The supports containing 70 nm silica nanoparticles (NPs) exhibited higher activity but also slighlty lower regioselecitvity towards the desired linear product (Figure 2). Causes of the performance differences were investigated and further optimized, e.g. pore filling degree and liquid phase composition. Progress pertaining other building blocks such as, e.g. the membrane as well as the the crucial interplay of components will also be presented.

*[*]ar@kemi.dtu.dk*

**Introduction.** Supported liquid-phase (SLP) catalysis has successfully been established as an industrially attractive approach to heterogenize homogeneous catalysts [1]. Monolithic SLP systems have recently shown great potential in gas-phase hydroformylation (HyFo) of $C_4$ olefins to yield n-pentanal [2] and the MACBETH consortium [3] is on the verge of larger scale deployment at industrial site (TRL 7). This entails in-situ impregnation of support materials with a catalyst stock solution containing the SLP components (Table 1) under inert conditions. Dichloromethane (DCM), which was used for lab scale studies, is not an viable option for upscaling due to EHS concerns. Here, an in silico solvent selection has been performed and promising solvent candidates validated experimentally against DCM.

**Experimental/methodology.** A rational solvent pre-screening on over 5000 compounds was performed employing the following criteria: (i) boiling points, (ii) COSMO based activity coefficients, (iii) QSAR based carcinogenicity and mutagenicity predictions. The shortlisted solvents were checked for, e.g. toxicity and pyrogenicity and cost estimates served as the last filter. The solubilites of bpp and sebacate were measured experimentally in the most promising solvents and benchmarked against DCM. Gas-phase HyFo of 1-butene was performed for SLP catalysts impregnated with DCM and methyl tert-butyl ether (MTBE).

**Results and discussion.** The final list of solvent candidates was heavily dominated by esters and ethers, including MTBE - an economic and widely available DCM replacement. Solubilities of bpp in MTBE, dimethoxymethane and methylpropionate were measured to be 18.0, 20.6 and 24.5 g/L, respectively. The corresponding sebacate solubilities were 282, 425 and 194 g/L. The constraints posed by the relatively low bpp solubilities are aligned with efforts to minimize its use due to its waste intensive synthesis. Importantly, replacing DCM with MTBE did not significantly alter the HyFo performance (Figure 1), thus making MTBE a promising solvent option for the preparation and larger-scale implementation of monolithic HyFo SLP catalysts.

**Table 1: Catalyst stock solution components**

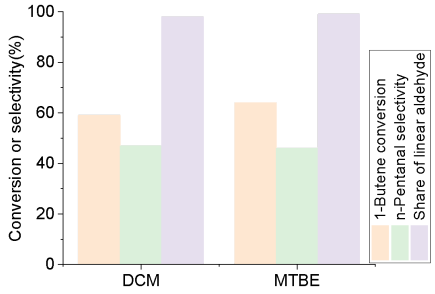

**Figure 1: HyFo performance of SLP catalysts produced with DCM or MTBE.**

# Supported catalytic active liquid metal solution catalysts on hierarchical $SiO_2$ supra particles in propane dehydrogenation – effects of support pore size and surface roughness

N. Madubuko[1], D. Lehmann[1], U. Sultan[1], N. Taccardi[1], M. Haumann[1], N. Vogel[1], P. Wasserscheid[1,2*]

**Keywords**: catalyst, SCALMS, support, dehydrogenation, agglomeration, stability

In several high-temperature applications, heterogeneous catalysts suffer from deactivation, mainly induced by agglomeration and coke deposition (coking). Improving the efficiency and stability of such catalysts is a major challenge. Supported Catalytically Active Liquid Metal Solution (SCALMS) systems offer unique benefits in addressing these challenges.[1] In SCALMS catalysts, small amounts of an active metal (e.g. Pt) are placed in a low melting metal (e.g. Ga) matrix, resulting in liquid alloys at reaction conditions. The unique reactivity and catalytic performance of SCALMS is attributed to the presence of its highly active and dynamic single active sites (Figure 1a).[1-3]

Current synthesis of GaPt-SCALMS by ultrasonication leads to a broad particle size distribution of 0.01 – 1µm. The formed alloy particles are deposited on the external surface of porous supports like $SiO_2$ and $Al_2O_3$ with pore sizes in the range of 5 – 15 nm.[3] Under reaction conditions in propane dehydrogenation, the mobility of the GaPt particles on the support's external surface leads to agglomeration and eventual catalyst deactivation.[3,4]

In this contribution, we improve the SCALMS catalyst synthesis technique by systematically controlling the GaPt particle size distribution to obtain alloy particles with mean particle size of 180 nm. These formed alloy particles are impregnated onto µm-sized hierarchal supra particles support with improved surface roughness and pore sizes above 100 nm. The influence of the controlled alloy particle size and the supra particle surface roughness entraps the GaPt alloys and decreases the mobility and agglomeration (Figure 1b). This effect results in stable and selective GaPt-SCALMS catalyst with a 35 % decrease in catalyst deactivation rate.

b

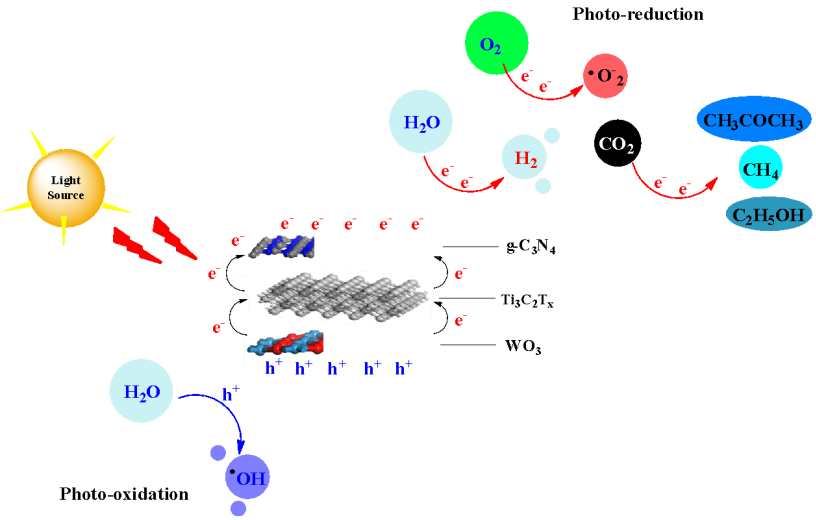
**Keywords:** ternary photocatalyst, Z-scheme, multijunction heterostructure, $WO_3$, $Ti_3C_2$ MXene, g-$C_3N_4$

**Introduction.**



In recent years, advancement in the field of nanotechnology has evolved new strategies to address energy and environmental issues. Amongst the developing technologies, visible-light-driven photocatalysis is regarded as a sustainable approach for energy production and environmental detoxifications, where transition metal oxides (TMOs) and metal-free carbon-based semiconductors such as graphitic carbon nitride (CN) evidenced notable potential in this matter [1-3].

**Experimental/methodology.**

Herein, g-$C_3N_4$@$WO_3$@$Ti_3C_2T_x$ three-component multijunction photocatalyst was fabricated via facile ultrasonic-assisted self-assembly, followed by calcination to facilitate extensive integrations of the materials. A series of different $Ti_3C_2$ wt% loading in the g-$C_3N_4$@$WO_3$@$Ti_3C_2T_x$ were prepared and represented as 1-CWT, 3-CWT, 5-CWT, and 7-CWT corresponding to 1, 3, 5, and 7wt%, respectively. Systematic characterization using spectroscopic and microscopic techniques were employed to validate the successful preparation of the photocatalysts. Enhanced optoelectronic and photoelectrochemical properties were observed for the $WO_3$@$Ti_3C_2$@g-$C_3N_4$ heterostructure with respect to the individual materials.

**Results and discussion.**

Photoluminescence spectra and Nyquist plots show restrained recombination rates and improved photocarrier conductivities, respectively, and this was credited to the synergistic coupling effect and the presence of highly conductive $Ti_3C_2$ MXene [4]. The strong interfacial contact surfaces upon the formation of the composite were confirmed using XPS. Multiple charge transfer mechanisms were proposed for the $WO_3$@$Ti_3C_2$@g-$C_3N_4$, which couples Z-scheme and Schottky-junction mediated with $Ti_3C_2$ MXene. Bode phase plots show improved charge carrier life-times upon the formation of the multijunctional photocatalyst. Moreover, transient photocurrent density of 7-CWT is 40 and seven (7) times higher compared to that of g-$C_3N_4$ and $WO_3$, correspondingly. Unlike in the traditional Z-Scheme, the formed ternary heterostructure possesses interfaces through the metallic 2D $Ti_3C_2$ MXene which provided charge transfer channels for efficient photocarrier transfers with carrier concentrations ($N_D$) of $17.49\times10^{21}$ $cm^{-3}$ and 4.86% photo-to-chemical conversion efficiency. The as-prepared ternary g-$C_3N_4$@$WO_3$@$Ti_3C_2T_x$ exhibited excellent photoelectrochemical properties with reserved redox band potential potencies to facilitate efficient photo-oxidation and -reduction reactions. The fabricated multijunction photocatalyst exhibits potentials to be used in an extensive range of photocatalytic process vis., the production of valuable hydrocarbons from $CO_2$, production of $H_2$, and degradation of a plethora of pollutants from wastewater.

**Keywords:** Mn-Ti perovskites, Composition change, CO oxidation

**Introduction.** Mn-Ti-based perovskite oxides are a category of materials that exhibit structural flexibility, making them appropriate for various applications, including oxidation reactions. These materials can serve as efficient catalysts for a range of oxidation reactions, including environmental remediation, energy conversion, and organic synthesis [1]. The structural flexibility of Mn-Ti-based perovskites allows for tailoring the catalyst's properties by modifying the composition, doping with different elements, or controlling the oxidation state of the metal cations. These modifications can influence the perovskite catalysts' activity, selectivity, and stability, making them versatile for various oxidation reactions. In the present study, stoichiometric and non-stoichiometric Mn-Ti-based catalysts were prepared and a detailed investigation was done for structural alteration and their simultaneous influence on the CO oxidation activity.

**Experimental/methodology:** The stoichiometric as well as non-stoichiometric $LaSrMnTiO_{3x}$ catalysts were prepared by the traditional solid-state synthesis [2]. The catalytic activity for CO oxidations was performed in a fixed-bed stainless steel tube (9.5-mm inside diameter) reactor. The gaseous products were analyzed by online gas chromatography (Agilent GC 8890) connected with a dual system of a thermal conductivity detector (TCD) and a flame ionization detector (FID) using a Porapak Q column and a Molecular Sieve 5A packed column, respectively.

**Results and discussion.**

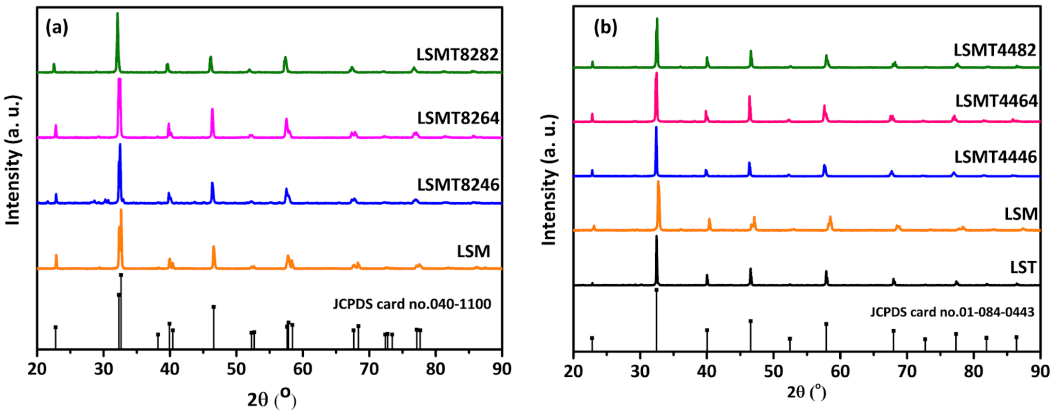

**Figure 1. XRD diffraction patterns of $LaSrMnTiO_3$ perovskite, (a) stoichiometric and (b) Non-stoichiometric.**

As shown in **Fig. 1** a and b the change in stoichiometry as well as the content of Mn led to a change in the crystal structure of the LSMT perovskites. Stoichiometric LSMT showed the monoclinic crystalline phase of $La_{0.8}Sr_{0.2}MnO_3$ (JCPDS#00-040-1100) having space group P 1 1/c 1 whereas, nonstoichiometric corresponds to the cubic structure of $SrTiO_3$ (JCPDS card no. 01-084-0443) with space group of Pm-3m. With an increase in the Mn content, the crystal structure of stoichiometric perovskite changes from monoclinic to trigonal with simultaneous changes in unit cell parameters. On the contrary in non-stoichiometric catalysts, there were no changes in the crystal structure as well as cell parameters. Further detailed investigations were conducted regarding the Mn oxidation states, the extent of reducibility, different oxygen species, and their consequent impact on CO oxidation activity.

**Keywords:** Co/Mn-spinels, OER, CAN test

**Introduction.** Co-based catalysts have shown promising activity towards chemical or electrochemical oxygen evolution reaction (OER).[1] While pure Mn oxides have relatively low activity in electrochemical OER, higher OER performance of mixed phases of Mn- and Co-based oxides has been reported in the past.[2,3] Therefore, in our work, we investigated the correlation between Mn incorporation into Co-spinel catalysts and the activity in chemical and electrochemical OER.

**Experimental/methodology.** $Co_{3-x}Mn_xO_4$ spinels with different particle morpholgies were synthesized by calcining the hydroxide (platelets) or hydroxycarbonate precursors (spheres) at 400 °C or 500 °C in air for 3 h. The precursors were prepared via co-precipitation in an automated synthesis station using NaOH or $Na_2CO_3$ as precipitation agent at a constant pH of 8.5 or 9. For the chemical OER, CAN test was performed: A 2.5 M $(NH_4)_2Ce(NO_3)_6$ solution was added to a dispersion of catalyst in water and the oxygen evolution was monitored for 2 h. Electrochemical OER was carried out in a three-electrode cell with 1 M KOH as electrolyte.

**Results and discussion.** $Co_{3-x}Mn_xO_4$ catalysts with anisotropic and isotropic particle morphologies were synthesized via co-precipitation and subsequent thermal decomposition. The phase purity of the catalysts was proven by powder X-ray diffraction (XRD) (Figure 1a). In addition, a shift of the reflections towards smaller 2θ values could be observed, indicating Mn incorporation. The Mn content and the particle morphology were confirmed experimentally. For electrochemical OER, a trend independent from spinel morphology was observed: the overpotentials were decreasing for both series with ~2.5% Mn and again increasing for ~7.5% Mn showing higher activity for the samples with lower Mn content (Figure 1b). In contrast, morphology seemed to have a bigger influence on the CAN test: As the Mn content increased, the initial rates for the isotropic samples decreased, while those for the anisotropic samples initially decreased and then increased for the 7.1%-sample. The results may be explained with an opposing effect of the catalyst's mesostructure on its specific surface area and its electric conductivity.[4]

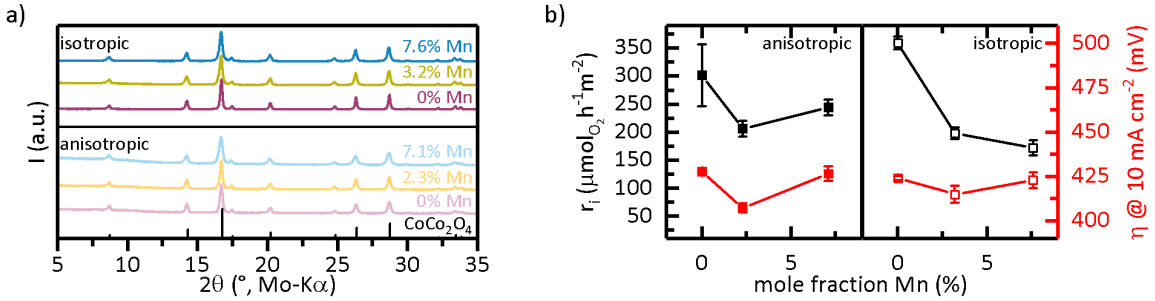

**Figure 1:** a) XRD pattern of the synthesized Co/Mn-spinels in comparison the pattern of $CoCo_2O_4$ (black; ICSD No. 150805)[5]. b) Comparison of the initial rate $r_i$ (black) and the overpotential η (red) at 10 mA $cm^{-2}$ determined for the Mn-substituted Co-spinels normalized to the BET surface area.

**Keywords:** gold nanoparticles, glucose oxidation, porous silicas

**Introduction.** Pore structure and texture parameters of support are crucial to develop an appropriate size and dispersion of gold nanoparticles (AuNPs), which translates directly to their catalytic activity and stability. It was reported that AuNPs smaller than 10 nm are highly active in oxidation processes [1]. However, their application is often limited by deactivation resulting from agglomeration, poisoning and changes of the oxidation state of the gold.

In this work, modified silica materials of various pore characteristics were used as AuNPs carriers to study the relationship of materials structure - AuNPs size/dispersion - catalytic activity/stability.

**Experimental/methodology.** Micro- and mesoporous silicas with pores in the range of 1.5 – 30 nm were obtained and functionalised with alumina and propylamino groups. AuNPs in the amount of 0.5, 1 and 2% wt. were deposited via the direct reduction method [2]. Materials were characterized using low-temperature nitrogen adsorption, TEM, UV-Vis spectroscopy and hyperspectral imaging. The catalytic properties were tested in glucose oxidation with oxygen in a batch reactor, and catalysts were recycled five times.

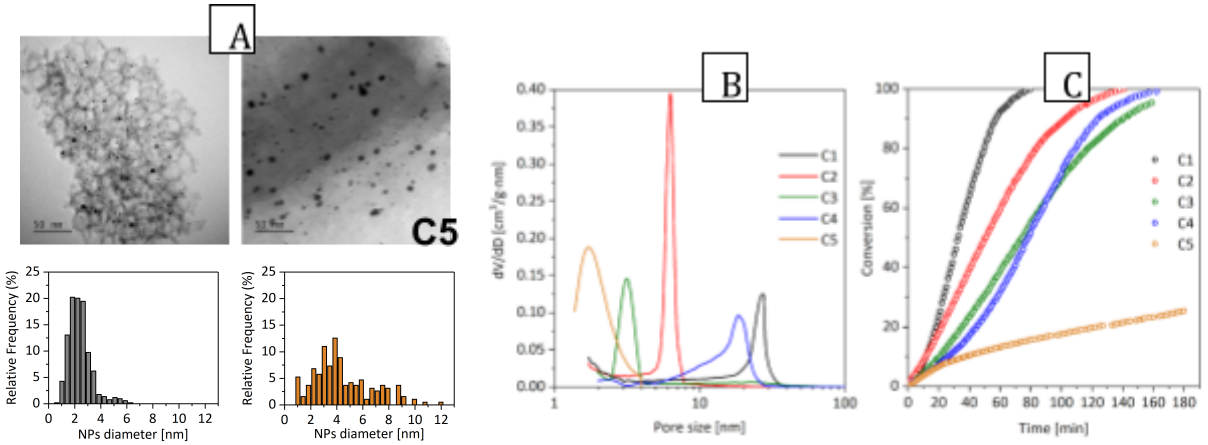

**Figure 1. TEM images and AuNPs particle size distribution in catalyst C1 and C5, B) pore size distributions in catalysts, C) conversion of glucose in 1st run of oxidation process**

**Results and discussion.** The size and dispersion of AuNPs strongly depended on the porous structure of the silica supports (Fig. 1A). The performance of the glucose oxidation coraborated well with the size distribution/dispersion of AuNPs and diffusion of substrates, which was limited by the size od pores (Fig. 1 B, C). It was shown that the pore size distribution in a support has siqnificant impact on the stability of deposited AuNPs, and thus on the performance of oxidation process. The most stable catalyst appeared to be that of the hexagonally ordered pores with diameter of about 6 nm. Moreover, a hyperspectral camera was proved to be an effective tool to follow the changes in the size of supported gold nanoparticles.

# Selective hydrogenation and hydrodeoxygenation using bimetallic $Fe_xPt_{100-x}$ nanoparticles immobilized on supported ionic liquid phases

Nataliia Marchenko[1*], Simon Tricard[1], Alexis Bordet[2], Walter Leitner[2]

[1] *Laboratoire de Physique et Chimie des Nano-Objets INSA, 135 Avenue de Rangueil, 31077 Toulouse, France;*

[2] *Max Planck Institute for Chemical Energy Conversion, Stiftstraße 34-36, 45470 Mülheim an der Ruhr, Germany;*

**marchenk@insa-toulouse.fr*

**Introduction.** For decades selectivity remains a main challenge in heterogeneous catalysis. Considering this issue NPs immobilized on supported ionic liquid phases (SILP) present an elegant solution since by easy modification of a structure of an ionic liquid, nature of metal NP or nature of support it is possible to activate specific functional groups leaving others untouched. Moreover, the use of bimetallic catalysts has the potential to afford high activity with the possibility to control selectivity in hydrogenation by adjusting ratios of metals in the catalyst[1]. In the present study, we aim at preparing bimetallic iron-platinum nanoparticles ($Fe_xPt_{100-x}$ NPs) combining the excellent hydrogen activation capability of platinum with the oxophilicity of iron to achieve the effective and selective hydrogenation and hydrodeoxygenation of C=O bonds.

**Experimental/methodology.** $Fe_xPt_{100-x}$@SILP were synthesized by decomposition of organometallic precursors of Fe ([bis(trimethylsilyl)amide]diiron (II)) and Pt (tris(dibenzylideneacetone)diplatinum (0)) in $H_2$ atmosphere in presence of the SILP (Figure 1a). This organometallic approach allowed precise control of the composition of bimetallic NPs ($Fe_{100}$, $Fe_{80}Pt_{20}$, $Fe_{60}Pt_{40}$, $Fe_{50}Pt_{50}$, $Fe_{40}Pt_{60}$, $Pt_{100}$). Morphology, NPs size (around 2 nm) and dispersion were studied by TEM and HR-TEM. Metal loading and ratio were confirmed using SEM-EDX. The oxidation states of metals were analyzed with XPS. FT-IR of $Fe_xPt_{100-x}$@SILP after CO adsorption was conducted as well. The analysis revealed electron density transfer from Fe to Pt sites that can be a reason for high selectivity in C=O hydrogenation.

**Results and discussion.** The reactivity of $Fe_xPt_{100-x}$@SILP catalysts was probed using the hydrogenation of acetophenone as a model reaction. The activity and selectivity of $Fe_xPt_{100-x}$@SILP catalysts were highly dependent on the Fe:Pt ratio. In particular, Pt@SILP led to the full hydrogenation of acetophenone to give the saturated alcohol in quantitative yield, while the incorporation of Fe in $Fe_{40}Pt_{60}$@SILP resulted in the hydrodeoxygenation of the ketone with conservation of the aromatic ring. The scope was extended to para-substituted acetophenones where excellent selectivities towards HDO products were reached (Figure 1b). Moreover, $Fe_{40}Pt_{60}$@SILP catalyst was used in the hydrogenation of a model unsaturated aldehyde – cinnamaldehyde. High selectivity toward unsaturated alcohol was achieved and remained after an extended reaction time (Figure 1c). These results illustrate that precise control of bimetallic NPs composition and structure can lead to high activities and tailor-made selectivities towards challenging products.

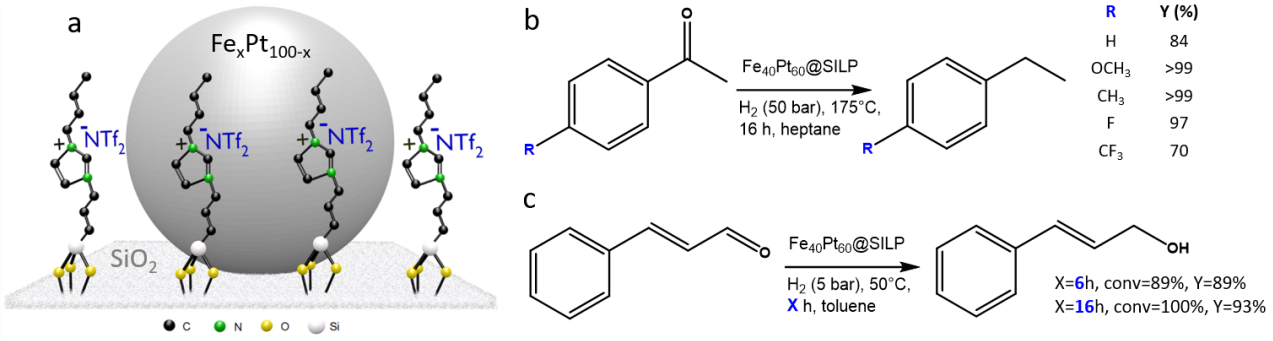

**Figure 1** a) Illustration of $Fe_xPt_{100-x}$@SILP system; b) hydrogenation of acetophenone; c) hydrogenation of cinnamaldehyde.

# Improved synthesis of nano Chevrel Phases for alkaline HER

Alexander M. L. Frisina[1], Anthony F. Masters[1], Thomas Maschmeyer*[1]
*Laboratory of Advanced Catalysis for Sustainability, University of Sydney, Australia*

**Keywords:** Hydrogen, Electrocatalysis, Molybdenum Sulfide, Chevrel Phase, Hydrothermal, Nanoparticles

**Introduction.** The production of hydrogen ($H_2$) from water ($H_2O$) using electrolysers is projected to become more common at commercial scale as the world seeks to decarbonise. It is vitally important to research new catalysts to supply the required electrolysers, and improve electrolyser performance.[1] Chevrel Phases (CPs) of type $MMo_6S_8$ (M = guest transition metal ion) are promising alternative catalysts to produce $H_2$ through electrocatalytic reactions.[2] However, their large particle size prevents full realisation of their electrocatalytic activity.[2] The discovery of reliable methods to create nanoparticulate CPs would allow chemists to fully explore CPs as next generation electrocatalysts.

**Experimental/methodology.** Starting materials: **Nano Cu CP***:* $CuNH_4MoS_4$, $N_2H_4{\cdot}H_2O$ and $H_2O$ *OR* **Nano CP Variants***:* Layered transition metal material (*e.g.* $Ni(OH)_2$), $(NH_4)_2MoS_4$, $N_2H_4{\cdot}H_2O$ and $H_2O$. The starting materials were heated to 200 °C in a sealed vessel under $N_2$ (1.72 bar) for 20 hours, reaching a max stable pressure of 18 bar. The resulting powder was isolated then treated in a furnace for 60 hours under 5% $H_2$/Ar, yielding nano Chevrel Phase material. Cu CP was deintercalated using HCl (1 M) and $O_2$ to give nano $Mo_6S_8$. CP electrocatalysts were prepared *in situ* by intercalation of nano $Mo_6S_8$ to give $MMo_6S_8$ (M=Ni, Cu, Zn) at a potential determined by cyclic voltammetry (CV). Linear sweep voltammograms (LSVs) were performed in 0.1 M NaOH according to procedures used in our laboratory.[2]

**Results and discussion.** Our findings were two fold. Firstly, we reported the hydrothermal preparation of nano CP precursors allowing the inclusion of a variety of transition metals in CP guest sites (Figs. 1a, 1b). This may prove to be the first method of nano CP synthesis that can be generalised to several guest metals. Secondly, our preliminary electrochemical investigations have revealed that nano Ni CPs may break a previously held belief that CPs containing guest ions are worse catalysts for the hydrogen evolution reaction than bare $Mo_6S_8$ (Fig. 1c).[2]

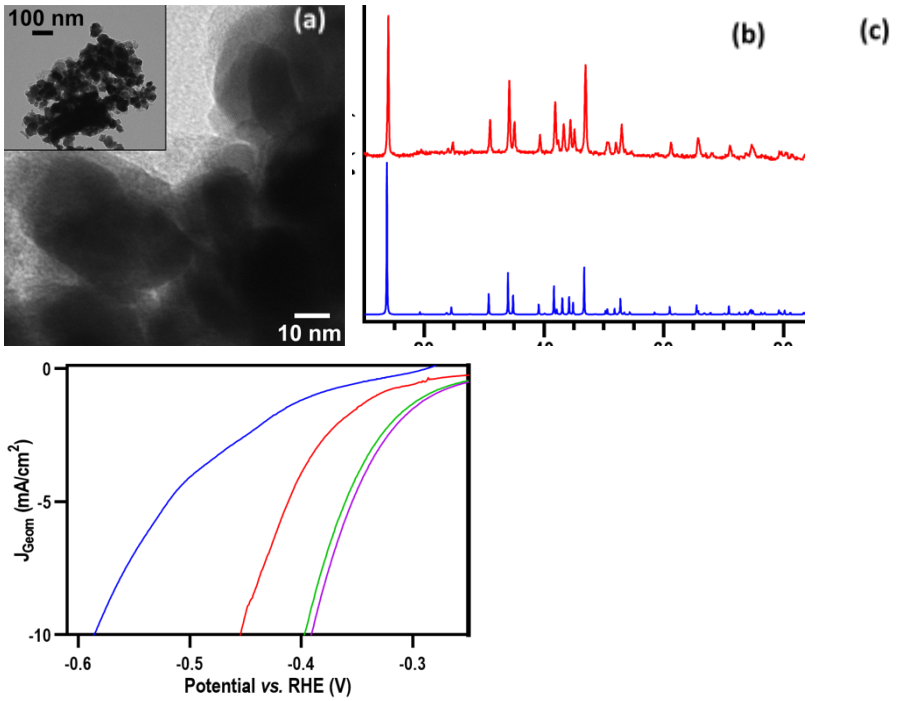

**Figure 1:** (a) TEM micrograph of nano Cu CP particles. (b) Powder XRD pattern for nano (red) and literature (blue) $Mo_6S_8$,[3] λ = 1.5406 Å. (c) Alkaline LSV (pH = 13) screening tests for nano NiCP (purple), ZnCP (blue), CuCP (red) and bare $Mo_6S_8$ (green). Scan rate 50 mV/s, performed under blanket $N_2$, working electrode $A_{Geom}$ = 0.071 cm$^2$. Reference electrode: Ag/AgCl 3 M KCl, counter electrode: graphite. Potentials corrected by $E_{RHE} = E_{Ag/AgCl} + 0.210\ V + pH*0.059\ V$.

**Keywords:** Hydrophoc zeolites, core-shell structures, complex immobilization, ethylene oligomerization.

**Introduction.** The dimerization and oligomerization of light olefins is an important route to produce linear and branched higher olefins. Transition metal based molecular complexes are performing catalysts towards butenes or linear alpha olefins (LAOs) $C_4$, $C_6$ and $C_8$ which are the main products of interest. Nevertheless, in such industrial processes, the catalyst is lost in the products and therefore cannot be reused nor recycled. It was found that Ni-exchanged zeolites can dimerize ethylene to light hydrocarbons [1, 2]. Indeed, the encapsulation of an active and selective molecular catalyst in a porous scaffold usually appears as an elegant heterogenization process. However, loss of catalyst activity and/or selectivity upon encapsulation is often reported as main limitation of this heterogenization approach. The objective of this work is to demonstrate that molecular catalyst encapsulation in hierarchical porous zeolites can afford efficient catalysts for ethylene oligomerization.

**Experimental/methodology.** We have chosen Ni-2,2'bipyridine (Nibipy) molecular complex for well-known activity and as its dimension can be compatible with cavity size of zeolites. As hosts, we have synthesized and selected commercial medium to large pore zeolites (MFI, BEA and FAU). For Faujasites, commercial CBV samples (from zeolyst) were used post-treated as received. Additionally, a hollow faujasite was synthesized according to a previous work [3]. The encapsulation process is a two steps synthesis. First, exchange of compensating cations by Ni cations followed by complexation with 2,2'bipyridine. The characterization of Ni-2,2'bipyridine complexes in zeolites was achieved by combining TGA, Infrared-, UV-visible spectroscopies and $N_2$ physisorption measurements. Finally, the oligomerization of ethylene was carried out in batch reactors at 308K and 30 bars for 1h in n-heptane ($n_{Ni}$ = 10 µmol) in the presence of $Et_2AlCl$ as cocatalyst (100 eq.)

**Results and discussion.** The confirmation of Ni-Ligand formation in the pore cavities and also importantly the ligand to Ni ratio are important. Indeed, we have found that for molecular catalysts, only the 1:1 ratio is very active. Consequently, it was necessary to control this ratio during the immobilization of the complex in the different supports in order to optimize the catalytic activity. In addition to that, we propose that the activity increases after complexation and with the creation of mesoporosity and macroporosity. Moreover, the selectivity towards branched olefins seems to enhance with the porosity. This may be explained by increasing the number of silanol defects during the creation of larger porosity by dealumination. Finally, these trends were observed when comparing plain and hollow zeolites of MFI and BEA topologies.

**Keywords:** Zeolites; Pd nanoparticles; dry methane reforming; metal-silanol interactions; sintering resistance.

**Introduction.** Metal nanoparticles encapsulated into zeolite matrix are efficient heterogeneous catalysts. Advantages of zeolites as supports are their high surface areas, rigid porous structures, physical and chemical stability, and tunable acid sites. [1]. Most of current synthesis strategies highly rely on the usage of protective organic ligands, which is expensive and not eco-friendly approach. [2] Facile and sustainable scale-up of metal@zeolite materials synthesis is highly desired. Recently, Ryoo et al. [3] and Yu et al. [4] reported the confinement of nanosized metal clusters in nanosponge MFI zeolites by post-synthesis method (wet impregnation). Resulting materials possess uniform small metal clusters evenly distributed and showing good thermal stability.

Herein, we utilize commercial zeolite as the parent material for and creation of silanols by dealumination. Subsequently, simple impregnation and calcination, the final materials possess a good dispersion of subnanometric metal particles on the materials and uniform size distribution. In contrast to the previous report, our strategy avoids the employment of expensive non-recycled organic SDA. This breaks the limitation for larger scale usage in a possible industrial scenario.

**Experimental/methodology.** Zeolite support (denoted as deAl-USY) had silanols generated throughout acid dealumination of commercial zeolite USY (CBV-720, Si/Al=15, zeolyst). The Pd@deAl-USY and Pd@USY were synthesized via a facile impregnation followed by calcination.

**Results and discussion.** We investigated the thermal stability of Pd nanoparticles in different support by performing *in-situ* step-wise heating (from the room temperature up to 700 °C) in scanning transmission electron microscope (STEM). Properties of prepared materials were investigated by PXRD, Ar sorption, SEM, and XANES. Obtained materials were tested in the dry reforming of methane at 600 °C. Catalytic results reveal that Pd@deAl-USY shows a longer lifetime and higher methane conversion compared with Pd@USY. This could be attributed to the improved thermal stability of Pd in silanol-rich Pd@deAl-USY.

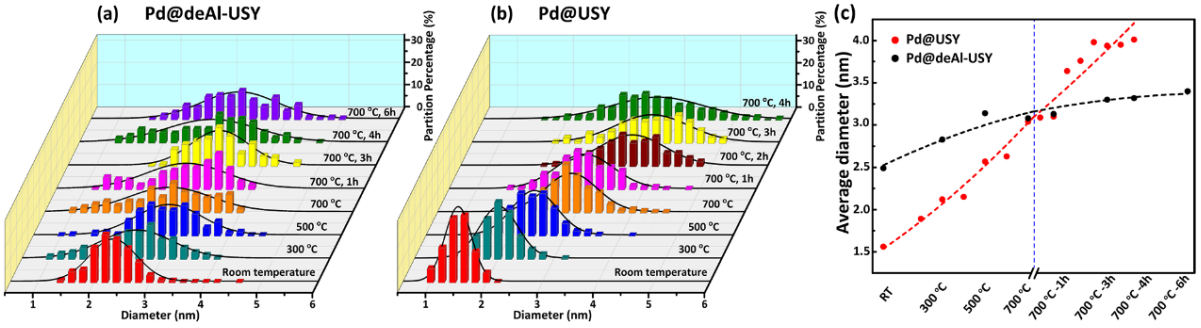

***Figure 1.*** *Pd particles size distributions evolution of Pd@deAl-USY (a) and Pd@USY (b) during heating; (c) Average sizes of Pd from in-situ heating STEM imaging.*

# Development and up-scaling of iron-based catalysts for sustainable Fischer-Tropsch synthesis of higher alcohols

M. Medicus[1*], J. Mettke[1], E. Reichelt[1], M. Jahn[1]

[1]*Fraunhofer Institute for Ceramic Technology and Systems IKTS, Dresden, Germany*

**Keywords:** Fischer-Tropsch synthesis, catalyst scale-up, structured catalyst, process integration, promotion, catalyst support, higher alcohols

**Introduction.** Due to depletion of fossil feedstocks and regulations concerning $CO_2$ emission reduction goals, mobility and chemical sector demand for new production pathways towards fuels and fine chemicals. Focusing on carbon feedstocks like waste, biogas or $CO_2$ chemicals can be produced in two-step approaches combining syngas production via gasification, biogas reforming or co-electrolysis of $H_2O$ and $CO_2$ and subsequent Fischer-Tropsch synthesis [1]. Prospects for short- to mid-term economic feasibility are better for high-margin chemicals like higher alcohols (HA), being linear 1-alcohols with more than 4 C-atoms per molecule. Promising and tunable selectivity for HA was confirmed for cheap bulk iron powder catalysts but structuring and scaling has been neglected so far [2]. Herein we present the development of scaled and optimized iron catalysts operated with sustainably sourced syngas under statistically optimized reaction conditions in easy-to-scale fixed-bed reactors to allow for the assessment of the process potential.

**Experimental/methodology.** Bulk iron catalysts were produced by co-precipitation and promoted by incipient-wetness impregnation (IWI). Supported powder catalysts were fabricated and promoted by IWI of different support materials. Recipes for thermoplastic extrusion of pellets were developed and optimized. The optimized catalyst was investigated under varying operation conditions adding 10 % $CO_2$ mimicking the typical composition of sustainable syngas. A predictive model for performance depending on conditions and TOS was developed. Experiments on tail gas recycling in a scaled reactor setup were conducted to increase overall conversion. Fresh and spent catalysts were extensively characterized.

**Results and discussion.** For bulk iron catalysts besides the known promoters K, Cu, Mo, Li was found to significantly improve catalyst activation, CO conversion and HA selectivity. Its effect could be exploited on powder and structured $Al_2O_3$-supported catalysts, while beneficial effects of other promoters did leak expectations. Besides $Al_2O_3$, $ZrO_2$ and SiC were found to be promising structural promoters and structural performance descriptors were identified. Presence of 10 % $CO_2$ in the syngas feed caused a significant decrease in conversion and HA selectivity. Nevertheless, precise tuning of reaction conditions and data analyses by statistical methods allowed for a model-based prediction of promising condition sets, that were experimentally confirmed giving CO conversion of 25-30 % at HA selectivity of 10 %, outperforming powdered catalysts. Even though slight deactivation occurred, the optimized catalyst could be fully reactivated after 2000 h TOS. For the first time tail gas recycling experiments were conducted on an optimized shaped iron catalyst allowing for a HA yield of 8 % which is 3.5 times the highest value reported so far for iron-based HA synthesis [2-4]. Options for further yield increase are discussed in the outlook. However, also the by-products can be fed to existing petrochemical pathways for additional value creation. The results also allowed to gain basic data for the assessment of the complete production process of HA.

**Introduction.** To run a PEM Fuel Cell, a $H_2$-rich fuel gas is produced from liquid fuels like diesel or kerosene using the fuel processing technology. The initial step of fuel processing is reforming, followed by the water-gas shift reaction [1], which reduces the CO concentration in the product gas from reforming to below 1 vol.%. To operate a PEMFC, however, the concentration of CO needs to be lowered below 100 ppm [1, 2]. Typically, this is accomplished using the PrOx (preferential oxidation) reaction. This paper reports on an improved method for the preparation of a $CuO/CeO_2$ based monolithic catalyst for the Prox-reaction.

**Experimental/methodology.** Using Avgouropoulos' et al. [3] work in particular, ceramic monoliths (cordierite, 400 cpsi honeycomb structure) were coated directly with a mixed oxide of $CuO/CeO_2$. No washcoat was applied. Instead, the monoliths were dipped twice in a viscous precursor solution and calcined at 450°C. Thus, the catalyst was directly formed on the cordierite surface. The catalyst was characterized by means of XRD, SEM/EDX, and EPR.

**Results and discussion.**

Experiments were conducted with a dry (FG1: 39 vol.% $H_2$, 20 vol.% $CO_2$, 1 vol.% CO, balance: $N_2$) and a moist fuel gas (FG2: 35 vol.% $H_2$, 16 vol.% $CO_2$, 1 vol.% CO, 20 vol.% $H_2O$, balance: $N_2$). Fig. 1a and 1b depict the CO conversions using FG1 and FG2, respectively, as a function of the temperature at varying space velocities (GHSV). With FG1 X(CO) was > 99 % up to GHSV=5,000 $h^{-1}$. At 10,000 $h^{-1}$ a marginally lower maximum of 97% was observed. Slightly different CO conversions were observed in the presence of steam (cf. Fig. 1b). The temperature interval of maximum CO conversions became smaller while the temperature level increased. It is assumed by Zou et al. [4] that a competing adsorption of $H_2O$ on the catalytic sites of $CuO/CeO_2$ catalysts and the formation of $H_2O$/CO surface complexes causes the inhibition of the CO oxidation.

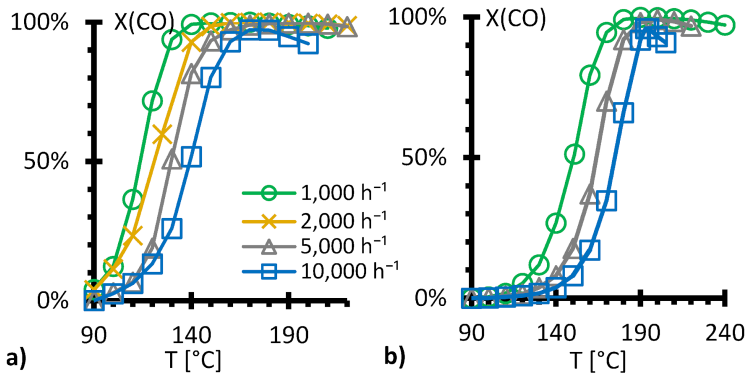

**Figure 1. CO conversion as a function of the temperature with varying values for the GHSV at λ = 2.5, a) dry fuel gas (FG1), b) moist fuel gas (FG2).**

In addition, a long term test for 311 h was carried out with FG2. The temperature at which the maximum conversion could be achieved marginally rose from 193 °C to 203 °C at the end of the run. In parallel, the maximum CO conversion decreased by 1.4 percentage points from 96.8% to 95.4%. It can be concluded that the application of the new preparation method for the monolithic $CuO/CeO_2$ was successful.

# Towards a Machine Learning Model for Zeolite Synthesis

D.P. Costa, L. Frazão, M.F. Ribeiro, P.S.F. Mendes

*Centro de Química Estrutural, Instituto Superior Técnico, Universidade de Lisboa, Av. Rovisco Pais, Lisbon 1049-001, Portugal*

**Keywords:** Zeolite, Synthesis, Machine-Learning, Model

**Introduction.**

Zeolites are crystalline aluminosilicate featuring a well-defined 3D structure with micropores and acid sites, both key to its catalytic success, but not straightforward to tune since the physical processes that occur during the zeolite synthesis are very complex and difficult to describe.[1] Nowadays zeolite tunning to a given set of properties is made via time-consuming trial and error. Model-based optimization can potentially provide clear synthesis guidelines for a target set of properties. However, fundamental (white) modelling of the zeolite synthesis process is hampered by its complex nature. Hence, the objective of this work is to develop a sound black-box model correlating the synthesis conditions with the zeolite properties.

**Experimental databases.**

Two different datasets needed to be created. Since machine learning algorithms need a large amount of data and some convergence problems could happen, a dataset of artifical data needed to be created to test how the choosen algorithms describe the desired patterns. This dataset nedded to mimic the patterns found after a litterature analysis between preparation conditions and zeolite properties by using previously known empirical functions for key parameters. The choosen functions needed to represent the expected non-linearity of the complex physical processes involved. Then a dataset containing the zeolite textural, acid and strucutural properties and their respective synthesis conditions, needed to be obtained by using data from scientific papers.

**Machine learning.**

Some machine learning algorithms have been recently benchmarked already for catalysis by some of us [2]. The starting point will thus be the pool of successful tecnhiques, i.e. artificial neural networks and random forest regression. These will be applied to the artificial dataset to determines which algorithms describe better the high non-linear patterns specific of the relationship between zeolite synthesis-properties. After that, the real dataset should be analyzed to understand the key variables that should be modelled and the degree of the model complexity required. The qualitative assessement of key variables must be done by clustering and dimensionality reduction, while the main trends between sythesis conditions and zeolite properties must be identified by quantitative trend analysis. Then, the machine learning algorithms that showed the best performance with the artificial dataset needed to be used to create the model using the real dataset.

**Conclusion.**

In conclusion, this develops a sound approach to create a model correlating the zeolite proparation condtions and their properties. This way, a step further can be taken in order to controll the zeolite synthesis, which to this day is not fully understood. Having such a model will facilitate the optimization of novel zeolite catalysts in old and new chemical processes. In the future, it is expected that this model is tested and improved with experimental data.

# MOF(Al)-derived catalysts with enhanced activity in $CO_2$ methanation

M. Mihet*, A.M. Kasza, O. Grad, A. Turza, M. Dan, M.D. Lazar

*National Institute for Research & Development of Isotopic and Molecular Technologies – INCDTIM, 67–103 Donat Str., 400293 Cluj–Napoca, Romania*

**Keywords:** MIL-53(Al)(as), MIL-53(Al)-derived Ni catalysts, $CO_2$ methanation.

**Introduction.** Despite the unique properties of metal-organic frameworks (MOFs) such as very high surface area, large porosity in the micro- and meso range with a well-defined pore size distribution, as well as compositional versatility which make them attractive for a multitude of applications, their use on a large scale is limited due to their low stability when exposed to moisture or higher temperatures. However, when used as templates/precursors, MOFs can be transformed into more stable porous materials which inherit to a large extent the properties of the initial MOF [1]. Thus, MOF-derived materials are envisaged as promising candidates in different areas, especially in catalysis, owing to the abundant and well-dispersed active sites that can be obtained in this way. Recently, we have shown that Ni deposited on alumina derived from either the as-synthesized (*as*) or the activated (*lt*) form of MIL-53(Al), a microporous flexible Al-based MOF, leads to catalysts with enhanced performance in the $CO_2$ methanation process as a result of improved structural and functional properties [2]. The aim of this work is to report on a different approach to obtain MIL-53(Al)-derived Ni catalysts, that is deposition of the metal through the metal salt of choice directly on the as-synthesized MOF, followed by the thermal treatment which allows both the decomposition of the MOF to alumina and of the Ni salt to NiO. The advantage of using directly the (*as*) form relies on the fact that the long and tedious activation procedure can be thus avoided.

**Experimental/methodology.** MIL-53(Al)-derived Ni catalysts (10wt.% loading) were obtained by metal deposition either by the incipient wetness impregnation method (IWI), or the melting infiltration procedure (MI) on the as-synthesized (*as*) and activated (*lt*) forms of MIL-53(Al) which was synthesized by a less energy and time-consuming approach (190°C, 12 h). The derivation sequence performed at 600°C, for 5 h (0.5°C/min) allowed the concomitant decomposition of MIL-53(Al) to $Al_2O_3$ and of the starting Ni salt, to NiO. All samples were further reduced in $H_2$ flow, at 750°C. Characterization was performed by XRD, $N_2$ sorption isotherms (BET), TPR, TEM/EDX, $H_2$, and $CO_2$-TPD. The catalytic performance in the methanation of $CO_2$ was investigated under plug-flow conditions at atmospheric pressure, in the 200 – 500°C temperature range, $CO_2/H_2/Ar$ = 1/4/1, 36 L $g^{-1}$ $h^{-1}$, while effluent gases were analyzed by GC equipped with a TCD.

**Results and discussion.** Characterization results revealed that besides the MIL-53(Al) form used as starting material (either *as* or *lt* form), both the employed deposition technique, and the time have an important impact on the structural, morphological, and functional characteristics of the MIL-53(Al)-derived Ni samples. Thus, small, and very well-dispersed Ni nanoparticles are obtained using the IWI technique on MIL-53(Al)(lt) or the MI method on MIL-53(Al)(as) (< 7 nm). On the other hand, the longer the time used in the case of the MI method, the smaller the deposited Ni nanoparticles, and the less reducible the initial NiO. All samples exhibit lower surface areas than the starting microporous MIL-53(Al), but larger pore volumes, while pore size distribution proves their mesoporous structure. Temperature-programmed desorption of either $H_2$ or $CO_2$ reveals an enhanced adsorption capacity of the MIL-53(Al)-derived Ni catalysts as compared to the reference $Ni/Al_2O_3$ prepared by impregnation of commercial γ-alumina, with consequent improved catalytic performance in the $CO_2$ methanation process.

**Keywords:** Olefins, 3D printing, casting, oxidative coupling of methane

**Introduction.** 3D printing give possibility of the creation of almost any physical object from a digital 3D CAD (Computer Aided Design) model. In a typical scenario, the digital 3D model is converted to STL (STereoLithography) format and then sliced into a series of two-dimensional layers using specialized software. The 3D printer then builds the corresponding physical object by deposition of a material (e.g. polymers, metals, ceramics and others), using a layer-by-layer approach. The fast development of 3D printing technology observed in the last decade has led to a wide array of promising applications in various fields. In the catalysis 3D printing technologies were used to fabrication of electrochemical electrodes which are the platform of various catalytic device, supports as well as heterogeneous catalysts [1,2].
In this communication we demonstrate that a high resolution 3D printer using DLP (Digital Light Processing) technology can be a useful tool for the preparation of multicomponent monolithic catalysts.

**Experimental/methodology.** Casting pathway was applied for multicomponent catalysts preparation. In this approach a polymeric matrix, projected as a 3D digital model and then printed with high resolution in DLP technology, can be used as a hard template in order to control the shape and size of channels in monoliths. Based on these templates, a series of Mn, Na, W, Al and Si containing catalysts were prepared. The catalytic performances of the prepared monoliths were investigated in the oxidative coupling of methane (OCM). The conditions and procedures are described previously [3].

**Results and discussion.** Among many effective OCM catalysts, multicomponent Mn-$Na_2WO_4$/$SiO_2$ system is considered to be one of the most promising for practical application due to its high activity, selectivity to $C_{2+}$ and reasonable stability. Typically, in flow type reactors (T = 750–850 °C, $CH_4$:$O_2$ = 2.0–4.0, GHSV = 2000-36000 $h^{-1}$), the selectivity to $C_{2+}$ is in the range 60–80% when $CH_4$ conversion varies between 20–30 %. [4]. The rational design of monoliths allows to obtain a similar or higher yield of $C_{2+}$ (ethane, ethene, propane and propene) at the range of GHSV compared to powder catalysts. Additional benefits of the developed monoliths are higher selectivity towards $C_{2+}$ (5-7 %) and much lower drop of pressure vs. GHSV. Moreover, we have found that in the catalyst formulation studied the presence of W is not crucial for catalytic performance in OCM. The monoliths with Mn loading of 2-10 wt. % exhibit as high activity as monoliths containing additionally $Na_2WO_4$. It seems that the presence of both Mn and Na in the monolith composition is necessary for activity as well as high selectivity towards $C_{2+}$ hydrocarbons. Moreover, we have found that controlling of channels size and density in the monoliths allow to control of methane and oxygen conversion and, to a lesser extent, the selectivity to $C_{2+}$. The catalytic behaviour varies with feed gas composition and GHSV. Under the OCM conditions tested in this work, it is preferable to select the monoliths with moderate channel diameters (0.6-0.8 mm) and as high as possible channels density.

**Keywords:** $LaMnO_3$, acid treatment, CO oxidation, needle-like $MnO_x$

**Introduction.** The post treatment of $LaMnO_3$-based perovskites in acid solutions has received a considerable attention as interesting approach to improve the textural properties of the perovskite as well as its catalytic performance in VOC oxidation [1-2]. In this work, we studied in detail the effect of the acid concentration and time on the evolution of textural, morphological, redox and catalytic properties of acid modified $LaMnO_3$ in CO oxidation.

**Experimental/methodology.** 1 g of $LaMnO_3$ (LM, Treibacher Industrie AG) was treated in 240 ml of $HNO_3$ solution under stirring at room temperature. The solid, then, was washed with distilled water, centrifuged three times and dried overnight at 373 K. To evaluate the effect of the $HNO_3$ concentration, LM was treated in 0.025, 0.1, 0.8, 3, 6, 9 M and 15 M $HNO_3$ solutions for 1 hour. To study the effect of time, $HNO_3$ concentration was kept at 3 M, extending the treatment to 6 or 18 hours. The samples were named as follow "LM c-t", where c indicates the molar (M) $HNO_3$ concentration and t denotes the treatment time (h). The samples were characterized by means of ICP analysis, $N_2$ adsorption/desorption measurements, XRD, $H_2$-TPR, XPS, HRTEM and HAADF-STEM. CO oxidation test were carried out in 1% CO, 10% $O_2$ in $N_2$ at GHSV of around 135000 $h^{-1}$. Tha gas composition was monitired by on-line MKS 2030 FTIR multi gas analyzer.

**Results and discussion.** Depending on the strenght of the acid treatment, the catalyst composition significanly changes: La/Mn ratio gradually decreases from 0.96 on LM to 0.59-0.41 for the samples treated in 0.025-3 M solutions. On LM 3-6 and LM 6-1, La/Mn further decreases to 0.18 and 0.23, respectively, approaching zero on LM 3-18, 9-1 and 15-1. The BET surface area increases from 20.1 $m^2/g$ on LM up to 166 $m^2/g$, with a corresponding increase of the pore volume from 0.13 $cm^3/g$ up to 0.60 $cm^3/g$ and larger pore size (30-700 Å), suggesting the formation of meso-macroporous network. In parallel, LM turns to a $MnO_x/LaMnO_3$-type catalysts with $LaMnO_3$ as main phase and traces of $Mn_3O_4$ (0.025-3 M) or $MnO_x$ ($MnO_2$ and $Mn_3O_4$) (LM 3-6 and 6-1). Under severe acid conditions, $LaMnO_3$ structure collapses, resulting in pure $MnO_x$ ($MnO_2$, $Mn_3O_4$ or $Mn_2O_3$). HRTEM analysis (Figure 1(a-b)) evidences the co-presence of perovskite and $MnO_x$ in needle-shaped structures. Looking at Figure 1(c), $MnO_x/LaMnO_3$-type catalysts oxidized CO more efficiently, achieving 10% of CO conversion in the range of 102-126 °C, against 186°C on LM. The positive effect of the acid dissolution disappears when the catayst is pure $MnO_x$, denoting a positive effect from $LaMnO_3$-$MnO_x$ interaction towards CO oxidation.

**Keywords:** CO Oxidation, Metallic Glasses, Cerium dioxide, Mechanochemistry, Catalyst design

**Introduction.** The research of new catalysts with improved reaction performance and durability is of utmost importance for sustainable development and environmental protection. Among various solid-gas reactions, the oxidation of carbon monoxide (CO) is a key process in environmental care and the advancement of fuel cell technology. In particular, the preferential oxidation of carbon monoxide (COPrOx) in rich hydrogen ($H_2$) gas streams has been recognized as an effective route to purify $H_2$ produced by bioalcohol steam reforming reactions to extend the lifetime of the current electrocatalysts employed in low temperature fuel cells [1]. Metallic glasses have been identified as amorphous alloys with enhanced catalytic properties [2]. The lack of crystalline order introduces free volume in the material, thus producing an exponential increase in diffusivity of the chemical species. In addition, the highly defective structure increases the kinetics of many chemical reactions [3]. Here we will share new findings on metallic glass catalysts for CO oxidation and explore challenges in optimizing amorphous/crystalline interfaces for this reaction.

**Experimental/methodology.** We have produced **Cu-Zr-Al metallic glasses** by rapid quenching. The cooling rate during the quenching of the melted material is estimated to be $10^5$ K $s^{-1}$, this ultra-fast cooling inhibits crystallization thus obtaining the metal in a disordered, glassy state. The absence of crystalline Bragg reflections indicates an amorphous structure of the alloy.

**Results and discussion.** The catalytic performance of amorphous $Cu_{47}Zr_{47}Al_6$ metallic glass-based samples was inspected by monitoring the CO conversion at different temperatures. The as synthesized $Cu_{47}Zr_{47}Al_6$ ribbons were ball milled to increase its specific surface area. As shown in Figure 1, 100% CO conversion was achieved at temperatures above 240°C when the metallic glass was ball milled with $CeO_2$ crystalline powder. Nevertheless, a lower catalytic efficiency was obtained when the pure counterparts ($CeO_2$ or the $Cu_{47}Zr_{47}Al_6$ metallic glass) were tested under identical experimental conditions. Our results demonstrate that the combination of amorphous Cu-based metallic glasses and crystalline $CeO_2$ display a remarkable catalytic activity and stability for CO oxidation.

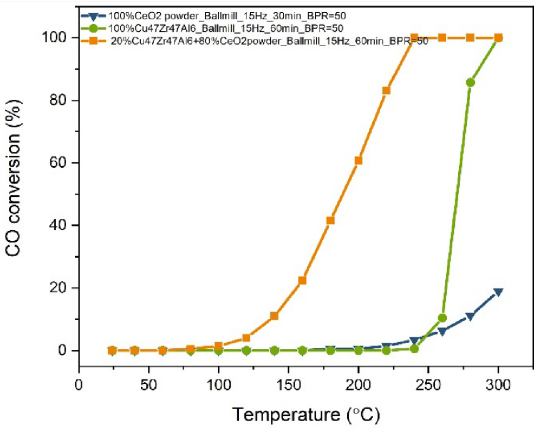

**Figure SEQ Figure * ARABIC 1. CO conversion obtained during operation with a Cu-based metallic glass ($Cu_{47}Zr_{47}Al_6$) ball milled with $CeO_2$ as a model of amorphous phase catalyst for CO oxidation.**

**Keywords:** Solid Base Catalyst, Oxynitride, Knoevenagel Condensation

**Introduction.** Solid base catalysts using oxide-based materials have been widely used for the application for C-C bond formation. [1] It is well known that oxides modified by alkali-metal compounds exhibited strong solid base profiles. [2] However, these typical catalysts suffer from a wide distribution of basic strength due to disordered alkali-metal doping and surface reconstruction during synthesis, it is not clear which structures exhibit strong basicity. Herein, we repoted the solid base catalyst with the site selective replacement of oxygen to nitrogen and vacancies in hexagonal-$BaTiO_{3-x}$. Increasing the electron density around $N^{3-}$ site and the surface Lewis basicity promotes the catalytic activity for Knoevenagel condensation.

**Experimental/methodology.** A series of hexagonal-$BaTiO_{3-x}A_y$ (A = O, H, N) were prepared through the anion substitution of hydride in *h*-$BaTiO_{3-x}H_x$, prepared by direct reaction of $BaH_2$ and $TiO_2$ under $H_2$ at 800°C. *h*-$BaTiO_{3-x}N_y$ was prepared from *h*-$BaTiO_{3-x}H_x$ heated under a $N_2$ gas flow at 600°C. *h*-$BaTiO_{3-x}H_x$ was calcinated in air at 800°C to obtain *h*-$BaTiO_{3-x}$. Knoevenagel condensation reaction was conducted in a glass vial tube. Ethanol solution of methylene compounds, benzaldehyde, and *n*-dodecane was added to the catalysts in the vial under air at 70°C.

**Results and discussion.** The surface basic site of prepared materials are characterized via $CO_2$-TPD in Figure 1. All prepared catalysts exhibited weak basicity can be assined to $CO_2$ chemisorbed on the lattice oxygen near BaO- or $TiO_2$-terminated surface, and the strongest basic sites observed on *h*-$BaTiO_{3-x}N_y$. Based on the DFT calculation and XAFS measurements, the strong basicity on *h*-$BaTiO_{3-x}N_y$ was assign to the increase in the electron density of nitrogen caused by electron donation from adjacent vacancy site. To investigate the catalytic base activity, Knoevenagel condensation reaction between benzaldehyde and active nitrile compoinds with various p$K_a$ was conducted. All of catalysts afforded in good yield of products with nitrile of low p$K_a$ value, however, only *h*-$BaTiO_{3-x}N_y$ showed high catalytic activity for various nitlile up to p$K_a$ = 23.8. Moreover, $BaTaO_2N$ and $LaTiO_2N$ without vacacies exhibited much lower yield than *h*-$BaTiO_{3-x}N_y$, indicating only $N^{3-}$ sites adjacent to vacancies work as strong base sites in oxynitrides.

**Keywords:** Al-rich gel method, Al distribution, syntesis of zeolites, ZSM-5 zeolite.

**Introduction.** Control of Al organization in Si-rich zeolite matrices represents an important issue as it governs the catalytic performance of both acid and redox sites and represents one of the key parameters of the zeolite-based catalyst.[1,2] Isolated Al atoms, Al pairs (Al-O-$(Si\text{-}O)_2$-Al sequences in one zeolite ring), and close unpaired Al atoms (two close Al atoms located in different rings) were reported for silicon-rich zeolites.[1,2] ZSM-5 of MFI topology represents the most prominent Si-rich zeolite for catalytic applications. For this reason, synthesizing ZSM-5 materials with a maximized concentration of Al species, providing a high concentration of active sites suitable for selected processes, attracts significant attention. Isolated Al atoms and Al pairs were reported to be present in this matrix, and significant effort was spent to reach (semi)monomodal ZSM-5 matrices with prevailing single Al atoms or Al pairs using control of synthesis conditions (nature of Al and Si sources, presence of co-cations, etc.).[3,4] However, the preparation of ZSM-5 zeolites with a high fraction of Al pairs was limited to materials with rather higher framework Al content (Si/Al < 40). In this contribution, a new synthesis protocol enabling the preparation of Si-rich (Si/Al > 50) ZSM-5 zeolite matrices with over 80 % of Al atoms in Al pairs is reported. This method is based on the preparation of two gels (all-silica one and Al-rich one), which are aged and subsequently combined together before final crystallization under hydrothermal conditions.

**Experimental/methodology.** Sets of ZSM-5 zeolite synthesis gels of the same Si/Al were prepared. The gels varied in the procedure of preparation (sequence of mixing) while applied chemical reagents were the same (TEOS or TPAOH as SDA, $AlCl_3$ or $Al(NO_3)_3$ as Al source). The Al-rich gels of Si/Al = 4, 7, 7.5, 8.5, 12.5, 15, 30 and pure Si (Si/Al=∞) with SDA were prepared and combined to obtain final Si/Al=30 gels, which were subjected to crystallization under hydrothermal conditions (170 °C, 6 days, agitation). Crystalline products were characterized by XRD and SEM. Both synthesis gels and prepared zeolites after calcination were characterized using $^{27}Al$ and $^{29}Si$ MAS NMR spectroscopy, selected gels by $^{27}Al$-$^{27}Al$ double-quantum single-quantum MAS NMR spectroscopy. Al distribution in the zeolite product was analysed by Co(II) ions as a probe monitored by UV-Vis spectroscopy of dehydrated maximum Co(II) exchanged samples.[1,2]

**Results and discussion.** Zeolites prepared by mixing of Al-rich and pure silica gels exhibited significantly higher concentration of Al pairs in the framework (up to twice higher for syntheses using $AlCl_3$ and five-times higher for synthesis with $Al(NO_3)_3$ as Al source). This allowed preparing of ZSM-5 zeolite with Si//Al 30-60 and ~90 % of Al atoms in Al pairs. According multinuclear ss-NMR study, close Al atoms serving as precursor of Al-O-$(Si\text{-}O)_2$-Al sequences in zeolite are formed in the Al-rich gel with Si/Al < 9, and they are preserved after mixing of Al-rich gel with the all-silica one and transferred to the ZSM-5 framework. The suggested here mechanism of transferring larger Al-O-Si-O-Al sequences into ZSM-5 product can be considered in analogy to the one already proved for SSZ-13 zeolite synthesized using various zeolites as Al and Si sources.[5]

The synthesis strategy to maximize the concentration of Al pairs in silicon-rich matrices is reported. This strategy can be suggested to be not limited by the structure directing agent or Si and Al sources used in the synthesis gel preparation. Thus, it represents a very promising tool for tuning Al distribution in various silicon-rich zeolite matrices.

**Keywords:** Perovskite, lanthanum aluminate, sol-gel, methane, and carbon dioxide.

**Introduction.** Dry reforming of methane (DRM) has received considerable attention because it can reduce greenhouse gas emissions ($CO_2$ and $CH_4$) while converting them into valuable syngas ($H_2$ and CO) [1]. The $Ni/LaAlO_3$ catalysts are considered promising materials for the application of this technology. However, there are several challenges when using Ni-based catalysts such as sintering of the active phase and carbon deposition on the catalyst surface due to the high temperatures used in the DRM reaction [2]. Therefore, the textural properties of the catalytic support play an important role [3], for this reason, the present study reports for the first time a simple strategy to prepare the pure perovskite phase of $LaAlO_3$ with a high specific surface area as catalytic support. This study demonstrates that the textural, structural, and catalytic properties can be modulated by optimizing the solvothermal treatment time.

**Experimental/methodology.** The perovskite supports were obtained after the reaction between an organic ligand and the precursor salts of Al and La in ethanol at 120 °C at several times (t = 4, 6, 12 and 24 h) (*MOX-(t)-Al-La*), then these were calcined at 750 °C (*MOX-(t)-Al-La-750*). A material called MOX-Ex-Al-La-750 was also prepared by the addition of La to the MOG-Al-100 gel precursor and finally, the reference material was synthesized by using the citrate sol-gel method (C-Al-La-750), both materials were calcined at 750 °C. The catalysts were prepared by incipient impregnation with 10 wt.% of Ni and these were denoted *as MOX-(t)-$LaAlO_3$-Ni* (t = 12 and 24 h) or C-$LaAlO_3$-Ni. The catalysts were evaluated in the DRM reaction for 20 h at 700 °C.

**Results and discussion.** Among the MOGs evaluated, the *MOX-(t)-Al-La* (t = 12 and 24 h) had the highest specific surface areas and showed sponge-like porous structures. The X-ray diffraction results of the samples calcined and solvo-thermally treated materials for t = 6, 12, and 24 h (*MOX-(t)-Al-La-750*) showed diffraction peaks of the crystallographic planes coincided with the theoretical pattern of lanthanum aluminate (JCPDS card No. 96-220-6577) without the presence of impurities such as $La_2O_3$. It should be noted that the *MOX-(t)-Al-La* (t = 12 and 24 h) materials maintained the mesoporous characteristics of the La-Al-MOG precursors with high specific surface areas, these were up to three times higher than the reference material, the aforementioned due to the low calcination temperature necessary for crystallization. The properties obtained on perovskite-type supports of solvo-thermally treated materials for 12 and 24 h allowed a high dispersion of the active sites of Ni. However MOX-(12h)-$LaAlO_3$-Ni showed the best catalytic performance with an $H_2$/CO ratio close to 1, $CO_2$ conversion of 80% and methane conversion of 75% after 20 h of reaction, which was superior compared to reference catalyst and catalysts based on lanthanum aluminate previously reported in the literature. The explanations for this catalytic behavior in the DRM reaction were derived from the following physicochemical properties: *(i)* improved textural properties of the support; *(ii)* the presence of $\alpha$- and $\beta_1$-Ni species; *(iii)* NiO species with a strong oxide/support interaction and *(iv)* resistance to the formation of a dense network of interconnected carbon filaments.

**Keywords:** base catalyst, polyoxometalate, polyoxoniobate

**Introduction.** Acid and base catalysts are essential for industrial processes in petroleum chemistry and biomass conversion. Group V metal oxides such as $Nb_2O_5$ are generally known to act as acid catalysts.[1)] On the other hand, we recently reported that niobium oxide clusters(PONb), exhibit Brønsted and Lewis base catalysis for Knoevenagel condensation (KC) and $CO_2$ fixation reactions, respectively[2)]. The Brønsted base properties of $[Nb_6O_{19}]^{8-}$came from highly negative charges of surface oxygen, as calculated by DFT calculations. However, the origin of the strong basicity of niobium oxide clusters is not fully understood yet. In this study, we synthesized a series of niobium oxide clusters with different sizes, such as $[Nb_6O_{19}]^{8-}$ [2)], $[Nb_{10}O_{28}]^{6-}$ [3)], and $[Nb_{20}O_{54}]^{8-}$ [4)], with the same counter cation of tetrabutylammonium ion (TBA+) by using a microwave-assisted hydrothermal synthesis and applied them to KC reaction to evaluate their basicity (Fig. 1).

**Fig. 1 Structure of Nb6, Nb10, Nb20. NBO charges of surface oxygen.**

**Experimental/methodology.** The TBA salts of $[Nb_6O_{19}]^{8-}$(Nb6) and $[Nb_{10}O_{28}]^{6-}$(Nb10)were prepared by a microwave-assisted hydrothermal synthesis, which $Nb_2O_5{\cdot}nH_2O$ were treated in aquaeous solution of TBAOH with the optimized heating conditions. The TBA salts of $[Nb_{20}O_{54}]^{8-}$(Nb20) were obtained by precipitation filtration collection of TBA salts of Nb10 dissolved in dichloromethane in ethyl acetate. Base catalytic properties were evaluated by KC reactions, where nitrile compounds of different p$K_a$ (16.0, 21.9, 23.8) were reacted with benzaldehyde (BA) in DMSO at 70°C for 24 h under $N_2$ atmosphere. DFT calculations (B3LYP functional) were performed using Gaussian16 with the basis functions of Lanl2dz for Nb and 6-31++G** for O and H.

**Results and discussion.** Elemental analysis, ESI-MS and ATR-IR revealed that clusters of the target composition could be synthesized**.** Fig. 2 shows the BA conversion at 70°C in KC reactions using substrates having various pKa. As for the substrates of pKa of 21.9 and 23.8, Nb6 showed high activities, followed by Nb10. Nb20. The catalytic activity of Nb20 for KC reaction with the substrate having pKa = 16.0 was higher than that of bulk $Nb_2O_5{\cdot}nH_2O$, although Nb20 hardly worked as a base catalyst for KC reactions above pKa of 21.9. The order in base catalytic activity corresponded to that in their negative charges of surface oxygens which are considered to be the basic active sites. We also discuss the relationship between the base strength and KC activities by using DFT calculations .

**Fig. 2 BA conversion in KC reactions using substrates having different pKa.**

**Keywords:** Carbon-neutral society, Energy (Hydrogen) carrier, Green ammonia

**Introduction.** Ammonia has gained a lot of attentions as a potential energy ($H_2$) carrier for utilizing renewable energy. To construct such a system, there is a strong need to develop an innovative catalytic process for ammonia synthesis. Ammonia is currently produced by the Haber-Bosch process and is manufactured at high temperature and high pressure (>450 °C and >20 MPa) over an iron-based catalyst. It is expected to develop a catalyst that produces ammonia efficiently under mild reaction conditions (300-400 °C, <10 MPa) that can reduce energy consumption in the green ammonia synthesis process. We have reported that Ru catalysts supported on composite rare earth oxides such as $La_{0.5}Ce_{0.5}O_{0.75}$ [1] and $Ba_{0.1}La_{0.45}Ce_{0.45}O_{1.68}$ [2] exhibit high $NH_3$ synthesis rates under mild conditions (300 - 400 °C, 1.0 MPa) when reduced at an unusually high temperature of 650 °C. These catalysts are easy to prepare, stable in air, and suitable for practical use. By further applying these concepts to inexpensive Co catalysts, we have succeeded in discovering Co/Ba/MgO [3] and Co/Ba/$La_2O_3$ [4] catalysts. Especially, Co/Ba/MgO pre-reduced at 700 °C shows higher $NH_3$ synthesis rate than benchmark Ru catalysts at 350 °C and 3 MPa. In this contribution, we will address the performance of the Co/Ba/MgO and formation mechanism of active site, i.e. Co@BaO core-shell structure, during pre-reduction.

**Experimental/methodology.** Oxide-supported metal catalysts were prepared by wet impregnation. Co and Ru loadings were 20 and 5 wt%, respectively. The $NH_3$ synthesis rate was evaluated using a conventional flow system.

**Results and discussion.** Fig. 1 represents pressure dependence of $NH_3$ synthesis rate at 350 °C. At 0.1 MPa, the Co/Ba/MgO_700°Cred (xxx°Cred means that the catalyst was pre-reduced at xxx °C) catalyst exhibited a lower $NH_3$ synthesis rate than the two benchmark Ru catalysts. However, the $NH_3$ synthesis rates of these Ru catalysts did not rise much even when the reaction pressure was increased to 3.0 MPa due to strong hydrogen adsorption property of Ru, so-called hydrogen poisoning. By contrast, the $NH_3$ synthesis rate of Co/Ba/MgO_700°Cred increased drastically when the reaction pressure was increased to 3.0 MPa, and at this pressure the synthesis rate was much higher than those of the Ru catalysts. The reaction order for $H_2$ for the Co catalyst is 0.37, revealing that this catalyst is not poisoned by $H_2$. We have shown that pre-reduction of the catalyst at high temperature leads to surface rearrangement, forming BaO-encapsulated Co nanoparticles (Co@BaO) on the MgO surface, with all available Co sites on the surface adjacent to BaO nanofractions, and that such a structure promotes the dissociation of N≡N bond, the rate-determining step in ammonia synthesis. The formation of this unique structure is thought to consist of the reduction of oxidized Co to metallic Co, decomposition of $BaCO_3$ to BaO via $Ba(OH)_2$, and migration of BaO and Co nanoparticles.

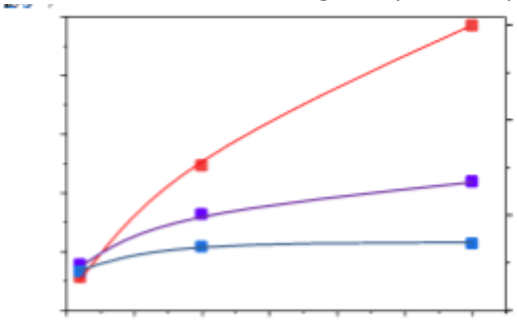

Fig. 1. Effect of pressure on the rate of $NH_3$ synthesis at 350 °C.

**Keywords:** Supported catalytically active liquid metal solutions (SCALMS), alloy, dynamic liquid interface, catalyst poisoning, dehydrogenation

Supported catalytically active liquid metal solutions (SCALMS) catalysts consist of small amounts of catalytically active metal dissolved in a low melting point liquid metal. The resulting alloy is deposited on a porous support. The catalyst composition plays an important role in determining whether the metal alloy will be present in liquid phase under reaction conditions. The liquid nature leads to highly dynamic interfaces.[1] Various bimetallic alloys with Ga as the liquid metal matrix have been tested as SCALMS for different chemical reactions, namely GaPd for n-butane dehydrogenation [1], GaRh for propane dehydrogenation [2], GaPt for methylcyclohexane dehydrogenation [3], and GaNi for ethylene oligomerization reaction.[4] The influence of support material has also been studied for GaPt based SCALMS.[5] All these studies indicated towards the high specific activity of SCALMS catalysts.

For industrial catalytic processes, deactivation via catalyst poisoning and coking is a major issue. Feedstock purification and commercial catalyst regeneration processes have contributed to significant expenses. Pre-liminary studies based on SCALMS catalysts indicate towards the role of the unique nature of the atomically dispersed active metal sites at the liquid interface in altering the coking behaviour. We extend our investigation to poisoning studies where we will deliberately expose the GaPt based SCALMS catalyst to typical catalyst poisons **(Fig. 1)** i.e., CO and $H_2S$.[6] The objective of our work is to study the influence of various factors on further enhancing the performance of the SCALMS catalysts under harsh reaction conditions. These factors include the catalyst composition, pre-treatment conditions, duration of exposure to poison etc. We choose isobutane dehydrogenation reaction as it is a clean reaction with few by-products thereby ideal to understand the effect of these factors on the SCALMS catalyst performance.

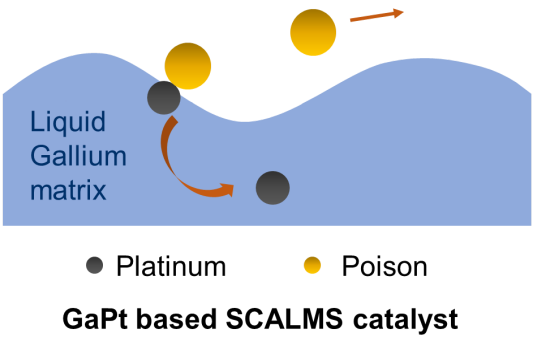

**Figure 1: Schematic showing the influence of catalyst poison on GaPt based SCALMS catalyst performance.**

**Keywords:** CHA, Zeolite, Methane conversion,

**Introduction.** Direct conversion of methane to methanol (MTM) reaction is a hot topic. We have investigated on the zeolite-based catalytic process that can produce lower hydrocarbons from methane *via* methanol.[1] In this process, copper-containing CHA-type zeolite with high Al content is applied as a catalyst; abundant acid sites can work as ion-exchange site for capturing Cu species, which produce methanol, and remaining acid site enhance the conversion of the methanol produced into lower hydrocarbons. Recently, it has been well-recognized that the control of Al atoms in the framework is particularly important for catalytic performance. We have reported that the Al distribution in zeolite framework of CHA-type zeolite can be controlled by changing the starting materials.[2] In this study, we prepared Fe-exchanged CHA-type aluminosilicate zeolites with different Al distributions. The effect of framework Al distribution in CHA-type zeolites on the ion-exchange properties and methane conversion properties was investigated.

**Experimental/methodology.** The CHA-aluminosilicate zeolite was synthesized under organic-directing agents (OSDA)-free method by hydrothermal synthesis. In addition to amorphous silica and alumina, FAU-type zeolite (Si/Al=15) was applied as the starting material; the uses of amorphous and FAU were named CHA-Am and CHA-FAU, respectively. Fe species were introduced into the $NH_4^+$ form CHA by ion-exchange method. The obtained samples were characterized by XRD, ICP-AES, $^{29}Si$, $^{27}Al$ MAS NMR, UV-vis spectrum analysis, and FT-IR. Catalytic oxidative methane conversion reaction was carried out in a continuous flow reactor under atmospheric pressure. The reaction was carried out at 350 °C with a mixture of $CH_4$, $N_2O$, and $H_2O$ ($P_{CH4}$ = 0.08 atm, $P_{N2O}$ = 0.08 atm, $P_{H2O}$ = 0.08 atm, $P_{Ar}$ = balance) at 25 mL $min^{-1}$.

**Result and discussion.** The XRD patterns of all the products showed a typical CHA-type structure. The CHA structure was retained even after the Fe loading. The $^{29}Si$ MAS NMR spectra of the $NH_4^+$ form CHA-Am and CHA-FAU samples indicated that, based on the deconvolution of the all the peaks, the proportion of $Q^4(1Al)$ species in CHA-FAU was significantly higher than that in CHA-Am, indicating that the Al distribution is different depending on the starting material ($Q^4(nAl) = (Si(OSi)_{4-n}(OAl)_n)$). The ICP-AES analysis results showed that the Si/Al ratios of Fe/CHA-Am and Fe/CHA-FAU were found to be 5.5 and 4.6, respectively and that Fe content was nearly equal in Fe/CHA-Am (Fe/Al = 0.10, 1.48 wt%) and Fe/CHA-FAU (Fe/Al = 0.10, 1.65 wt%). Figure 1 shows the catalytic performance of Fe/CHA-Am and Fe/CHA-FAU. Note that there was marked difference in total yield of hydrocarbons between Fe/CHA-Am and Fe/CHA-FAU; Fe/CHA-FAU (about 5 %) gave twice as high as Fe/CHA-Am. The difference in reactivity would be caused by the Al distribution in the framework. In this presentation, we will discuss the effects of the Al distribution on Fe ion state and reaction results based on FT-IR.

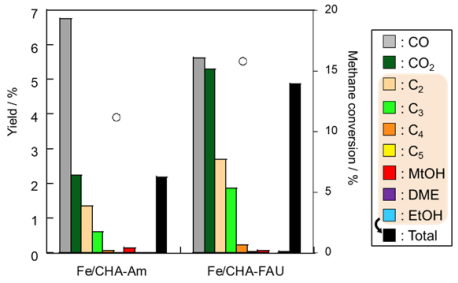

**Figure 1. Oxidative conversion of $CH_4$ with $N_2O$ over CHA zeolite catalysts. (○) Conversion of $CH_4$, the bars represent the yields to $CH_3OH$, DME, $C_2H_5OH$, hydrocarbons (C2~C5), CO and $CO_2$, respectively. Black bars show the total yield of hydrocarbons (C2~C5, methanol, DME, ethanol).**

**Keywords:** Au clusters, layered double hydroxides, alcohol oxidation

**Introduction.** Au catalysts have attracted much attention due to their unique catalytic performance. Because the catalytic activity of Au strongly depends on the size of Au, minimization of Au particle size has been intensively studied. However, deposition of Au clusters and single atoms is still challenging and there is a still room for improvement; such as low Au loading and/or limited types of supports (e.g., $CeO_2$, $Co_3O_4$, and NiO). Layered double hydroxides (LDHs) are composed of M(II) hydroxides in which M(III) is partly replaced with M(II). Zhang et al. reported that the lateral planes of LDHs could stabilize Au as clusters more efficiently than the basal planes.[1] Therefore, LDH nanoparticles (NPs) having abundant edges are expected to be a suitable support for small Au particles. Here, we aimed at deposition of Au single atoms and clusters using Mg-Al LDH NPs, which are supported on $SiO_2$. The changes of electronic states and size of Au during reduction of Au(III) was analyzed by in-situ XAFS, and the catalytic activity was evaluated by benzyl alcohol oxidation.

**Experimental.** Mg-Al LDH NPs were prepared according to the literature.[2] Then, aqueous solution of $HAuCl_4$ (Au 2 wt%) was added to a dispersion of LDH NPs, and the mixture was stirred at 0 °C for 4 h. Subsequently, $SiO_2$ was added and stirred at 0 °C for another 1 h to obtain 0.8 wt% Au(III)@LDH/$SiO_2$. The obtained Au(III)@LDH/$SiO_2$ was treated in 10 vol% $H_2/N_2$ (50 mL $min^{-1}$) at 120 °C for 2 h to obtain Au(0)@LDH/$SiO_2$, or in air at 400 °C for 4 h to transform LDH into mixed metal oxide (MMO) to give Au(0)@MMO/$SiO_2$. The prepared catalysts were analyzed by in-situ X-ray absorption fine structure (XAFS) and transmission electron microscopy (TEM). For the catalytic reaction, benzyl alcohol (20 mmol), tridecane (30 mg), and a catalyst (Au 0.001 mol%) were placed in an autoclave. The reaction was carried out under pressurized $O_2$ (2.0 MPa) at 150 °C for 1 h. The conversions and yields were analyzed by GC.

**Results and discussion.** In-situ XAFS measurements of 0.8 wt% Au(III)@LDH/$SiO_2$ was performed under $H_2$ flow from room temperature to 120 °C. Au(III) was gradually reduced to Au(0) (Fig. 1a), but the peak corresponding to Au-Au bonds were not observed (Fig. 1b) suggesting the formation of Au single atoms. HRTEM revealed that Au single-atoms were observed together with Au clusters (1.2±0.7 nm) on Au(0)@LDH/$SiO_2$. Although Au single-atoms were disappeared on Au(0)@MMO/$SiO_2$, the diameter of Au was still 1.2±0.5 nm. Au(0)@MMO/$SiO_2$ showed superior activity for benzyl alcohol oxidation (TOF: 52,071 $h^{-1}$, selectivity: 81.0 %) to Au(0)@LDH/$SiO_2$ (TOF: 3,117 $h^{-1}$, selectivity: 99.6 %). Although Au was aggregated on Au(0)@LDH/$SiO_2$, the size of Au for Au(0)@MMO/$SiO_2$ was maintained. The high durability Au(0)@MMO/$SiO_2$ led to its high activity.

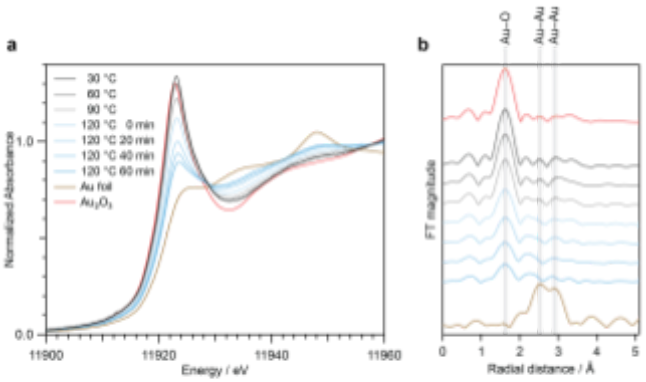

**Fig. 1 Au $L_3$-edge in-situ XANES spectra (a) and radial structure functions (b) of Au(III)@LDH/$SiO_2$ during heat treatment in the flow of 10 vol% $H_2/N_2$.**

# Reduction of nitroarenes to anilines in water solution catalyzed by Cu/SteelSlags new material

D. Nefedova*, M. Mali, G. Romanazzi, P. Mastrorilli, M. M. Dell'Anna

*Politecnico di Bari, 70126 Bari, Italy*
**darya.nefedova@poliba.it*

**Keywords:** Steel slags, copper catalyst, nitroarenes reduction

**Introduction.** The chemical reduction of nitroarenes to form anilines is a crucial step in the synthesis of a variety of industrially important compounds such as drugs, dyes, and materials.[1] Copper-based catalysts have gained significant attention in recent years for promoting this reaction as they can activate hydrogen molecules and facilitate their addition to the nitro group.[2] This enhances the efficiency of the process and can result in higher yields of the desired anilines. Conversely, basic steel slags are produced during the steelmaking process and contain a variety of metals such as iron, calcium, silicon, magnesium, and aluminium.[3] Their unique characteristics enable steel slags to act as catalysts for some chemical reactions. Thus, the use of copper catalyst supported on steel slags matrix for the nitroarene reaction could be promising in the development of new and more efficient synthetic methods for the synthesis of anilines and other nitrogen-containing compounds.

**Experimental/methodology.** The precursor of Cu/SteelSlags catalyst was obtained by mixing 9,4 mmol of copper sulphate pentahydrate ($CuSO_4 \cdot 5H_2O$) and 3.4 g of steel slags in 200 ml of $H_2O$ for 2 hours, followed by separation of the solid fraction by centrifugation and drying at 80°C during 12h. The transformation of copper oxide into an active metal form occurred under reaction reductive conditions.

The reductive reactions of nitroarenes to corresponding anilines were carried out at room tempreture in a round flask equipped with a magnetic stirrer and a gas bubbler in the presence of 0.5 mmol of nitroarene, 3.0 mmol of $NaBH_4$, 50.0 mg of Cu/SteelSlags catalyst precursor and 5.0 ml of $H_2O$.

Recyclability test was carried out at room tempreture in round flask equipped with a magnetic stirrer and a gas bubbler in the presence of 2.0 mmol of nitrobenzene, 6.0 mmol of $NaBH_4$, 200 mg of Cu/SteelSlags catalyst precursor and 10 ml of $H_2O$. After each cycle of reaction the catalyst was washed with distilled water and methanol, and dried at 80°C and used for a subsequent run.

**Results and discussion.** The synthesized catalyst was tested in the reduction of different nitroarenes (table 1). The reduction of the active component from $Cu^{2+}$ to $Cu^0$ occurred *in-situ* under reaction conditions, as evidenced by the change in the color of the catalyst from blue-gray to black. The recyclability test showed a consistently high yield of aniline over 4 cycles.

**Table 1. Activity of Cu/SteelSlags catalyst in reactions of nitroarenes reduction**

| Entry | Substrate | Product | Time, h | Yield, % |
|---|---|---|---|---|
| 1 | Nitrobenzene | Aniline | 2 | >99 |
| 2 | 4-Fluoronitrobenzene | 4-Fluoroaniline | 2 | >99 |
| 3 | 4-Cloronitrobenzene | 4-Cloroaniline | 4 | >99 |
| 4 | 4-Bromonitrobenzene | 4-Bromoaniline | 4 | >99 |
| 6 | 2-Nitrotoluene | 2-methylaniline | 1 | >99 |
| 7 | 3-Nitrotoluene | 3-methylaniline | 2 | >99 |
| 8 | 4-Nitrotoluene | 4-methylaniline | 2 | >99 |
| 9 | 3-Nitroanisole | 3-anisidine | 2 | >99 |

*eassaf@iqsc.usp.br*

**Introduction.** The oxidative coupling of methane is a very promising way of mitigating the methane concentration in the atmosphere, and at the same time transforming this pollutant into added-value products. In this work, we synthesized La-Ce fluorite-type catalysts with different La/Ce ratios by the surfactant-assisted hydrothermal method. Here, we aim to investigate the catalysts' physicochemical characteristics and correlate them with the catalytic properties in this reaction.

**Experimental/methodology.** In a typical synthesis, lanthanum and cerium nitrates were used as La and Ce sources, respectively. Polyvinylpyrrolidone was the surfactant and $NH_4OH$ was the precipitant. The hydrothermal synthesis was carried out at 180 °C, for 24 h. Samples were washed and calcinated at 850 ºC. The reactions were performed at 550, 650, 750, and 850 °C, in a continuous-flow fixed-reactor (30:6:24 mL/min for $CH_4$:$O_2$:$N_2$), under a GHSV of 18,000 mL $h^{-1}$ $g^{-1}$. The samples, with nominal La/Ce ratios of 0.075, 0.333, 1, and 3, were named LaCe-0.075, LaCe-0.333, LaCe-1, and LaCe-3, respectively.

**Results and discussion.** From the XRD patterns (Fig. 1a), the fluorite phase (marked as a grey *) and the $La_2O_3$ phase (marked as the red "X"), formed with increasing La content, were both identified. Additionally, new peaks (marked as yellow *) emerged with increasing La/Ce ratio, evidencing the formation of solid solutions between La and Ce atoms. From TPD-$CO_2$ (Fig. 1b), the basic sites concentration present on the surface of the catalysts are according to the following order: LaCe-0.075 < LaCe-0.333 < LaCe-1 < LaCe-3.

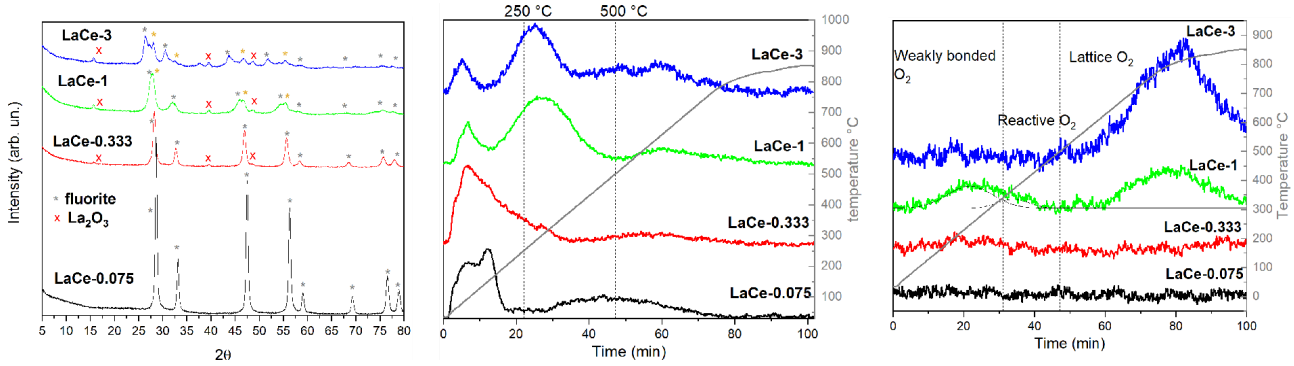

**Figure 1**: (a) X-ray diffraction patterns; (b) TPD-$CO_2$ and (c) TPD-$O_2$ curves of the calcinated samples.

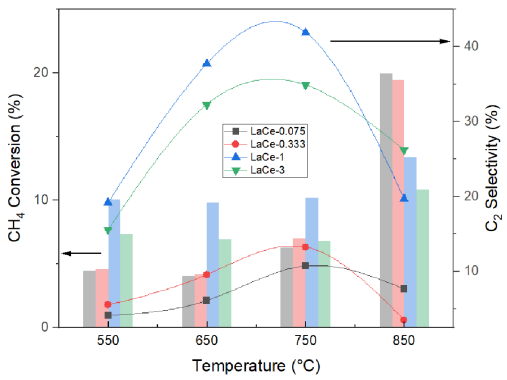

**Figure 2**: $CH_4$ conversion and $C_2$ selectivity for La-Ce catalysts.

However, the LaCe-1 catalyst showed the highest amount of moderate basic sites (between 250 and 500 °C), associated with a good $C_2$ selectivity for this reaction. Furthermore, this sample presented a higher amount of reactive $O_2$ for the AOM, as can be seen in Fig. 1c, from TPD-$O_2$. Fig. 2 depicts the methane conversion and selectivities to $C_2$ compounds (ethane and ethylene) as a function of temperature. The by-products, CO and $CO_2$, were omitted. The LaCe-1 catalyst presented the highest $CH_4$ conversion and $C_2$ selectivity, except at 850 °C. Such sample presented higher amounts of moderate basic sites and reactive oxygen, both properties notably known for selective conversion to $C_2$ compounds [1].

# Palladium Phosphide Catalysts for the Wacker-Tsuji-Oxidation of Alkenes

A. Neyyathala[1], F. Flecken[1] , JProf. S. Hanf[1]*

[1]*Karlsruhe Institute of Technology, Karlsruhe, Germany*

** schirin.hanf@kit.edu*

**Keywords:** Wacker-Tsuji-oxidation, alkenes, palladium phosphide, supported catalysts, heterogeneous-catalysis

**Introduction.**

The oxidation of alkenes to methyl ketones is an industrially important chemical reaction and it is used in the manufacturing of a wide spectrum of products, such as fine chemicals, organic intermediates and agrochemicals.[1,2] Therefore, the development of active, reusable and easily separatable solid state catalysts for oxidation catalysis has great significance in an industrial context. Consequently in this work, a supported palladium phosphide catalyst was synthesized and applied in the Wacker-Tsuji oxidation of styrene. The goal was hereby to reduce the noble metal content with respect to a sustainable use of metal resources, while maintaining or even enhancing the catalytic activity through the incorporation of phosphorus.

**Experimental/methodology.**

Silica supported palladium phosphide ($Pd_3P/SiO_2$) with 10 wt.% Pd loading was synthesized using an impregnation method followed by thermal treatment in hydrogen. The synthesized catalyst was characterized by PXRD, XPS, SEM-EDX, ICP-AES, and FTIR. Catalytic tests were performed in batch reactors, considering four reaction systems with variations in co-catalysts and oxidants, followed by an assessment of reaction time and temperature dependency. Recovery tests and filtration tests were performed to access the reusability of catalyst and heterogeneous nature of the catalytic system.

**Results and discussion.**

PXRD analysis of the synthesized catalyst confirmed the formation of the $Pd_3P$ phase on $SiO_2$ and XPS unveiled zero valent surface Pd species. Superior catalytic performance is observed for $Pd_3P$ in comparison to a purely Pd-based supported catalyst, which shall be attributed to the more defined active sites of $Pd_3P$ in comparison to pure Pd.[3]

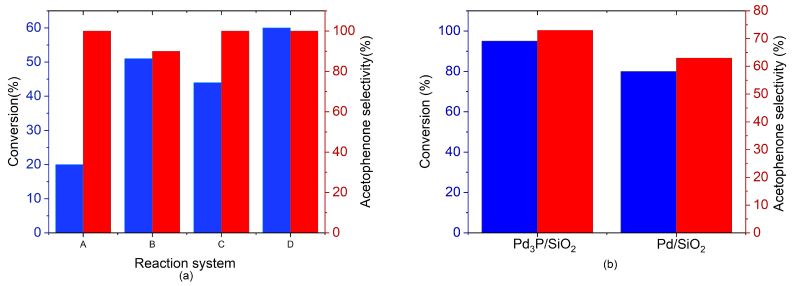

***Figure 1 a) Comparison of different reaction systems: A: styrene, CuCl, THF, $H_2O$, $O_2$; B: styrene, $CuCl_2$, THF, $H_2O$, $O_2$; C: styrene, 30 % $H_2O_2$, 70 % $H_2SO_4$, MeCN and D: styrene, 30 % $H_2O_2$, acetic acid, $H_2O$. Test conducted at 50°C for 6h with $Pd_3P/SiO_2$ catalyst. b) Performance comparison of $Pd_3P$ and Pd in reaction system B at 50°C for 16h.***

# Photo-induced Active Lewis Acid-base Pairs in Metal-Organic Framework for $H_2$ Activation

Bryan Kit Yue Ng[1], Xin-Ping Wu[2], Shik Chi Edman Tsang[1*]

[1]*Department of Chemistry, University of Oxford, United Kingdom*
[2]*Key Laboratory for Advance Materials, East China University of Science and Technology, China*
**edman.tsang@chem.ox.ac.uk*

**Keywords:** Metal-organic Frameworks (MOFs), hydrogen activation, photocatalysis

**Introduction.** The establishment of active sites as Frustrated Lewis Pair (FLP) has recently attracted much attention from homogeneous to heterogeneous systems in the field of catalysis[1]. Their unquenched reactivity of Lewis acid and base pairs in close proximity that are unable to form stable adducts has shown to be able to activate small molecules such as dihydrogen heterolytically.

**Experimental/methodology.** Herein, by utilising the chemical stability and wide tuneability of UiO series metal-organic frameworks, we demonstrate that grafted Ru metal-organic framework-based catalysts prepared via N-containing linkers are rather catalytically inactive for H2 activation despite the application of elevated temperatures.

**Results and discussion.** However, upon light illumination, charge polarization of anchored Ru bipyridine complex can form transient Lewis acid-base pair, $Ru^{+}$-$N^{-}$ via metal-to-ligand charge transfer, and this is confirmed by time-dependent density functional theory (TDDFT) calculations to carry out effective H2-D2 exchange. FTIR and 2-D NMR endorse the formation of such reactive intermediate(s) upon light irradiation.

# Bridging the Gap between Molecular and Solid Catalysts: Nanoporous Phosphine-Based Macroligands for the Activation of $CO_2$

Arne Nisters[1], Marcus Rose[1*]

[1] *Chemical Technology II, Technische Universität Darmstadt, Darmstadt, Germany*
[*] *marcus.rose@tu-darmstadt.de*

**Keywords:** $CO_2$ hydrogenation, phosphine-based macroligands, hyper-cross-linked polymers

**Introduction:** In the last two decades, the hydrogenation of $CO_2$ as C1 building block has attracted increasing attention. Due to its high stability, the development of catalysts plays a crucial role and was addressed by various studies, leading to a large variety of active homogeneous catalysts.[1] Despite their excellent catalytic performance, difficulties occur in the catalyst recyclability and the product separation. Therefore, the heterogenization of the molecular species has evolved with great opportunities in catalyst development. In recent years, porous organic polymers, which combine a high accessibility of functional moieties with an adjustable topology, were subject of several investigations.[2] Among this class of materials, polyphosphines with permanent porosity have been reported.[3,4] In our work, we developed novel phosphine-based macroligands for the immobilization of molecular ruthenium centers. The versatility of the topological design and the coordination sphere enabled a systematic investigation about the influence of the macroligand on the catalytic reactivity of the metal species.[5]

**Experimental/Methodology:** The versatile macroligands, which refer to the class of hyper-crosslinked polymers, are synthesized by the external knitting of phosphine units. Bifunctional crosslinkers such as α,α′-dibromo-*p*-xylene, 4,4′-bis(chloromethyl)-1,1′-biphenyl or dimethoxymethane connect the phosphines via Friedel-Craft-alkylations in the presence of the Lewis catalyst $AlCl_3$. These obtained insoluble networks are afterwards impregnated with ruthenium precursors by ligand exchange from solution. The thus formed catalysts are evaluated in the aqueous phase hydrogenation reaction of $CO_2$ to formic acid. The base-mediated catalysis is conducted in batch autoclaves at 110 °C and an elevated pressure of 60 bar.

**Results and Discussion:** The network formation and the incorporation of phosphine units were proven by ATR-IR and XRF analytics, additionally the high thermal stability of the network up to 250 °C was shown by TGA measurements. Electronic microscopy and physisorption measurements indicated a permanent micro- and mesoporosity of the amorphous networks (up to 1450 $m^2\ g^{-1}$), which was tailored by the choice of the external crosslinking agents. $^{31}$P-MAS-NMR and XPS measurements revealed the electronic structure of the partially oxidized phosphorus species and the cationic character of the metal centers.

In the catalytic experiments, high activities for the hydrogenation of $CO_2$ to formic acid were achieved, proving the concept of the solid molecular catalyst. The investigations about the structural influence of varying phosphine monomers showed the beneficial properties of bidentate ligands like bis(diphenylphosphino)methane (dppm), 1,2-bis(diphenylphosphino)ethane (dppe) or Xantphos for their application as macroligand. Comparative catalytic experiments with homogeneous analogues suggested the retention of the molecular ligand sphere in the immobilized catalysts. Recyclability experiments showed a decrease of the catalytic activity after the first run, resulting in a constant catalytic performance over the following runs. This change can be associated to topological modifications under the catalytic conditions that results in an active and stable catalyst after a certain induction phase.

**Keywords:** vat 3D printing, composites, monolithic catalysts, OCM

**Introduction.** A monolithic catalyst is a block of material with parallel channels that can be, for example, square, round or hexagonal in shape. Through the channels, a stream of liquid or gaseous reactants is transported and the reaction takes way on the inner surface of the hollow channels. Different types of monoliths are used for the processes, including ceramic (e.g. cordierite) or metal (e.g. FeCr alloys) [1-3]. Monoliths are most often obtained by extruding or corrugating the raw material [4], but an innovative method is 3D printing [5]. Monolithic catalysts can be obtained by coating an active layer onto a pure carrier or by adding active components to the finished paste before extruding the monolith [4]. Nowadays, monolithic catalysts are used for the removal of volatile organic compounds (VOCs) and selective catalytic reduction (SCR) of NOx [4,6]. In this presentation, the monolithic catalysts prepared by 3D printing in DLP (digital light processing) technique using composite resins dedicated to oxidative coupling of methane (OCM) have been reported.

**Experimental/methodology.** Four photo-curable composite (organic – inorganic) resins were prepared for the 3D printer containing 45% alumina and/or kaolin in their composition. Printed ceramic monoliths of the composite resin were burned and then impregnated with solutions containing the active ingredients - 2 wt.% of Mn and 5 wt.% of $Na_2WO_4$. Next, on each series of monolithic catalysts obtained, the oxidative coupling of methane was carried out at 820°C using a ratio of methane/oxygen of 3.8/1. In addition, X-ray fluorescence (XRF), X-ray diffraction (XRD) and scanning electron microscopy (SEM) with energy dispersive spectroscopy (EDS) were performed for the printed monoliths.

**Results and discussion.** The application of 3D printing as a technology to obtain monoliths, allowed for the production of precisely defined structures. The development of a method to remove the organic part from the resin made it possible to obtain a pure carrier which, after impregnation with Mn and $Na_2WO_4$, could be successfully used for oxidative coupling of methane. When the process was performed with a monolithic catalyst and a powder catalyst (the same composition), a comparative yield of $C_{2+}$ hydrocarbons of approximately 18% was obtained in the GHSV value range. However, the great advantage of monolithic catalysts is the lower pressure drop during the reaction than when this occurs with powder catalysts.

**Keywords:** Solution combustion, n-octane, TEM, XRD, fuel effect

**Introduction:** The conversion of the long-chain linear paraffins into value-added products such as olefins and aromatics is an important industrial process. The oxidative dehydrogenation (ODH) of n-octane may be seen as a viable route to produce the corresponding octenes and C8 aromatics[1]. In ODH of alkanes, the $VO_x$/MgO system has been reported to form minimum oxygenates and/or cracking products with reasonable selectivity towards ODH products[1]. To attain high activity and selectivity in ODH, it is important to find a catalyst that can activate the C-H bond[2]. This study reports findings of the structural characterization and application of VOx/MgO catalysts prepared by solution combustion synthesis (SCS) using different fuels on the oxidative dehydrogenation of n-octane.

**Experimental/methodology:** The $VO_x$/MgO powders were prepared via SCS, using different fuels. The catalysts were then characterized using X-ray diffraction, Raman spectroscopy, SEM and aberration corrected TEM and related techniques. Testing of the catalysts was performed on a continuous flow, fixed-bed reactor operating in vertical flow mode.

**Results and discussion:** The data demonstrated distinguishable differences in morphology, elemental distribution, phase composition and crystallite size and distribution for the catalyst powders investigated. By correlating experimentally extracted microstructural parameters to calculated thermodynamic parameters we demonstrate the important role of the fuel in controlling the reaction kinetics and in turn the resultant microstructure of the catalyst. Specifically, we highlight the role of a fuel's reducing valency in regulating the maximum temperature and heating rate of a reaction. The best performing catalyst with respect to conversion as well as octene (ODH) selectivity displayed synergistic effects caused by the co-existence of different magnesium vanadate phases (Fig 2). Based on the findings we propose a model of formation for the material system, demonstrating the potential of this novel one-step method for the controlled synthesis of $VO_x$/MgO powders for catalytic applications.

**Keywords:** $CO_2$ methanation, RWGS, ultrathin surface layers, ceria nanoshapes, highly dispersed Pt and Ru

**Introduction.** Catalytic hydrogenation using green hydrogen sources is currently explored as a route for the valorization of $CO_2$ into fuels and chemicals. Ceria supported noble metal catalysts stand among systems with potential application in this process, in which both activity and selectivity are influenced by the nature of the metal, their dispersion state and the occurrence of interactions at the metal-ceria interface. Thus, Ru based catalysts seem to favor methanation, whereas those loading Pt directs preferentially the process towards RWGS [1]. In both cases, interaction with $Ce^{3+}$ species and oxygen vacancies play a major role at this respect [2].
Morphology has proven to largely modify the redox response of ceria nanocrystals, as it is also the case of compositional modifications affecting their first few surface layers. Likewise, the activity of noble metals relates intimately to the atomicity of the species (i.e. isolated atoms, subnanometric clusters or metal nanoparticles). Therefore, controlling these variables offer a possible route to modulate both activity and selectivity issues in this reaction.
We have synthesized a series of very low metal loadings (0.1-0.3% wt.) Pt and Ru catalysts highly dispersed onto the surface of ceria nanoxides of different shapes (NanoCubes, NanoRods and NanOctahedra). Furthermore, the redox and acid-base properties of these oxides were modified by mixing Ce with other elements (La, Pr, Zr) at the level of the very first atomic surface layers. Careful characterization of these systems has been undertaken to determine how structure and chemical properties influence performance. Preliminary results point out not only to a large intrinsic activity of the highly dispersed metals but also to a combined contribution of surface crystallography and redox promoters on catalytic performance.

**Experimental/methodology.** Macroscopic chemical composition was established by ICP-OES and XRF. Macroscopic structural features were determined by XRD. Redox characterization was accomplished using quantitative $H_2$-TPR experiments and XPS. Metal dispersion was investigated at macroscopic level by EXAFS and FTIR studies of adsorbed CO and, at atomic level, by STEM-HAADF-XEDS.

**Results and discussion.** As expected, both surface crystallography and the presence of a redox promoter in the first surface layers significantly modify the reducibility of ceria. In all cases, the incorporation of $La^{3+}$ and $Pr^{3+}$ increases $Ce^{3+}$ content in low temperature range (200-500°C). However, such modification affects in a different manner to catalytic performance, which indicates an influence of surface crystallography. Among the different systems, a Ru (0.15% wt.)/$ZrO_2$ (10%mol)-$CeO_2$-NC has demonstrated a quite good performance (67% $CO_2$ conversion, 99% selectivity towards $CH_4$ at 300°C, $H_2$:$CO_2$= 4:1, and 16,000 $cm^3g^{-1}h^{-1}$ GHSV). A large influence of nanoxide morphology is observed in this case. Using a similar feeding, a Pt (0.3% wt)/$La_2O_3$ (10%mol)-$CeO_2$-NC catalyst showed almost 50% $CO_2$ conversion and 96% CO selectivity at 400 °C. Further analysis of these results is currently underway.

# Precious-metal-free Catalysts Based on Apatite-type Lanthanum Silicate for Toluene Combustion

N. Nunotani, K. Matsuo, N. Imanaka*

*Department of Applied Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka, Japan*
**imanaka@chem.eng.osaka-u.ac.jp*

**Keywords:** precious-metal-free, toluene combustion, apatite-type

**Introduction.** Toluene is one of volatile organic compounds (VOCs), which are harmful to human health and the environment. One of effective ways to eliminate toluene is the catalytic combustion. Although Pt-based catalysts have been widely studied due to their high oxidation abilities, such precious-group-metals are expensive and limited resource. Therefore, the development of precious-metal-free catalysts is desired.

Among the precious-metal-free catalysts, $LaCoO_3$ is effective for toluene combustion; however, it requires the elevated temperature of 410°C [1] to oxidize toluene completely. In order to improve the catalytic activity, it is important to introduce promoters which can supply oxygen species toward active sites in $LaCoO_3$. Our previous study demonstrated that apatite-type $La_{10}Si_5CoO_{27-\delta}$ [2] had high oxygen release and storage abilities caused by its one-dimensional tunnel structure suitable for oxide ion conduction and the redox property due to the valence change of $Co^{2+/3+}$ ions. In this study, novel $LaCoO_3/La_{10}Si_5CoO_{27-\delta}/\gamma\text{-}Al_2O_3$ catalysts, composed of $LaCoO_3$ as the activator, $La_{10}Si_5CoO_{27-\delta}$ as the promoter, and $\gamma\text{-}Al_2O_3$ as the support material, were synthesized, and their catalytic activities for toluene combustion were investigated [3].

**Experimental.** $La_{10}Si_5CoO_{27-\delta}$ was prepared by a sol-gel method. $La_{10}Si_5CoO_{27-\delta}$ was mixed with commercial $\gamma\text{-}Al_2O_3$, and then, $LaCoO_3$ was supported via an impregnation process to obtain 10 wt% $LaCoO_3$/ *x* wt% $La_{10}Si_5CoO_{27-\delta}/\gamma\text{-}Al_2O_3$. Here, the $La_{10}Si_5CoO_{27-\delta}$ loading amount (*x*) was adjusted in the range of 10-30wt%.

**Results and discussion.** Figure 1 shows the temperature dependence of toluene conversion over the 10 wt% $LaCoO_3$/ x wt% $La_{10}Si_5CoO_{27-\delta}/\gamma\text{-}Al_2O_3$ catalysts. With increasing the $La_{10}Si_5CoO_{27-\delta}$ loading amount (x), the catalytic activity was improved up to *x* = 20, while the specific surface area was decreased (x = 0: 135 $m^2 \cdot g^{-1}$, x = 10: 113 $m^2 \cdot g^{-1}$, x = 20: 87 $m^2 \cdot g^{-1}$, x = 30: 64 $m^2 \cdot g^{-1}$). This improvement might be attributed to the effective oxygen supply from the $La_{10}Si_5CoO_{27-\delta}$ solid. On the other hand, excess introduction of $La_{10}Si_5CoO_{27-\delta}$ decreased the activity, likely due to the low surface area. The highest activity was obtained for the *x* = 20 catalyst among the prepared catalysts, and toluene was completely oxidized at 300°C, lower than $LaCoO_3$ (410°C [1]).

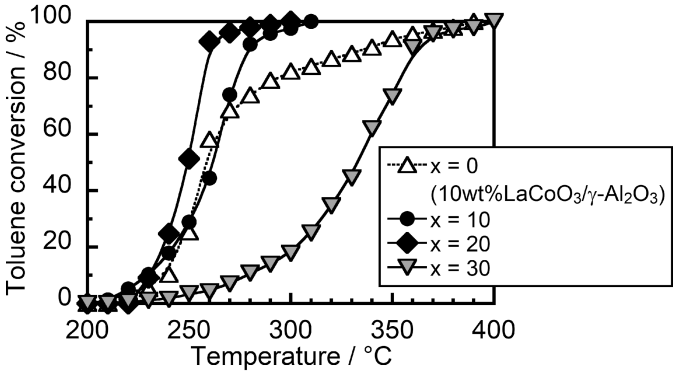

**Figure 1.** Temperature dependence of toluene conversion over the 10 wt% $LaCoO_3$/ *x* wt% $La_{10}Si_5CoO_{27-\delta}/\gamma\text{-}Al_2O_3$ catalysts.

# Development of new catalytic system driven by vibration energy

Y. Oba, T. Uno, S. Kikkawa, S. Yamazoe*

*Tokyo Metropolitan University, Tokyo, Japan*
**yamazoe@tmu.ac.jp*

**Keywords:** Piezoelectric material, Vibration energy, Resonance, Water-splitting

**Introduction.** Vibrational energy is one of energy sources generated on a daily basis, although the utilization efficiency is not still sufficient. Among the energy from environmental sources, such as solar, geothermal, and vibration, vibration energy can be persistently obtained in natural and man-made structures[1]. The polarization in piezoelectric materials occurs due to the piezoelectric effect when physical stress is applied to piezoelectric devices, resulting in generation of more than 10 V of voltages. In recent years, catalytic reactions using the piezoelectric effect have been reported, such as catalytic reactions using ultrasonic-wave-induced and mechanochemical reactions using ball milling[2,3]. However, the catalytic reaction system driven by low-frequency vibration obtained in our daily life have not been reported. In this study, we demonstrated the low-frequency vibration induced catalytic system using piezoelectric device based on perovskite $Pb(Zr,Ti)O_3$ (PZT), which produces $H_2$ from $H_2O$. In addition, a PZT thick-film device was fabricated for the tailor-made design of the "vibro-catalyst".

**Experimental/methodology.** PZT thick-film devices were fabricated by several methods, such as hydrothermal synthesis, squeegee method, screen printing, and sticking the bulk PZT plate. The vibro-catalytic device consists of a PZT piezoelectric thick film and upper Ag electrode on lower SUS304 plate electrode. Ag electrode was sputtered on the fabricated device. For the evaluation of piezoelectric property and vibro-catalytic activity, one end of the vibro-catalyst was fixed to a holder on a vibrator, and the vessel was vibrated at 150Hz. The vibration was controlled by a waveform generator, amplified by a high-voltage amplifier, and applied them to a vibrator. The $H_2$ production utilizing a low-frequency vibration was tested by using a flow reactor equipped with a humidifier. The $H_2$ production activity over a vibro-catalyst was tested under a flow of $H_2O$-saturated Ar gas at 313 K with applying the vibration at the resonance frequency of 150Hz with connecting SUS to ground. The applied AC voltage between upper and lower electrodes of vibration catalyst (Ag and stainless, respectively) measured by using an oscilloscope was controlled by a high-voltage amplifier and fixed to 13.5 V.

**Results and discussion.** The XRD patterns of the fabricated PZT devices revealed that the device fabricated by sticking bulk PZT plate showed higher c-axis orientation and morphotropic phase boundaries of tetragonal and rhombohedral structure, which is favorable to high piezoelectric properties. From the time course of catalytic reaction under a vibration applied to the vibro-catalyst at the resonance frequency of 150Hz, $H_2$ production by $H_2O$ splitting was observed and the formation rate increased with time. The $H_2$-formation rate reached to 1.0 μmol/h after 24 hours of catalytic reaction. The $H_2$ production was drastically suppressed when SUS electrode connecting to ground. Thus, we consider that the vibro-catalytic $H_2O$ splitting proceeded by a modulation of electronic state of Ag electrode by the applied AC voltage.

**Keywords:** Ni nanoparticles, relevant industrial oxides, structure-activity relationship, greenhouse gases

**Introduction.** In dry methane reforming (DMR), the two greenhouse gases $CO_2$ and $CH_4$ are simultaneously converted to the syngas (CO and $H_2$). Highly active Ni-based catalysts are often used for this reaction, with particle size- and shape dependence determining the catalyst's performance,[1] yet their applications are hampered due to susceptibility to sintering as well as deactivation caused by coke formation. In addition to the exploitation of size effects, the modulation of the metal-surface interactions offers control of the oxidation state, stability and performance of the catalyst over time. In this study, well-defined model catalysts are investigated to identify structure-function relationships derived from size and support effects and to leverage the gained insights for the design of real-world catalysts.

**Methodology.** Ni NPs are prepared by solvothermal synthesis and deposited on the 2D supporting material with $SiO_2$, $ZrO_2$, $SnO_2$, $TiO_2$, and $Al_2O_3$ layers obtained by the ALD on the Si substrate. Materials are characterized *ex-situ* with Scanning and Transition Electron Microscopy, Atomic Force Microscopy, Ellipsometry, and X-Ray Photoelectron Spectroscopy (XPS). Central for the understanding of the factors determining the oxidation state of Ni under working conditions is the characterization by synchrotron-based X-Ray Photoemission Electron Microscopy and XPS with single particle resolution[2] under a flow of $CO_2$ or $CH_4$ and their mixture to mimic conditions of DMR.

**Selected results.** Distinct behavior in the reducibility of Ni NPs is observed when on different supporting materials under DMR conditions. During sequential experiments, a reoxidation of Ni NPs on $ZrO_2$ is observed by $CO_2$, followed by subsequent reduction by $CH_4$. *In-situ* experiments under DMR conditions reveal a reduced Ni and *in-situ* XPS C1s spectra suggest different distributions of the C impurities on the Ni NPs and support material before the reaction, which unifies under high-temperature conditions. SEM images collected on various catalysts after the reaction often reveal a formation of additional carbon deposit over Ni NPs in an encapsulating form of carbon, which might be connected with the porosity of the Ni nanoparticles and the high density of available nucleation sites. Microscopic analysis reveals that in the case of $TiO_2$ deposited on $SiO_2$, the thin oxide film can restructure under reaction conditions into islands and depending on the composition of the reactant gas mixture a reduction of $TiO_2$ to metallic Ti can take place. The presentation will detail correlations between particle size, and the effect of the support and oxidation state of Ni as main parameters for balancing and optimizing performance and stability.

# Ge outperforms other zeolite sites in sucrose-to-HMF conversion

M. Opanasenko*, P. Rani, M. Shamzhy

*Charles University, Prague, Czech Republic*
**maksym.opanasenko@natur.cuni.cz*

**Introduction.** In a view of utilization of catalysis for emerging applications, enormous efforts are being made to transform renewable biomass (cellulose, carbohydrates, etc.) into fuels and value-added chemicals. Among biomass-derived platform chemicals, 5-hydroxymethylfurfural (HMF) is regarded as versatile building block which can be further transformed into valuable derivatives (furandicarboxylic acid, dimethylfuran, bis(hydroxymethyl)furan, etc.) used as precursors in the polymer industry and liquid fuels. The synthesis of HMF from sucrose is a multistep process. All steps are facilitated by the acid sites. Classical zeolites (aluminosilicates), as well as 4-valent element (Sn, Zr) substituted zeolites, have high acidity and therefore exhibit high activity for biomass transformation. In particular, 10-ring and 12-ring zeolite catalysts found to be promising candidates in most studies [2, 3].

**Experimental/methodology.** Different types of zeolites, such as extra-large UTL and CTH and large-pore IWW were prepared. The most sustainable germanosilicate (Ge-IWW) was modified with the different heteroatoms such as Sn, Zr, and Al (the elements shown to be the most promising for HMF synthesis up to now) for a comparative study. The idea of the work consisted in the design of materials with fixed structure and variable nature of active sites (and vice versa). Although the selected solids are costly and complex in preparation, they allow to incorporate all desired elements and thus they can be used as model systems to understand the influence of the mentioned aspects on the catalytic activity of zeolites in HMF synthesis.

**Results and discussion.** Catalytic investigation showed that Ge-IWW zeolite exhibits the optimum activity and stability compared to Ge-UTL and Ge-CTH. Heteroatom substitution in the IWW framework allowed to relate the output of sucrose to HMF transformation with the nature of acid sites in catalysts. Zr-IWW zeolite exhibited moderate product selectivity; however, the HMF yields obtained over heteroatom-substituted IWW zeolites are lower than those obtained on the Ge-IWW zeolite confirming that the presence of Ge atoms in the zeolite framework enhances the efficiency of the catalyst for this particular reaction. The presence of labile Ge-O-Si bond enhances the possibility for creation of Brønsted acid sites which are required for hydrolysis of sucrose to hexose. This study demonstrates that germanosilicates are worth considering for synthesis of value-added chemicals via biomass-based catalysis.

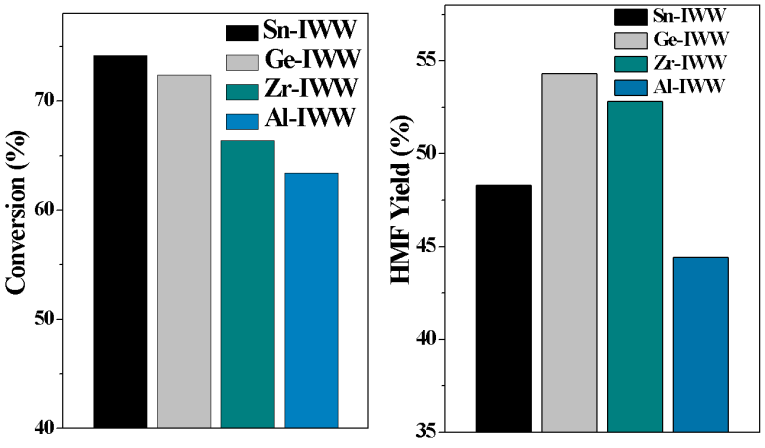

**Figure 1. Sucrose conversion (a) and HMF yield (b) over zeolites with the same structure but different active sites.**

# Concomitant oxidative and reductive transformations from *N*-Heterocyclic carbene organocatalysis

Nadhrata ASSANI,[1] Ludivine DELFAU,[2] Eder TOMAS-MENDIVIL,[2] Sébastien REDON,[1] Patrice VANELLE,[1] David MARTIN,[2] Julie BROGGI[1*]

[1]*Aix Marseille Université, ICR, UMR 7273, Faculté de Pharmacie, 13005 Marseille, France. (e-mail: julie.broggi@univ-amu.fr)*
[2]*Département de Chimie Moléculaire, UMR CNRS 5250, CS 40700, 38000 Grenoble, France. (e-mail: david.martin@univ-grenoble-alpes.fr)*

The last decade, a multitude of organocatalyzed transformations of carbonyl derivatives took advantage of the oxidation of Breslow intermediates, arising from the reaction of these carbonyl substrates with stable N-Heterocyclic Carbenes (NHCs). However, valorization of the electrons lost during these oxidative transformations had not been addressed until recently. In 2021, Ohmiya and Bertrand independently demonstrated that these Breslow intermediates can also be used as formal reductants.[1][2] NHC-organocatalyzed arylacylations of diverse alkenes were thus performed upon reduction of iodoaryl derivatives into radical species. In their reaction, the aldehyde used to generate the Breslow enaminol was also integrated in the final addition product.

In this new study, our objective was to develop a strategy where the Breslow enolate catalyst both serves as an electron source for challenging reductive transformations and as key intermediate for the valorization of aldehydes through oxidative transformations. Our strategy thus allowed the interdependent formation of two distinct products through concomitant oxidative and reductive transformations. We also focused on novel sources of NHCs and aldehydes to generate more powerful Organic Electron Donors (OEDs).[3][4] Imidazolylidene-based enaminols proved to be powerful donors for the single-electron transfer reduction of various challenging substrates. The generated radical intermediates were further exploited in arylations of alkenes while the sacrificial aldehydes were valorized through oxidation reactions.

**Keywords:** catalysis, COF, heterogenization, Schiff chemistry, iron.

**Introduction.** Transition metal Schiff base complexes are known to act as efficient homogeneous catalysts for organic reactions such as oxidation, alkylation, isomerization, etc. However, they often suffer from low stability and are difficult to separate from the reaction medium after use.

**Experimental/methodology.** In this work, we propose a method of heterogenization of this kind of catalysts using a Covalent Organic Framework material (COF) synthesized by Schiff chemistry, which can incorporate metal ions such as $Fe^{3+}$. A slightly modified procedure for the synthesis of LZU1 COF was proposed by using hydroxyl substituted 2,5-diaminohydroquinone with 1,3,5-triformylbenzene.

**Results and discussion.** It resulted in the generation of sites containing two hydroxyl groups and imine groups able to coordinate with Fe(III) cations like in a conventional Schiff complex (Figure 1). The prepared material possesses a two-dimensional eclipsed layered-sheet structure with uniform distribution of Fe and demonstrated a high catalytic activity, comparable to those of the homogeneous Fe catalyst, together with high stability and recyclability in the model reaction of epoxidation of styrene to styrene oxide by $H_2O_2$.

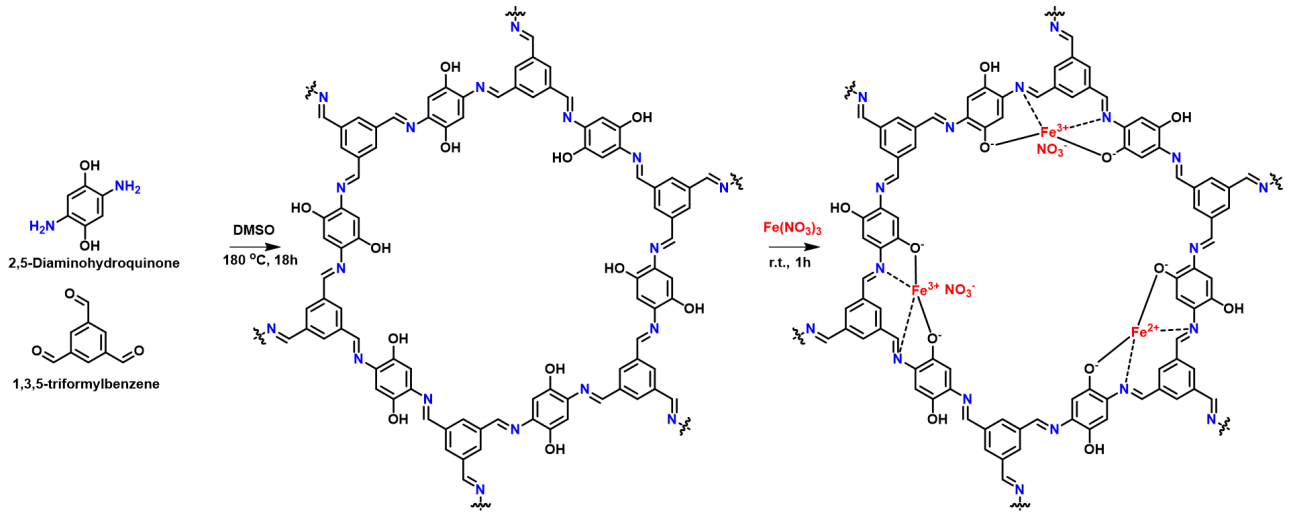

**Figure 1. Scheme of the synthesis of COF and Fe-COF**

**Keywords:** Copper-Ceria catalysts**,** aerosol processing, mesoporous materials, CO oxidation

**Introduction.** Among the alternatives to the noble metal based systems for the abatement of carbon monoxide, Cu is often chosen to enhance the ceria reactivity, and the system has proven to be promising [1,2]. Moreover, beneficial effects on catalytic performance have been evidenced when favoring (i) a stronger interaction between CuO and $CeO_2$, (ii) higher specific surface area, (iii) small pores with a homogeneous distribution [3]. Nevertheless, in this system, most catalysts reported in literature are synthesized by methods that neither allow to precisely control textural and morphological properties nor favor an intimate mixing between the two phases. Exploring innovative catalysts syntheses is arguably the keystone to round these corners and to reach higher catalytic performance. Along this line, the aerosol-assisted sol-gel process (AASG), which is emerging as a powerful route to produce various nanomaterials and in particular tailored heterogeneous catalysts [4,5] is primed to solve the above-mentioned challenges.

**Experimental/methodology.** Here we report, for the first time, aerosol assisted sol gel made CuO-$CeO_2$ catalysts (denoted as A-CuxCe, where "x" is the Cu wt. loading) employed for the Low Temperature CO Oxidation (LTCO). AASG catalysts have been synhtesized by atomization of the precursors solution (cerium and copper nitrates witha templating agent, in an ethanol/water solution), followed by rapid processing (reactive drying) in a tubular furnace. Templating agent removal and porosity formation has been carried out by a controlled calcination step under static air, up to 723 K. Aerosol made materials are then compared with a series of benchmark catalysts made by impregnation (denoted as I-CuxCe). Catalysts were tested for CO oxidation using a temperature ramp or sets of isothermal steps, with an online IR monitoring of reactants/products concentrations. Performance is interpreted in the light of in-depth characterization surveys (XRD, in situ XRD, $N_2$ physisorption, DRIFT, TPD, XPS, Raman, (S)TEM).

**Results and discussion.** Considering pristine $CeO_2$, X-ray diffraction patterns show that the commercial $CeO_2$ is composed of 40 nm-sized crystallites, while A-$CeO_2$ features much smaller crystallites (8 nm). The aerosol-made $CeO_2$ had a specific surface area (SSA) as high as 130 m²/g, with a narrow pores distribution centred around 5-6 nm while the commercial ceria shows only a SSA of 5 $m^2/g$ and a bigger pore distribution centred at 25 nm. For A-CuxCe catalysts, up to 10% wt of Copper, characteristics peaks of CuO are not detected, revealing very small dimensions compared to the impregnated one with the same loading, i.e. CuO cristallites of 35 nm.Upon introduction of Cu, the textural properties remained similar (115 $m^2/g$ for A-Cu10Ce versus 3 $m^2/g$ for I-Cu10Ce). Thus, is clear that the fast atomization and polycondensation of the precursors allows to produce materials with a higher surface area and porosity, with smaller cristallites and much more dispersed active species. Looking at the catalytic activity, aerosol-made catalysts are impressive. For example, A-Cu10Ce (only 10% Cu) shows already ~20% conversion at 323 K and reaching complete CO conversion at 360 K. This temperature is at least 30 K lower than the state-of-the-art catalysts [6].

**Keywords:** Ionic liquid, carbon dioxide hydrogenation, nanoparticle, formate

While the coordination of ligands to homogenous metal complexes is well-defined, the interaction between heterogenous metal clusters and functionalized supports is still not understood. Polymer immobilized ionic liquids (PIILs) have been shown to be effective supports for the stabilization of metal nanoparticles for use as catalysts in a range of transformations.[1] The modular synthesis of PIILs allows for the control of the support ionic microenvironment and for the employment of surface functionality, thereby influencing nanoparticle size/morphology as well as their efficacy and stability as catalysts. Moreover, there is mounting evidence that the surface electronic structure of a catalyst can be manipulated by the incorporation of a heteroatom donor which has been shown to enhance efficacy.[2] Recently, we reported that platinum nanoparticles stabilized by a phosphine-modified PIIL catalyze the hydrolytic release of hydrogen from sodium borohydride,[3] while phosphine oxide functionalized PIIL supported ruthenium nanoparticles catalyzed the selective reduction of nitrobenzene to *N*-phenylhydroxylamine under mild conditions.[4]

In this work, amine-modified PIIL supports were used to stabilize *in-situ* generated palladium nanoparticles (PdNP) for the thermal hydrogenation of $CO_2$ to formate in the presence of base. PdNP stabilized by an arylamine functionalized PIIL outperformed its benzylamine counterpart, and both catalysts were found to be superiour to unmodified PIIL-supported PdNP (**Figure 1**). Further, catalyst performance was shown to improve with increasing loading of the amine on the polymer support. Influence of the amine on catalyst efficacy is now being explored with XPS and HRTEM.

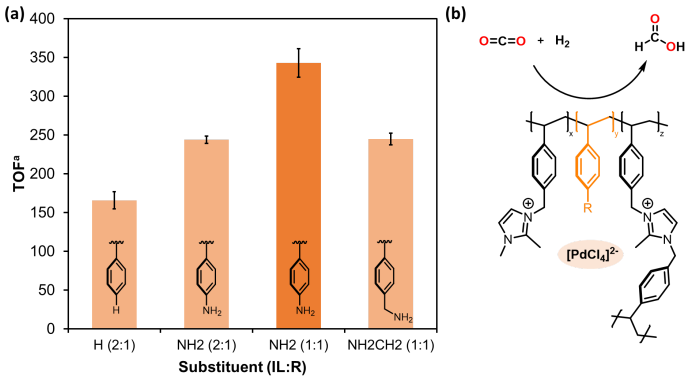

**Figure 1: (a)** Plot of turnover frequency against catalyst support, where polymer composition IL:R = (x+z):y . **(b)** Schematic of $CO_2$ hydrogenation to formic acid by catalyst precursor $PdCl_4$@PIIL, where substituents R are described in (a). [a] $mol_{formate}/mol_{Pd}/hour$

**Keywords:** Hydrogen, ammonia decomposition, bimetallic catalysts

**Introduction.** Decomposition of ammonia ($NH_3$) is an efficient technology for generating $CO_x$-free hydrogen ($H_2$). The design of an active catalyst to optimize the reaction conditions is one of the main challenges of this technology. In this sense, both the active phase as well as the support, have an important role in the catalytic activity [1]. Carbide species have shown excellent results as support of different catalytic metals. Previous studies of our research group indicated that ruthenium and cobalt supported on silicon carbide (SiC) exhibited suitable ammonia conversion at low temperatures [2]. However, bimetallic catalysts have not yet been studied over SiC. Therefore, the target of this work was to develop for the first time Ru-Co bimetallic catalyst supported on structured SiC for the $H_2$ production from $NH_3$. The influence of the order of incorporation of the metals into the support and the Ru/Co ratio were optimized.

**Experimental/methodology.** Firstly, three different sets of catalysts were prepared in a different way, with a total metal loading of 5 wt% and Ru/Co weight ratio equal to 50/50. They were called Co/Ru/SiC and Ru/Co/SiC, which refers to the metal impregnation order with an intermediate calcination step (500 °C, 1 h), and Co-Ru/SiC which refers to the catalyst prepared by co-impregnation. Finally, all catalysts were calcined at 500 °C, 1 h (under $N_2$). The influence of the Ru/Co ratio (50/50 and 20/80) was studied using the catalysts prepared by co-impregnation with a total metal loading of 2.5 wt%.

**Results and discussion.** Table 1 shows the metal content (from EDS analysis), the mean particle size evaluated by TEM images, and the catalytic activity at 350 °C of prepared catalysts. For comparative purposes monometallic samples has been included. It was shown that the metal order impregnation affected the particle diameter, and hence, the catalytic activity, due to the structure-sensitive character of the reaction [2]. The lower metal particle size and the suitable metal content of the catalyst prepared by co-impregnation method could explain the superior catalytic activity showed by Co-Ru/SiC catalyst being only a 30% lower than Ru/SiC even when Ru content was halved. On the other hand, the study of metal loading (not shown here) concluded that it is possible reduce the metal content until 2.5 wt% by keeping an excellent activity [2]. Finally, the Ru/Co ratio (Table 1) indicates that the Ru presence was essential to achieve high conversion, exhibiting the 50Co-50Ru/SiC better catalytic activity than pure cobalt catalysts. Ru has been established to be highly active for this reaction [1] but it is limited and expensive. However, this work has allowed to synthesize a novel bimetallic catalyst with low metal loading of this critical noble metal.

**Table 1. Metal content, particle size and $NH_3$ conversion at 350 °C (5v/v%$NH_3$-Ar, GHSV=60000 mL·g$^{-1}$·h$^{-1}$, 1 atm)**

**Keywords:** PEM electrolysis, low-CRM, catalysts

**Introduction.** Proton exchange membrane water electrolysers (PEMWE) are widely regarded as the most active and flexible of all electrolyser technologies. However, the catalyst materials needed for the oxygen evolution reaction (OER) in PEM conditions are one of the main limiting factors towards a widespread market uptake of the technology, due to their scarcity, price and challenges with long-term stability. [1] Reducing the amount of critical raw materials (CRM) in the anodes of PEMWEs, is crucial to bring the technology to the scale needed to efficiently store renewable electricity as green hydrogen.

**Experimental/methodology.** Supported Ir and IrRu nanoparticles were synthesized on Sb-doped $SnO_2$ (ATO) in a supercritical flow synthesis, which allows for a fine tuning of the nanoparticles size and oxidation state. [2] The catalyst materials were hereafter characterised using scanning electron microscopy with energy dispersive X-ray spectroscopy (SEM-EDX) to assess their elemental composition, X-ray diffraction (XRD) and pair distribution function (PDF) analysis to assess their crystalline properties, transmission electrode microscopy (TEM) to visualize their microstructure, and rotating disk electrode (RDE), gas diffusion electrode (GDE) and single cell measurements to assess their electrochemical activity.

**Results and discussion.** The supported Ir nanoparticles exhibited a considerable boost in activity in comparison to unsupported Ir (Figure 1), which was further enhanced by adding Ru in the catalyst. Moreover, the presence of Ni during the synthesis promoted the creation of a more active phase with a more amorphous character. [3] This allowed obtaining high performance with lower catalyst loadings in single cell measurements, albeit with stability issues that will need to be resolved with microstructural optimisation.

**Introduction.** Hydrogen is an advantageous energy vector. A new sustainable approach for synthesizing hydrogen could be Methane Dry Reforming (MDR). However, applying this reaction at an industrial level could be impeded by its high endothermicity, and the difficulty to formulate a robust catalyst. Among the metals Ni has attracted the most attention due to its good activity for MDR. However, it can also catalyze side reactions such as Bouduard or Methane Cracking leading to coke formation. Vanadium element was selected as promoter because it can improve the dispersion of nickel, enhancing the activity and preventing the sintering process [1]. Furthermore, the ability to adsorb $CO_2$ can be improved, forming monodentate carbonates, that are the intermediates responsible of $CO_2$ activation [2]. As co-promoter calcium was selected because it should limit carbon coke formation. All these characteristics can be suitable for this work purposes. In this study, three samples were compared: bare $Ni/Al_2O_3$ as reference, $Ni\text{-}V/Al_2O_3$, and $Ni\text{-}V\text{-}Ca/Al_2O_3$ to evaluate whether the introduction of these additional doping agents can further improve the activity and the stability of the catalyst.

**Experimental/methodology.** The catalysts were prepared by incipient wetness impregnation to obtain 10 wt. % of Ni, 1 wt.% of V and 10 wt.% of Ca in the final material. Catalysts were also characterized using different techniques such as ICP-OES, $N_2$ physisorption, TPR, XRD, DRUV-Vis, SEM-EDX, and TPO. The catalytic tests were carried out at 650 °C in a fixed bed reactor with a GHSV of 12000 $h^{-1}$ and a reagent ratio ($CH_4$:$CO_2$:He) of 1:1:18.

**Results and discussion.** The introduction of vanadium in Ni based MDR catalysts was effective, and a homogeneous metal dispersion was obtained, as confirmed by EDX analyses. Activity tests confirmed that vanadium enhanced the activity and stability of catalyst over 100 h reaction compared to the non-doped catalyst, which suffered from a faster deactivation. In fact, for the promoted sample containing vanadium, also a boost of hydrogen yield was obtained in diluted conditions test. Furthermore, from spent catalysts characterizations, a lower deposition of nanotubes was detected on promoted $Ni\text{-}V/Al_2O_3$ catalyst. With the introduction of Ca, this phenomenon was further enhanced as it could be seen in SEM-EDX images. In addition, in stress tests vanadium led to a higher conversion of reagents with a 30% increase for $CH_4$, and 15% increase for $CO_2$. It can be concluded that vanadium is a valuable promoter for $Ni/Al_2O_3$ catalysts for Methane Dry Reforming.

# MgO-Induced Structure Sensitivity in Cu-Based Catalysts Synthesized via a Novel Precursor Route for $CO_2$ to Methanol Conversion

*Meenakshi Pokhriyal*[1], *Aakash Bhardwaj*[1], *Sreedevi Upadhyayula*[1]*

[1]*Department of Chemical Engineering, Indian Institute of Technology, Delhi, India*

* *sreedevi@chemical.iitd.ac.in*

**Introduction.** Methanol today is not only the most important feedstock for chemicals and fuel components but also is an important chemical and a potential energy carrier in the future. Since the early 1960s hitherto, $Cu/ZnO/Al_2O_3$ ternary catalysts developed by Imperical Chemical Industries have been used commercially for methanol synthesis derived from the malachite rosasite synthesized precursors [1]. In recent years $Mg^{2+}$ which is an interesting replacement for $Zn^{2+}$, not only because of the close match in the ionic radii, charge but also of the similarity in precursor formation chemistry with $Cu^{2+}$. Moreover, it promotes the number of $CO_2$ and $H_2$ adsorption active sites and increased the metal-support interaction with high metallic Cu surface area [2]. These catalysts have been found to be structure sensitive and the activity varies depending on the conditions employed in the very first stage of catalyst synthesis i.e., precursor formation [3]. However, conventional methods of precursor synthesis suffer from interference of competing phases which ultimately lead to the activity deterioration in the final catalyst. To overcome these difficulties in the present case Cu/MgO catalyst has been synthesized using an optimized hydrothermal based precursor formation approach for the first time with an improved and efficient outcome for hydrogenation of $CO_2$ to methanol. The precursor and final catalyst have been characterized with an array of instrumental techniques.

**Experimental.** For the synthesis and optimizations of Cu-MgO catalyst, firstly the synthesis of hydroxy carbonate precursor has been carried out using a hydrothermal route using nitrate salts as reactant in the presence of carbonating agent at different set of temperature and varied durations. The pure catalyst formed were then calcined at 350 °C and 400 °C for 3 h in static air individually. The catalytic activity tests were performed in a fixed-bed reactor connected with gas chromatography for product analysis.

**Results and discussion.** The PXRD pattern of the product obtained is shown in Figure 1. The pattern showed a complete resemblance with the Mcguinnessite which is a Rosasite like structure. The precursor as well as catalyst obtained after calcination showed low crystallite size, high surface area with a unique spongy ball like shape unlike already reported catalysts. The catalytic activity optimizations and results using CM-HT showed that the best optimized operating condition was T= 240 °C and P= 40 bar, at which the highest catalytic performance was achieved. The $CO_2$ conversion of 21.78%, methanol selectivity of 73.43%, and methanol yield of 8.62 $mg_{methanol}.gcat^{-1}.hr^{-1}$ were calculated in terms of space-time yield.

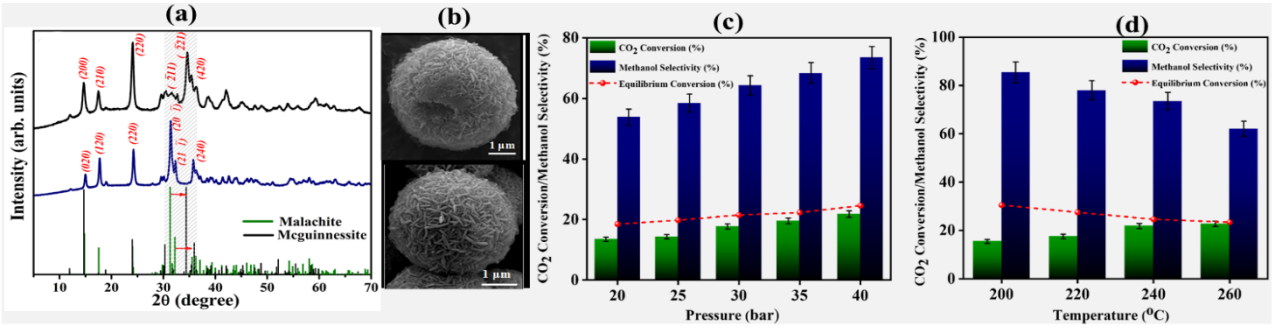

**Figure 1: (a) PXRD pattern of Cu-Mg hydroxy carbonate precursor synthesized via hydrothermal route, (b) FESEM images of precursor and calcined catalyst, (c) Effect of pressure at 240 °C and (d) Effect of Temperature at 40 bar pressure and 2600 WHSV on the catalytic performance.**

**Keywords:** bimetallic, alloy, supported, composite, catalyst

**Introduction.** Noble metal catalysts have proven to be effective for numerous applications, one of the most researched topics currently being ammonia decomposition. Ammonia can be safely transported and decomposed to produce hydrogen on-demand. Among noble metals, Ru boasts the best catalytic performance, however, it is scarce and costly. Alloying it with abundant metals could help lower the required Ru content due to increased activity [1].

**Experimental/methodology.** The catalysts were prepared by adsorption of RuCo precursor nanoparticles onto a high-surface area alumina support followed by reduction of the precursor to metallic RuCo. In the first step, the support was prepared. AlN was hydrolyzed in an aqueous suspension of silica nanoparticles (30 wt.%) which serve as nucleation seeds for boehmite. The boehmite was dehydrated to form *γ*-alumina by heat treatment at 500 °C in stagnant air. RuCo precursor nanoparticles were prepared by co-precipitation of $Ru^{3+}$ and $Co^{2+}$ achieved by a drop-wise addition of 2 M NaOH during vigorous stirring until achieving a pH level of 10. The precursor nanoparticles were mixed with the support for 10 min to give the particles ample time to adsorb. The material was freeze-dried and reduced in a tubular furnace at 500 °C in hydrogen (150 mL/min). The catalysts were characterized using Transmission electron microscopy (TEM) and Vibrating sample magnetometry (VSM). Catalytic activity was determined using a fixed-bed reactor.

**Results and discussion.** Co-precipitation of $Ru^{3+}$ and $Co^{2+}$ results in a formation of nanosized particles where both cations are relatively homogenously mixed. When alumina support is added, precursor nanoparticles adsorb onto its surface. Reduction at 500 °C in a hydrogen atmosphere leads to a complete conversion of precursors to alloyed RuCo nanoparticles. Detailed elemental analysis using Energy dispersive X-ray spectroscopy (EDXS) in TEM showed that composition of individual RuCo nanoparticles is close to the nominal composition of 10 wt.% of Ru and 90 wt.% of Co. The size of individual RuCo nanoparticles ranges from 10–20 nm (Figure 1 a and b) while their distribution over the support's surface is not exceptionally homogenous (Figure 1 a). Measurements of room temperature magnetization curves reveal soft ferromagnetic behavior, a saturation magnetization of 25 emu/g and coercivity of 635 Oe. Over the course of one month, the saturation magnetization drops to a value of 16 emu/g indicating surface oxidation. Observation of individual RuCo nanoparticles using TEM indicates a formation of a thin oxide shell (Figure 1 b). Further studies were devoted to improving homogeneity of RuCo nanoparticle distribution, detailed investigation of their oxidation behavior and the influence on magnetic and catalytic properties.

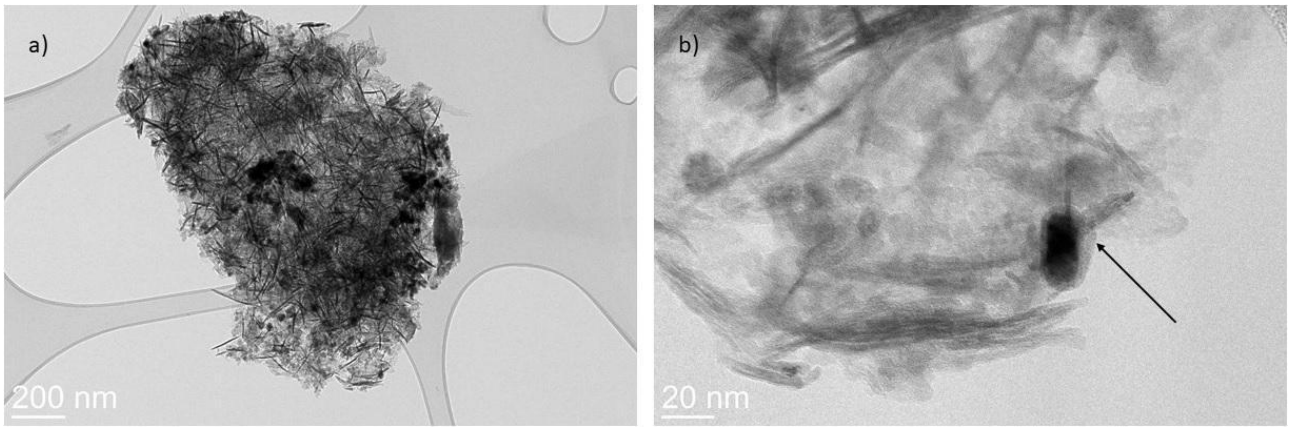

**Figure 1: A RuCo/alumina composite catalyst particle (a) and an embedded RuCo particle with the surrounding oxide shell marked with an arrow (b) observed using TEM.**

**Keywords:** Zeolite synthesis, Interzeolite transformation, Nanolayered catalyst

**Introduction.** Hierarchically nanostructured zeolites exhibit many benefits over conventional bulk zeolites in the conversion of petroleum-based and bio-based feedstocks to chemicals.[1, 2] However, the synthesis of such zeolites is typically time-consuming and requires complex organic templates or various steps to achieve well-defined and interconnected micro- and mesopores. Therefore, a fast and facile yet economically efficient synthesis of such zeolites would be very welcome.

**Experimental/methodology.** Herein, the one-pot synthesis of nanolayered MWW and FER zeolites was accelerated by the interzeolite transformation (IZT) approach. FAU (faujasite zeolite) was used as the Al source and partial Si source, while HMI (hexamethyleneimine) and CTAB (cetyltrimethylammonium bromide) served as micropore directing and intercalating agents, respectively. A combination of XRD, SEM, Ar physisorption, $^{29}$Si and $^{27}$Al NMR, and Raman spectroscopy were used to track morphological and structural changes as a function of crystallization time of these two approaches.

**Results and discussion.** Compared with conventional MWW synthesis at a similar gel $SiO_2/Al_2O_3$ ratio of 25, the IZT approach offers a reduction of the synthesis time from 164 h to 48 h and provided crystalline MWW with a similar nanolayered morphology (Figure 1). Adjustment of the $SiO_2/Al_2O_3$ to 15 for the IZT synthesis gel affords nanolayered FER. Characterization indicates that IZT accelerated the formation of MWW topology via transfer of sharing 4MR units from the FAU source to MWW, while CTAB intercalates between the layers, thereby directing the nanolayered morphology. These phenomena are similar to those observed

in conventionally microporous zeolite synthesis via IZT[3, 4] and conventional synthesis of nanolayered MWW.[1] The benefit of nanolayered zeolites follows from the strongly improved performance in Diels-Alder cycloaddition reactions useful for obtaining biobased p-xylene. Facile zeolite synthesis via IZT is versatile with respect to zeolite topology.

**Figure 1 Scheme of nanolayered zeolite synthesis accelerated by IZT compared with conventional synthesis.**

**Keywords:** graphitic carbon nitride, thermal synthesis, argon atmosphere, nitrogen vacancies, photocatalytic hydrogen evolution.

**Abstract.** Graphitic carbon nitride (g-$C_3N_4$) is a two-dimensional and metal free polymeric material with semiconducting properties that has been intensively studied during the last decade. Among its noteworthy properties are high thermal, physical, chemical, and photochemical stability. G-$C_3N_4$ absorbs visible light as a result of the band gap energy of ca. 2.7 eV. It can be prepared by physical or chemical vapour deposition but bulk synthesis from simple precursors by methods focused on the thermal condensation of nitrogen-rich precursors, such as cyanamide, dicyandiamide, melamine and so forth, are mostly used. Graphitic carbon nitride has been synthetized by heating of these precursors in air and other atmospheres, such as argon, hydrogen, and nitrogen [1], but only a few papers studied the influence of the atmosphere on its structural, textural, optical, and photocatalytic properties .

The aim of this work was to synthetise g-$C_3N_4$ in the argon atmosphere and to study its physico-chemical, textural, and morphological properties. The prepared materials were characterized by common techniques and the presence of vacancies was investigated by positron annihilation spectroscopy. The materials were used for the photocatalytic evolution of hydrogen. The best photocatalyst showed 3 times higher performance (1547 µmol/g) than bulk g-$C_3N_4$ synthetized in the air (547 µmol/g) [2].

# Simultaneous oxidative and reductive transformations by parallel catalysis with N-Heterocyclic Carbenes

Nadhrata ASSANI, Ludivine DELFAU, Eder TOMAS-MENDIVIL, Sébastien REDON, Patrice VANELLE, David MARTIN,[1] Julie BROGGI[2]

[1]*Aix-Marseille Université , Marseille, France*

[2] *Univ. Grenoble-Alpes, Grenoble, France*

[*]julie.broggi@univ-amu.fr, david.martin@univ-grenoble-alpes.fr

The last decade, a multitude of organocatalyzed transformations of carbonyl derivatives took advantage of the oxidation of Breslow intermediates, arising from the reaction of these carbonyl substrates with stable N-Heterocyclic Carbenes (NHCs). However, valorization of the electrons lost during these oxidative transformations had not been addressed until recently. In 2021, Ohmiya and Bertrand independently demonstrated that these Breslow intermediates can also be used as formal reductants.[1][2] NHC-organocatalyzed arylacylations of diverse alkenes were thus performed upon reduction of iodoaryl derivatives into radical species. In their reaction, the aldehyde used to generate the Breslow enaminol was also integrated in the final addition product.

Our goal was to develop a system enabling the use of aldehydes as sources of potent Organic Electron Donors (OEDs) for reductive transformations in organic chemistry.[3][4][5] Our strategy allows the coexistence of two distinct and interdependent catalytic cycles where the Breslow enolate catalyst both serves as an electron source for reduction reactions and as key intermediate for the valorization of aldehydes through oxidative transformations. Imidazolylidene-based enaminols proved to be powerful organic donors for the single-electron transfer reduction of various challenging substrates. The generated radical intermediates were further exploited in arylations of alkenes while the sacrificial aldehydes were valorized through oxidation reactions.

**Keywords:** Cations, Zeolite formation, Mordenite, port-size

**Introduction.** The mordenite framework is one of the handful of synthetic zeolite structures used extensively in petrochemical industrial applications. Classified as a large-pore zeolite (12-rings) it also contains a small-pore side pocket that can only be accessed via the 12-ring. The side-pocket has been shown to be crucial to small-molecule activation such as methane to methanol oxidation and DME carbonylation, driven in part by the spatial distribution of Al.[1] Interestingly, MOR also exists in two variants depending on the aperture size of the pore opening (i.e. port size), defined by the extent of benzene adsorption as noted by Sand as early as 1968.[2] Various hypothesis have been proposed over the years, among which cation location and dealumination suggest a link to Al distribution.[3] Here we report, for the first time, a single-parameter study leading to the successful variation in port size based solely on a synthesis approach.

**Experimental/methodology.** Zeolite synthesis was based on a modified approach reported by Chi & Sand.[4] We systematically varied the Na/K ratio in the gel by substituting NaOH for KOH (85%), maintaining all other parameters. Material characterization was accomplished with a suite of tools such as X-ray diffraction, $N_2$-physisorption, scanning electron microscopy, elemental analysis, and temperature programmed desorption using propylamine and $NH_3$. The port size was determined performing a toluene breakthrough experiment. Catalytic testing involved propene oligomerization and isobutane cracking.

**Results and discussion.** We successfully synthesized a range of MOR zeolites containing increasing fractions of $K^+$ in the gel (Figure 1). All materials crystallized at 185 °C. As the fraction of $K^+$ ions in the gel increased, both the induction period and the crystallization period slowed down requiring a longer time to achieve full crystallinity. When probing the protonic forms with toluene vapors (as benzene substituent) we found that the uptake becomes limited once the K concentration reaches a certain threshold (K/Na > 0.75 in MOR). Performing a temperature programmed desorption step of the adsorbed toluene allowed us to deduce that the pore size is slightly smaller in the K-MOR system. While we previously used propylamine TPD to determine the accessibility of acid sites in MOR, we find here that this descriptor seems to also correlate with propene oligomerization in the pores, with more extensive propene coking in the small-port K-MOR system. This is further supported by reactivity tests with propene and isobutane performed in a fixed bed reactor. Rietveld refinement of X-ray diffraction data highlights the spatial differences in the $Na^+$ and $K^+$ distribution of the crystallized MOR systems, which ultimately leads us to conclude on the cation-induced speciation of the MOR port-size. This promises to resolve a long-standing question related to this highly relevant, industrial catalyst.

**Keywords:** dark photocatalysis, trapping and releasing electron-hole pairs, indoor air quality, catalyst.
Fundamentally, catalyst for photocatalysis process requires a light source to produce electron-hole pairs [1] and it is a major challenge to implement this system to reduce indoor air pollutants continuously without having optimal light available continuously too. Band gap engineering may be a promising technique for adjusting energy required to meet the variation of light sources such as ultraviolet light, visible light, and near infrared light to activate the catalyst [2], [3]. The number of electron-hole pairs produced during irradiation varies depending on the light sources [4]. Therefore, it is possible to generate large amount of the pairs and the excess number of pairs can be stored in the photocatalysis material to be released at night. This mechanism can be adopted to overcome the limitations of the traditional photocatalysis and is known as dark photocatalysis which has two main processes such as harvesting and releasing of light energy [5]. The aim of this review paper is to propose an innovative mechanism to degrade indoor air pollutants around the clock. A general overview of the trapped and released electron-hole pairs is presented. Finally, the potential challenges in the further application of dark photocatalysis are discussed as an efficient indoor air purification technique.

**Keywords:** Hydrogen carrier, hydrogen production, ammonia decomposition, kinetic investigation

**Introduction.**
To achieve net-zero $CO_2$ emission in the coming decades, hydrogen is considered as one of the most promising energy carriers for the future energy systems [1]. To overcome the challenges for the storage and transportation of $H_2$, the generation of $CO_x$-free hydrogen from ammonia decomposition has attracted increasing attention, since $NH_3$ has high volumetric energy density (108 kg-$H_2$/$m^3$ $NH_3$ at 20 °C and 8.6 bar) and gravimetric energy density (17.8 wt.%), combined with its ease of storage and transportation [2]. According to the state of the art, Ru is the most active metal for $NH_3$ decomposition [3]. Although widely studied, the mechanism and kinetics of $NH_3$ decomposition over Ru-based catalysts are still discussed and fertile soil of new findings. In this work, a kinetic investigation of $NH_3$ decomposition was performed over home-made Ru-based catalysts. The effects of the main operating conditions (temperature, space velocity, feed composition) were systematically studied aiming at the identification of the prevailing kinetic dependences and a better understanding of the mechanism and rate controlling factors.

**Experimental/methodology.**
1% Ru/ $Al_2O_3$ (Cat. A) and 1% Ru/ MgO (Cat. B) catalysts were prepared via an incipient wetness impregnation by using $RuCl_3$ as precursor. Catalytic tests were carried out in a continuous fixed-bed flow reactor, after reduction in flowing $H_2$ at 450 °C. $NH_3$ decomposition was tested at varying gas hourly space velocity and ammonia concentration, from ppm to highly concentrated feeds. $H_2$ and $N_2$ co-feed exepriments were also performed. Product gas composition was analyzed by on-line MS.

**Results and discussion.**

The catalytic performance of catalysts Cat. A and Cat. B under selected feed conditions are compared in Figure 1. Results showed a negative effect of $NH_3$ feed concentration over conversion, suggesting a global kinetic order lower than 1. When co-feeding large quantities of $H_2$, $NH_3$ conversion dropped importantly and the conversion curves were shifted to much higher temperatures; this clearly suggests that $H_2$ adsorption strongly inhibits $NH_3$ activation on Ru. Additional tests showed that under large $H_2$-cofeed, the process gain a full first order dependence on $NH_3$ and conversion become independent on $NH_3$ content from low to very high concentrations (not reported). A Langmuir-Hinshelwood kinetic model can nicely describe the observed effects, assuming that H is MASI and that the rate determing step lies within the dehydrogenation path of $NH_3$ rather than the associative desorption of products.

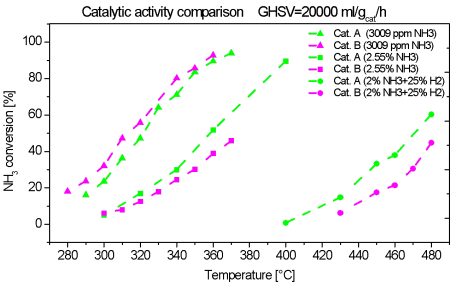

**Figure 1. Catalytic activities comparison between catalyst 1% Ru/$Al_2O_3$ and 1% Ru/MgO, GHSV = 20000 Nl/kg/h.**

The comparison between the two catalyst formulations showed however that the strength of $NH_3$ and $H_2$ inhibition have different intensity due to the nature of catalyst supports. Dynamic experiments reveal in fact differences of strength of adsorption and coverage of surface species.

**Keywords:** 3D printing, Hydrogen production, LOHC, Formic acid dehydrogenation, Monolithic catalysts

**Introduction.** The use of a liquid organic hydrogen carriers (LOHCs) has shown to be a safe, practical, and economic alternative for hydrogen ($H_2$) storage and transportation. Among them, formic acid (FA) is a probable candidate considering its high volumetric $H_2$ capacity and low toxicity [1]. The most efficient solid catalyst for the FA dehydrogenation reaction is Pd nanoparticles on activated carbon (AC) supports [2]. In this work, a catalyst consisting of supported Pd nanoparticles on robust and porous AC monoliths fabricated by 3D printing is developed and applied in the continuous production of $H_2$ from FA dehydrogenation reaction.

**Experimental/methodology.** Different compositions of AC powders (>100 nm particle size, Merck) and a colloidal dispersion of boehmite (41 wt.%) were mixed to prepare printable water-based inks. The inks were extruded with a three-axis robocasting system to fabricate cylindrical monoliths with square cells. The as-printed monoliths were heat-treated at 1300 ºC in a vacuum furnace for 30 min, resulting in 3D monoliths made of AC and $Al_2O_3$. Pd nanoparticles were immobilized on the 3D AC monoliths by the wetness impregnation method, using $PdCl_2$ as a precursor, followed by reduction in a gas stream ($H_2$:$N_2$= 50; 100 NmL/min) at 250 ºC for 2 h. The FA dehydrogenation experiments were carried out in an up-flow tubular reactor at: $C_{FA,0}$=[0.5-1] M, T=[25-55] ºC, $Q_L$= 0.25 mL $min^{-1}$, $Q_{He}$=17 mL $min^{-1}$ as a carrier gas, $W_{CAT}$=2.4 g (5 monolith pieces) and τ=160 g h $L^{-1}$.

**Results and discussion.** Figure 1a shows an image with the dimensions of the 3D Pd/AC monolithic catalyst where the shape of the open channels and filaments is preserved. The average size of the Pd nanoparticles was 1.9 ± 0.4 nm, which were homogeneously distributed on the scaffold surface, as was observed by SEM analysis (data do not shown). The atomic ratio $Pd^{2+}/Pd^0$ was 1.4 and the content of Pd was 4.8 wt.%, measured by XPS and TXRF, respectively. As expected by the physical and chemical properties of the supported Pd nanoparticles, the 3D Pd/AC monoliths exhibited high catalytic activity in the FA dehydrogenation reaction (see Figs. 1b and c) yielding only $H_2$ and $CO_2$ (with $H_2/CO_2$ ratio= 1-1.2). Under reaction conditions, FA conversions ($X_{FA}$) between 80 and 90% were achieved and gas produced flow rates were as high as 12 NmL/min. After a given period of time on stream, the 3D Pd/AC catalyst deactivates, particularly at high temperatures and initial FA concentration (Fig. 1c).The catalyst activity can be restored by drying the monoliths in air at 60 ºC for 24 h. These results demonstrate that structured catalysts such as 3D Pd/AC are promising candidates for the continuous production of CO-free $H_2$ using FA as carrier.

**Keywords:** Nitric oxide, catalytic reduction, SCR, carbon nanotube, copper, potassium

**Introduction.**

The reduction of nitrogen oxide ($NO_X$) emissions is one of the main environmental concerns, as they can cause global warming, acid rain, the greenhouse effect, and several problems for human health. Thus, it is imperative to develop advanced technologies and catalysts to control $NO_X$ emissions to comply with increasingly stringent legislation [1].

Selective catalytic reduction is a means of converting $NO_X$ with the aid of a catalyst into $N_2$. At low temperatures, carbon-based catalysts show greater catalytic activity in reducing NOx than conventional catalysts; therefore, selective catalytic reduction with carbon (SCR-C) is an excellent alternative for NOx reduction, with the additional advantage of avoiding the need for an external reducing agent [2]. Recent studies have shown that NO can be reduced to $N_2$ at temperatures below 500 °C, using carbon materials impregnated with transition metals or metallic oxides [3].

The main objective of this work is to study the reduction of NO using carbon nanotubes (CNT) as a catalyst or as a support for the metallic phases.

**Experimental/methodology.**

Two different supports were used for the incorporation of the metallic phase by incipient impregnation with copper or potassium: the original (CNT) and the nitrogen-doped (CNT_M_BM) samples. The textural and chemical properties of the materials were characterized by $N_2$ adsorption at -196 °C, inductively coupled plasma-optical emission spectrometry (ICP-OES), and elemental analysis (EA).

NO reduction experiments were performed in a fixed-bed, U-shaped flow reactor. The mass of the sample was 0.2 g, the flow rate was 100 $cm^3\ min^{-1}$, and the concentration of NO in He was 1000 ppm.

**Results and discussion.**

Carbon nanotubes (CNT) do not show significant catalytic activity in the reduction of NO. When incorporating copper the performance is a little better, obtaining a conversion of 26%. The introduction of nitrogen surface groups (CNT_M_MB) further increases the catalytic activity, thus observing that the nitrogen incorporated into carbon nanotubes increases their catalytic activity, thus showing a NO reduction of 78%. In this work, the effect of adding potassium to copper on both types of support for the reduction of NO was investigated and it was verified that the addition of potassium significantly improves its catalytic performance. Among the samples, the best results were obtained for copper supported on nitrogen-doped CNT and impregnated with potassium (CNT_M_BM@CuK), obtaining a NO reduction of 100% for a $T$ = 360 °C.

# Ru@C microspheres for Photo-Thermal catalysis applications

A. Rendón-Patiño[1*], D. Mateo[1], E. V. Ramos-Fernandez[2*] and J. Gascon[1*]

[1]*King Abdullah University of Science and Technology, Thuwal, Saudi Arabia*
[2] *Universidad de Alicante, Alicante, Spain*
[*]*alejandra.patino@kaust.edu.sa*

**Introduction.** Photothermal catalysis is a hybrid approach that combines the advantages of photocatalysis and thermocatalysis. [1] In this regard, carbon-based materials are promising candidates for applications in photothermal catalysis due to their broad light absorption and effective light-to-heat conversion. Furthermore, metal nanoparticles are also considered excellent nano-heaters so the combination of both elements can be crucial to improve the photo-thermal performance. With this in mind, in this work we have designed a novel photothermal catalyst based on Ru nanoparticles encapsulated within carbon microspheres (Ru@C).

**Experimental/methodology.** For the synthesis of these materials, 4 mL of 0.02 M $K_2RuCl_5$ solution were added drop by drop to a 40 mL 0.5 M glucose solution under vigorous stirring. [2] Then, the mixture was transferred into a 50 mL Teflon-sealed autoclave and maintained at 160 °C for 2 h. The puce powder was recovered by filtration, washed with ethanol and water several times, and oven-dried at 70 °C overnight. Ru@C microspheres were finally pyrolyzed at 300-700°C for 2 h under $N_2$ atmosphere. All the samples were characterized by Scanning Electron Microscopy (SEM), Transmission Electron Microscopy (TEM), elemental mapping using Energy Disperse X-Ray (EDX), Raman spectroscopy, Elemental Analysis (EA), Inductively Coupled Plasma (ICP), Thermogravimetry (TGA), and X-ray Photoelectron Spectroscopy (XPS).

**Results and discussion.** STEM images revealed that the nanoparticles of ruthenium are encapsulated within the carbon microspheres, displaying a range of sizes between 1 to 20 nm (Figure 1a). Moreover, according to SEM images, the carbon microspheres show diameters ranging from 0.2 to 8 μm (Figure 1b). The content of Ruthenium was determined by ICP analysis, obtaining an estimated amount of 0.5 %. The nature of carbon spheres was also characterized by Raman spectroscopy and XPS. The Raman spectra showed the expected G band at 1590 $cm^{-1}$ accompanied by a D band at 1350 $cm^{-1}$ that is associated with the presence of defects. Survey XPS analysis indicates that the deconvolution of the C1s presented a significantly larger contribution of Carbon $sp^2$. In view of these results, the as-prepared carbon microspheres with encapsulated ruthenium nanoparticles are expected to present a good photothermal performance combining the efficient light-to-heat capabilities of both elements.

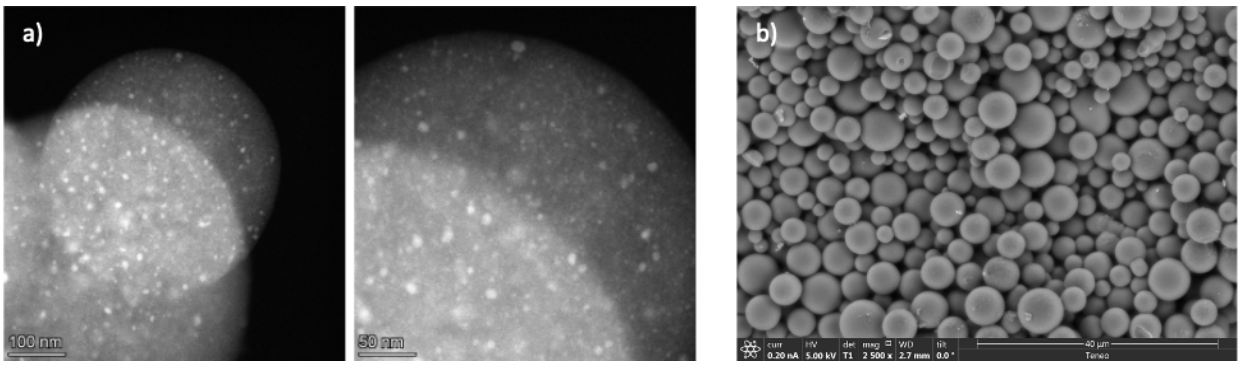

**Figure 1. (a) STEM and (b) SEM images of Ru@C microspheres.**

**Introduction.** For decades, Pt and $CrO_x$ have been the most commercialized catalysts in the non-oxidative dehydrogenation of alkanes by on-purpose technologies (UOP Oleflex/Lummus Catofin). The UOP commercial catalyst contains ca. 0.3 wt.% of Pt supported on alumina and promoted with Sn and alkaline metals. The temperatures to which the catalytic converter is subjected lead to the sintering of the active phase and coke formation. This depresses catalytic activity in few hours, requiring a complex regeneration process which involves coke gasification and Pt re-dispersion.[1,2] Several alternatives have been proposed to modify the physicochemical properties of Pt in order to improve its stability and selectivity in the dehydrogenation of alkanes. Among them, the suitability of Fe as an additive has been highlighted due to its influence on the electronic properties of Pt, with a shift of the d-band center towards the Fermi level, weakening the adsorption of alkenes and avoiding further transformations.[3] In this work, we have studied a series of Pt-Fe catalysts supported on SBA-15 for the non-oxidative dehydrogenation of isobutane. The high specific surface area of mesostructured silica allowed a high dispersion of the supported bimetallic phase thus generating small clusters/nanoparticles after a reduction pre-treatment in hydrogen at 600 °C.

**Experimental.** (*i*) Catalyst preparation: a series of Pt-Fe bimetallic catalysts were prepared by ultrasound-assisted co-impregnation of the metal precursors ($H_2PtCl_6$ +$Fe(NO_3)_3$) on a mesostructured SBA-15 support for different metal loadings and Pt/Fe ratios (Pt<<<Fe), dried at 110 °C for 16 h and calcined in a muffle for 3 h at 550 °C. (*ii*) Characterization: as-prepared catalysts were analyzed by XRD, TPR and Eletron Tomography. Next, pre-reduced catalytic systems were characterized by STEM-HAADF+EDS mapping and XAS (Fig. 1a and 1b, respectively) to determine the chemical environment of Pt on the $FeO_x$/SBA-15 matrix. (*iii*) Catalytic studies: the sized catalysts (150-250 μm) were tested in the non-oxid ative dehydrogenation of isobutane at atmospheric pressure ($P_{iC4H10}$=0.05 MPa) in a tubular quartz reactor (Ø=8 mm) in fixed-bed mode at 550 °C. Recyclability tests were carried out by subjecting the spent catalyst to consecutive reaction-regeneration cycles (regeneration conditions: 2% $O_2$ stream, heating ramp=2 °C·min$^{-1}$).

**Results and discussion.** Structural characterization of the calcined catalysts determined the preferential presence of the hematite phase (XRD) within the mesoporous channels of SBA-15 (Tomography). TPR profiles suggested the formation of bimetallic Pt-Fe phases at low temperature as well as hardly reducible iron silicates. TEM confirmed the high dispersion of the pre-reduced Fe phase in the bimetallic systems (< 5 nm particles) and the homogeneous distribution of Pt on the Fe matrix which appears to be atomically dispersed within an Fe matrix (see Fig.b right, EXAFS analysis). These characteristics seem to be responsible for its high activity ($X_{iC4H10}$=43%, $S_{iC4H8}$=96%) and stability in the dehydrogenation of isobutane.

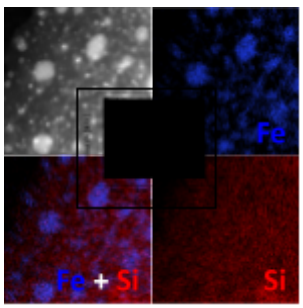

**Table 1.** Activity on the dehydrogenation of $iC_4H_{10}$ at 550 °C after TOS=10 hours.

| Catalyst (**x**Fe**y**Pt)/SBA-15 | $X_{iC4H10}$ | $S_{iC4H8}$ | $C_{balance.}$ (gas phase) |

# Development of Stable Ceria-Supported Noble Metal Catalysts with Sulfur Resistance for Waste-to-Hydrogen

H.-S. Roh[1*], K.-J. Kim[1], S.-J. Ryu[1]

[1]*Department of Environmental and Energy Engineering, Yonsei University, 1 Yonseidae-gil, Wonju, Gangwon 26493, Republic of Korea*
[*]*hsroh@yonsei.ac.kr*

**Introduction.** Waste-to-hydrogen technology is being proposed to solve the problem caused by the increasing amount of waste in worldwide. From the perspective of waste-to-hydrogen, waste gasification can obtain gaseous products (CO, $H_2$, $CH_4$, and $CO_2$) from waste. In our preceding study, we have been tried to establish an eco-friendly method for $H_2$ production through waste gasification combined with the high-temperature water-gas shift (HT-WGS, $CO + H_2O \leftrightarrow H_2 + CO_2$, $\Delta H$ = -41.2 kJ/mol) reaction [1-2]. However, impurities such as sulfur are partly contained in waste-derived synthesis gas, which act as a poison to the catalyst in the HT-WGS reaction [3]. Therefore, we aimed to develop a highly active and sulfur-tolerant catalysts for the conversion of waste-derived synthesis gas.

**Experimental/methodology.** $CeO_2$-supported catalysts with various noble metals (Pt, Rh, Ru, and Pd, 2 wt% each) were prepared by the incipient wetness impregnation method. The intrinsic catalytic activity of the prepared catalyst was tested at 400 ℃ for 18 h, and sulfur resistance of the catalyst was evaluated by injecting 500 ppm of $H_2S$ during the WGS reaction. The physico-chemical properties of the $CeO_2$-based catalysts were characterized using various techniques such as Brunauer-Emmett-Teller surface area and pore analysis, X-ray diffraction, $H_2$-temperature programmed reduction, X-ray photoelectron spectroscopy, $H_2$-$O_2$ pulse reaction, CO−chemisorption, Photoluminescence, high-angle annular dark-field scanning transmission electron microscopy and energy dispersive X-ray spectroscopy.

**Results and discussion.** In our previous research, among the various support candidates such as $CeO_2$, $ZrO_2$, MgO, and $Al_2O_3$, $CeO_2$-supported catalyst exhibited the best sulfur resistance and regeneration rate due to the superior redox property and high oxygen storage capacity of $CeO_2$, which accelerates the redox mechanism of HT-WGS [3]. In this study, Various noble metals (Pt, Rh, Ru, and Pd) were supported on $CeO_2$ to understand their sulfur-tolerant catalytic activity. Among the samples, the Pt-based catalyst showed the highest sulfur tolerance and recovery of catalytic activity. Considering the catalytic reaction results and physicochemical properties, the sulfur tolerance of the catalyst is affected by oxygen vacancies and redox properties, which are closely related to the interaction between the metal and the $CeO_2$ support. In addition, the oxygen storage capacity concentration was used as an indicator for classifying the recovered catalyst and the non-recovered catalyst which had been poisoned by sulfur.

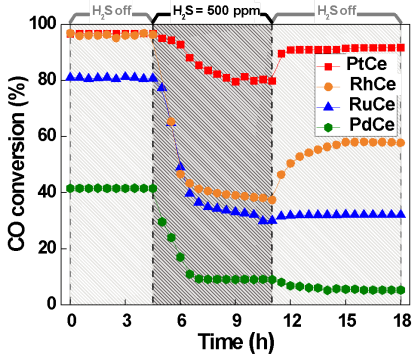

**Figure 1. Catalytic performance with time on stream over $CeO_2$-supported catalysts with various noble metals ($H_2O/(CH_4 + CO + CO_2)$ = 2.0; GHSV = 46,000 $h^{-1}$; $T$ = 400 ℃).**

| Catalyst | Oxygen storage capacity ($10^{-4}$ gmol/$g_{cat}$) |
|---|---|

**Keywords:** catalytic combustion of volatile organic compounds, $Co_3O_4$ catalysts, core-shell structures

**Introduction.** Core-shell structures are a new class of nanostuctured materials that have been attracting increasing interest in recent years due to their attractive properties and possible applications. The design of such materials, based on bottom-up or top-down strategies, gives the opportunity to produce catalysts with various physicochemical features dedicated to selected catalytic reactions [1,2]. Their catalytic activity often depends on the synergistic interactions between a core and a shell. However, the great advantage of the presence of the shell is also the protection of the active phase against sintering and the creation of a nanoreactor space for the catalytic reaction to take place. In this approach, an interesting idea may be yolk-shell structures containing highly dispersed nanoparticles of an active phase enclosed inside a mesoporous shell that guarantees relatively easy transport of reagents [3]. In the presented work, $Co_3O_4$@$SiO_2$ yolk-shell systems were developed for the elimination of volatile organic compounds (VOCs) from polluted air by the catalytic combustion.

**Experimental.** Spherical particles of diethyltriamine-functionalized poly(maleic anhydride) (MA-DETA) and polystyrene (PS) with uniform diameters within the range of 200-240 nm were synthesized. Subsequently, the polymer template was surrounded by a $SiO_2$ precursor using the modified Stöber strategy. An influence of type of solvent, amount of $SiO_2$ precursor, TEOS/$NH_3$ ratio and addition of surfactant on quality of the formed coatings was tested using scanning electron microscopy (SEM). As the result of optimization of $SiO_2$ deposition, the spherical silica materials with high specific surface area ($S_{BET}$ value above 1100 $m^2/g$) were obtained, containing mesopores enabling access to their interior. In the next step of the synthesis, a transition metal oxide (i.e. $Co_3O_4$) precursor was incorporated into the polymer@$SiO_2$ materials using various approaches, including wet impregnation and adsorption process. The kind of modification method and the amount of the introduced $Co_3O_4$ precursor determined properties of the active phase created within the yolk-shell structures after the polymer core removal by calcination at the oxidizing atmosphere. The structure, composition and reducibility of the $Co_3O_4$-containing materials were studied by XRD, XRF, UV-Vis-DR, XPS and $H_2$-TPR. Moreover, the synthesized catalysts were tested in the combustion of toluene.

**Results and discussion.** The nanostructures containing catalytically active $Co_3O_4$ spinel nanoparticles surrounded by mesoporous $SiO_2$ shells were formed. In comparison to conventional catalysts that contain the $Co_3O_4$ active phase deposited on a $SiO_2$ support, the proposed yolk-shell structure provides a better access of reactants to the surface of active phase nanoparticles, which results in their higher activity and selectivity in the VOCs combustion. The kind of the polymer template used for the synthesis of the $SiO_2$ spheres had a significant impact on the catalytic activity. The catalysts prepared on the basis of the MA-DETA template were characterized by significantly better catalytic activity compared to those constructed on the PS grains. The differences in the catalytic activity were related to the dispersion of $Co_3O_4$ nanoparticles inside the silica spheres. The high dispersion obtained in the case of using the MA-DETA matrix resulted from the presence of amino groups, which ensured the appropriate adsorption capacity of $Co^{3+}$ ions introduced during the modification. As a result, extremely active systems were achieved, far exceeding those described in the scientific literature.

**Keywords**: Spinel oxides, alcohol oxidation, batch reactor, kinetic study.

**Introduction.** The chemical industry relies on the selective oxidation of alcohols to aldehydes or ketones as a powerful and versatile transformation step for the synthesis of valuable compounds. Aldehydes and ketones are important intermediates in the synthesis of pharmaceutically active agents, antioxidants, agrochemicals and fine chemicals. While small alcohols are selectively oxidized in well-established industrial processes, the selective oxidation of higher alcohols still leaves room for improvement. The most active catalysts for this reaction are based on noble metals [1]. Metal oxide catalysts, despite being more complex and having less defined active sites, are based on abundant metals and are less prone to leaching. Hence, the exploration and design of highly active and selective oxide catalysts for alcohol oxidations plays a relevant role in promoting more environmentally sustainable synthesis paths for a wide range of organic molecules.

**Experimental/methodology.** The spinel oxide catalysts, based on Mn, Fe, Co, Ni, Cu, and Zn and with different compositions, were prepared via combustion synthesis and calcination. The synthesised solids were tested as catalysts for the liquid phase oxidation of alcohols, such as isopropanol and 2-butanol, to ketones (acetone and 2-butanone, respectively) in a 300 mL autoclave reactor. The catalyst powder was suspended by magnetic stirring in an aqueous solution of the alcohol. The suspension was pressurised with oxygen at different pressures (up to 50 bar) and heated at different temperatures (160-250°C). For each set of operating conditions, after different operating times, the composition of the liquid was determined by GC-FID. Both fresh and used catalysts, after the reaction and hydrothermal treatments, were characterised by XRD, $N_2$-physisorption, SEM-EDX, XPS, and FT-IR.

**Results and discussion.** The reaction rates were determined upon regression of experimental data. $Co_3O_4$ was used as the model catalyst, and the composition was modified to assess the influence of metal substitution and structure modifications on the catalytic activity and selectivity. The catalytic results obtained with batch conditions were compared to the ones obtained in flow. The characterisation results allowed to investigate changes in crystalline phases, catalyst surface and morphology due to exposure to reaction conditions.

**Keywords:** Graphene nanoplatelets, $CO_2$ methanation, carbon-supported catalysts

**Introduction.** $CO_2$ emission from fossil fuel combustion is one of the most common causes of global warming. The catalytic hydrogenation of $CO_2$ to methane is an efficient way to reduce $CO_2$ emissions. As an example, among noble and transition metals, supported nickel and ruthenium catalysts are the most promising candidate for $CO_2$ methanation reaction; nickel is sometimes preferred for its high activity and relatively low cost [1]. However, the role of support plays a central role in the activity and stability of the synthesized catalysts. Ni catalysts are generally supported on various oxides such as $Al_2O_3$, $SiO_2$, $ZrO_2$, and $CeO_2$ with quite variable loadings (5-50 wt.%) and suitable promoters. Carbon-supported catalysts are timely of interest for different green chemistry reactions and according to our previous work efficiently support cobalt nanoparticles in Ethanol Steam Reforming reaction [2]. As well, graphene, which possesses unique properties, has been already used to disperse monometallic and bimetallic nanoparticles, showing remarkable catalytic performances in many reactions. However, studies that use graphene as catalyst support in the heterogeneous catalysis field are still limited [3]. Conventional graphene production is mainly related to the Hummers' method and recently different other preparations have been attempted [4]. In this work, a green and sustainable process using the molten salt method has been applied to produce high-quality Graphene nanoplatelets (Gnp) to evaluate their possible use in the frame of $CO_2$ utilization reactions by comparing their activity with conventional and carbon nanotube-supported catalysts.

**Experimental/methodology.** Graphite powder has been used as the precursor to synthesize graphene using a molten salt method proposed by E. Ruse et al. [5]. Synthesis has been here optimized by also evaluating the possible recycling of used salts in the optic of circular economy approach. Briefly, graphite powder was mixed with a eutectic salts mixture (NaCl/KCl) with a graphite/salt ratio of 1:9. The graphite-salt mixture was then heated in an Ar atmosphere with a rate of 10 K $min^{-1}$ to 1023 K and kept for 360 min. After cooling down Gnp was recovered. Carbon nanotube-supported catalysts have been synthesized following the preparation procedure reported in the open literature [6] and as a reference, Ni and $Ru/Al_2O_3$ catalysts have been prepared for comparison purposes. Following our previous work [7], $CO_2$ hydrogenation experiments are actually under evaluation. Online products analysis will be performed using an FT-IR instrument.

**Results and discussion.** At the present, graphene nanoplatelets were successfully produced with a yield of 30-40 wt.% following molten salt procedure and, conversely supported Ni- over carbon nanotubes have been produced optimizing preparation parameters. Characterization by SEM, XRD, and FT-IR confirmed the achievement of desired products both for carbon-based and supported catalytic materials ($Ni/Al_2O_3$ and $Ru/Al_2O_3$). At the present, the optimization of metal introduction and possibly single-atom rational catalyst design are under deep investigation together with the evaluation of the catalytic activity.

**Introduction.** The inherent properties of a single atomic carbon layer in graphene offer opportunities for the creation of catalytically active centers tailored on a molecular level on a support with high thermal stability and very high specific surface area (~2600 $m^2 g^{-1}$). The wide range of means of functionalizing the graphene monolayer could be exploited in the development of heterogeneous catalysts with active sites controlled at the atomic level. However, utilization of the unique properties of graphene for application in a catalytic process relies on the development of a three-dimensional (3D) graphene-like catalytic material with connectivity of the pore network, providing good accessibility to the active sites. In this study, metal supported 3D graphene-like microporous carbons synthesized in the beta and faujasite zeolite templates, denoted as β-carbon and Y-carbon, respectively, were analysed with respect to their structure and catalytic properties in comparison with metal supported conventional catalytic materials.

**Experimental/methodology.** The well-defined and regular 3D channels system of the faujasite zeolite was replicated into the zeolite-templated carbon material by nanocasting. Carbonization of the zeolites was performed using chemical vapour deposition with propylene as a carbon precursor. In the process of zeolite nanocasting, carbon atoms were generated along the walls of the regular zeolite micropores. The subsequent selective removal of the structural lattice of the zeolite provided an ordered 3D microporous graphene-like carbon material [1].

**Results and discussion.** Structural analyses showed that the β-carbon and Y-carbon are characterized by 3D assembled and highly stable single atomic graphene layers forming an open porous system resembling the regular channel system of the zeolites with a specific surface area comparable to the surface area of graphene (≥2500 $m^2 g^{-1}$) [1]. The curved surface of the 3D graphene-like structure having accessible porosity through the channel system is characterized by the presence of unsaturated carbon atoms at the edges, together with a tunable concentration of oxygen-containing functional (hydroxyl/phenolic and carboxyl) groups. The metal clusters (Pt, Pd, Rh) were introduced into 3D graphene-like carbon materials as active centers for hydrogenation reactions. The relationships between catalytic properties and structural parameters including the effects of the size of metal clusters from a nanometre to a sub-nanometre scale, effects of the interactions of the metal-graphene support and reduced metal–metal coordination were analysed. The materials catalyse the hydrogenation of aromatics, alkenes, alkynes and cycloalkenes into the corresponding alkenes, alkanes and cycloalkanes with exceptionally high reaction rates and selectivity. The study demonstrates the potential of the 3D graphene-like materials for the preparation of metal catalysts with a very high concentration of well dispersed metal clusters of tuneable size.

Zeolite templated 3D graphene-like carbon catalysts represent a novel concept in the field of heterogeneous catalysis, which enables a dramatic increase in the surface area available for active centers and the tuning of catalysts functionality for a wide range of catalytic reactions for hydrogenation/dehydrogenation and processing of hydrocarbons. The results of the study illustrate a method for the exploitation of the unique properties of a single layer of carbon atoms in heterogeneous catalysts characterized by outstanding specific surface area and high thermal stability [1].

**Abstract**

The transformation of greenhouse gases (GHGs) i.e. methane and carbon dioxide into syngas (CO, $H_2$) via dry reforming of methane (DRM) serves as an excellent sustainable energy solution towards carbon neutrality. The DRM process gained attention to yield the ($H_2$/CO) syngas ratio as a building block for the production of value-added chemicals and fuels [1]. Therefore, robust and efficient catalysts with high thermal stability and activity are required. The noble metals (Ir, Rh, Ru, Pt, Pd) have been extensively explored as a catalyst owing to excellent conversion rate, stability and turnover frequencies. However, their industrial application is limited due to the high cost. Transition metal-based catalysts are considered a good alternative for the DRM reaction due to their low cost, availability and quick turnover frequencies [2]. Limitations of the Ni-based catalysts are deactivation, accumulation and sintering problems which are detrimental to the conversion efficiency and selectivity for syngas production. Coking is another challenge due to the decomposition of methane ($CH_4 + C \leftrightarrow 2H_2$) and the Boudouard reaction ($2CO \leftrightarrow CO_2 + C$). The aforementioned problems can be overcome using a catalyst with redox properties, and basic sites leading to uniform metal dispersion and resistance against deactivation. One of the possible solutions to address these challenges is the incorporation of active metals into crystalline oxides such as perovskite-type oxides (PTOs) [3]. Perovskite materials having general formula, $ABO_3$, are used as catalysts precursors or supports. The flexible structure of perovskite materials is capable of accepting a wide range of substitutions with the formation of oxygen vacancies. The higher concentration of oxygen vacancies at the catalyst surface supports the conversion of $CO_2$ and $CH_x$ species into gaseous products. Moreover, perovskite materials reflect good chemical and mechanical stability under high temperature reaction conditions. Currently, Ni-supported perovskite catalysts are considered useful to improve the activity, stability and carbon deposition-related problems [4].

In view of the above, different perovskite-type supports considering $ABO_3$ (such as A= Al, La with B=Ce and A=Mg, Mn with B=Zr) were prepared via the sol-gel method. Ni metal loading of 10 wt.% was deposited on prepared perovskite supports via the impregnation method. The catalysts were characterized using XRD and FTIR techniques. The DRM activity was carried out in a tubular reactor as described in our previous study [5]. The catalytic performance was assessed in the temperature range of 500–700 °C, $CH_4/CO_2$ = 1/1 and under GHSV of 12,000 $h^{-1}$. Among the prepared catalysts, Ni-doped perovskite combination (i.e. A=Mg with B=Zr)$O_{3-\delta}$ exhibited higher ($CH_4$, $CO_2$) conversion ca. (69, 59) percent and syngas yield of ca. ($H_2$/CO =0.72) at 700 °C. This indicates that the magnesium zirconate perovskite catalyst established strong interfacial metal-support interaction, redox properties and surface basic sites that linked with good performance of the catalyst during DRM process.

**Keywords**: perovskites, exsolution, lanthanide, reverse water-gas shift

**Introduction**: CO is a precursor of utmost importance in many chemical processes. In this context of decarbonisation and reutilisation of industrial by-products, such as $CO_2$, reverse water-gas shift (rWGS) reaction, where CO and $H_2O$ are generated, has gained attention. rWGS processes require high temperatures and the presence of catalysts that possess high selectivity towards CO as well as tolerance to high temperatures and agglomeration. Perovskites ($ABO_3$) with rare-earth elements (or lanthanides) in the A-site are well-known to be stable at high temperatures in catalytic processes whilst able to form oxygen vacancies hence improving $CO_2$ activation. Fe and Ni in the B-site are known to activate the rWGS reaction[1]. These perovskites can be decomposed into composites (exsolution process). Exsolution of metallic nanoparticles has proven to improve reactivity and their resistance towards coking formation and sintering[2]. Here we study and compare the effects of using different rare-earth elements in the A-site in a $Ln_{0.5}Ba_{0.5}Fe_{1-x}Ni_xO_3$ perovskite (Ln = Pr, Sm; x = 0, 0.1) as well as how the conversion towards desired products can be enhanced by the addition of a dopant when implemented in the rWGS reaction.

**Materials and Methods**: High purity precursors were used to prepare the $Ln_{0.5}Ba_{0.5}Fe_{1-x}Ni_xO_3$ catalysts by modified solid state method. Exsolution of particles was achieved by reducing the single-phase perovskites under 5% $H_2$ at 900 ºC for 10h. Purity and crystallinity study was done by Powder X-Ray Diffraction (XRD) and Rietveld refinement was carried out using TOPAS academic v7. Micro and nanostructure, morphology, atomic distribution were studied by scanning electron microscopy (SEM). Specific surface area was studied by $N_2$ adsorption, with the Brunauer-Emmett-Teller method (BET). rWGS catalytic tests were conducted in a continuous fixed bed quartz reactor, using 1 mmol of catalyst and $CO_2$:$H_2$ in a 1:2 ratio, 50 mL/min of reactant gases.

**Results and discussion**: Single-phase perovskites were synthesised and characterised by XRD and further by Rietveld refinement to confirm the high purity of the samples, SEM and BET. After exsolution Fe particles were observed for the non-doped perovskites (x = 0) and Fe-Ni alloys were confirmed for the Ni-doped perovskites (x = 0.1), shown in Figure 1. $Sm_{0.5}Ba_{0.5}FeO_3$ shows remarkably higher conversion (Figure 2) than the rest of catalysts, given its larger number of oxygen vacancies within its structure, hence activating $CO_2$. However, although more active, its selectivity towards CO is not as high as it is for Ni-doped samples. Ni-doped samples, despite not being as active as the latter, display a remarkably high selectivity towards CO, even at lower temperatures.

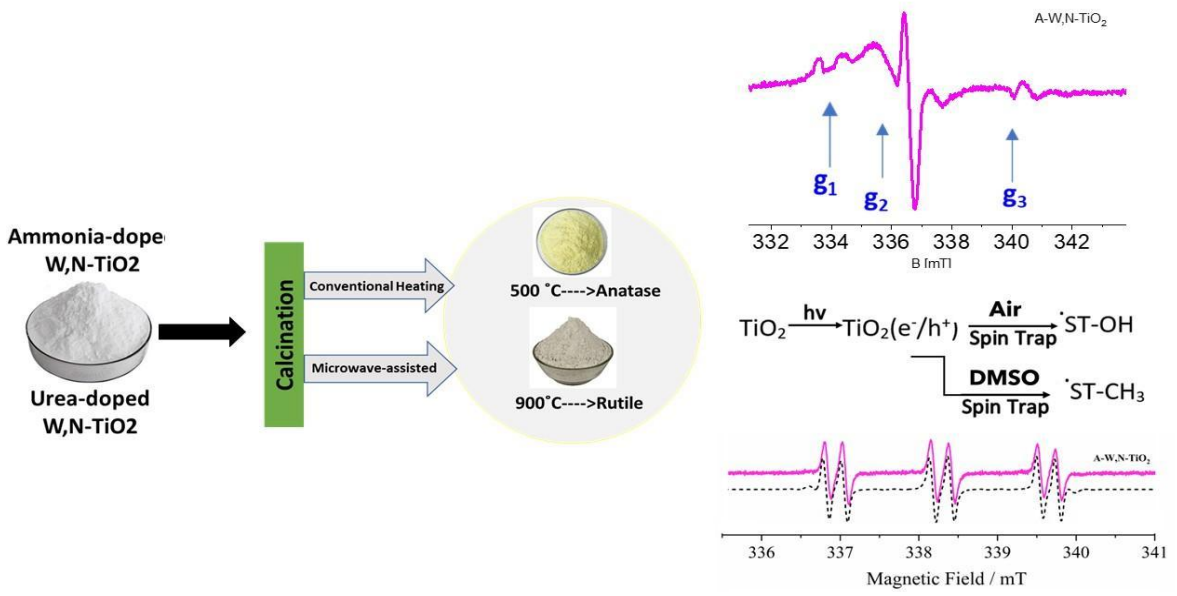
# $Ti_{1-y}W_yO_2N_x$ Photo-Oxidation Catalysts: From Synthesis to VOC Degradation

Sofia Salli, Kristina Maliutina and Emma Richards*

**School of Chemistry, Cardiff University, Main Building, Cardiff, UK, CF10 3AT*



**Keywords:** EPR spectroscopy, photocatalysis, materials characterisation, pollutants

**Introduction:** We report novel semiconducting nanoarchitectures based on earth-rich elements, with the general formula $Ti_{1-y}W_yO_2N_x$ as potential heterogeneous catalysts for VOC degradation and organic transformations. During irradiation of semiconducting materials, such as $TiO_2$, with energy exceeding their bandgap, electron and hole charge carriers ($e^-/h^+$) are produced. Subsequent migration of these charge carriers to the surface facilitates generation of Reactive Oxygen Species which exhibit superior oxidising power that promotes the degradation of organic compounds, such as toluene and formaldehyde.[1] The redox potential of the material and the performance upon visible light irradiation can be modified by introducing heteroatom dopants.[2]

**Experimental/methodology:** In our comparative study, we employ different nitrogen precursors (namely ammonia and urea) and calcination strategies, including microwave-assisted and furnace heating, to generate a series of $Ti_{1-y}W_yO_2N_x$ materials via sol-gel synthesis. Pure-phase anatase and rutile -$TiO_2$ polymorphs were prepared and fully characterised (BET, XPS, XRD, UV-Vis, SEM, Raman, FTIR).

**Results and discussion:** The introduction of intra-band gap states from both W-based acceptor levels, and N-based donor levels, the energy gap of the dopant material was lowered and thus improves alignment with incident solar radiation wavelengths.

To further explore the mechanism of photoactivity, we use Electron Paramagnetic Resonance (EPR) spectroscopy to characterise the transient charge-carriers and reactive radical species. The redox changes of the dopant defect sites formed in these materials are investigated upon in-situ irradiation, and the role of ˙OH/ ˙OOH radicals in the decomposition of dimethyl sulfoxide is determined.

**Keywords:** Zeolite, Boroaluminosilicate, Crystallization

**Introduction.** Recently, the zeolites with 10- and 12-ring pores have been paid attention in terms of their potential long catalytic lifetimes and high propylene selectivity compared to those with 8-ring systems[1]. We have first found that the CON-type boroaluminosilicate zeolite was an excellent catalyst for the selective formation of light olefins in the methanol to olefins (MTO) reaction[2,3]. It has been well known that in zeolite synthesis, the seed crystal affects the particle size as well as crystallization process. However, the impact of the seed crystal on the crystallization of the CON-type zeolite has not fully been investigated[4]. Originally, Beta zeolite has been used as seed crystals for crystallizing the CON structure. In this study, we synthesized the CON-type zeolites with either CIT-1 ([Al,B]-CIT-1_CIT-1) or beta ([Al,B]-CIT-1_Beta) as seed crystals, and clarified the influence of the seed crystals on the crystallization of the CON-type zeolite and their physicochemical and catalytic properties.

**Experimental/methodology.** The CON-type zeolites [Al,B]-CON were hydrothermally synthesized from the aqueous gel, containing a N,N,N-Trimethyl-(–)-cis-myrtanylammonium hydroxide (organic structure-directing agent), NaOH, boric acid, aluminum sulfate, fumed silica and 2 wt % of CIT-1, CON-type zeolite (Si/Al =20, 270) or zeolite beta (Si/Al = 12) as seed crystals. The prepared gel was crystallized at 170 °C for 7 days. The obtained samples were characterized by XRD, SEM, ICP-AES, $N_2$ adsorption, $NH_3$-TPD analysis.

**Result and discussion.** By the XRD patterns, the CON-type structure was crystallized regardless of the type of the seed after the hydrothermal treatment for 7 days. The SEM images showed that [Al,B]-CIT-1_CIT-1 and [Al,B]-CIT-1_Beta have almost similar particle morphology. The crystallization processes for both samples were monitored by the XRD patterns (Figure 1). There was a significant difference in the crystallization rate between CIT-1 and beta as seed crystals; the use of CIT-1 zeolite as seed crystals lead to the formation of the CON framework after 84 h, while that of beta required 108 h for the crystallization, indicating that the use of the seed crystals with targeted structure enables a faster crystallization. Note that, in the absence the seed crystals, the crystallization was unsuccessful even after 7 days. When beta zeolite is used as seed crystals, beta must be dissolved once, forming oligomers such as composite building unit (CBU), and then nucleation would start. On the other hand, the use of CIT-1 as seed crystals, the crystal growth would be initiated from the surface of the seed crystal, leading to the fast crystallization.

# Structured catalysts for electrified magnetic catalysis

**Keywords:** magnetic, electrification, ruthenium, cobalt, nickel, structured catalyst.

**Introduction.** Magnetic heating of the catalyst bed has several advantages, such as rapid heating, allowing on-demand ignition and hasty achievement of stationary conditions. With this, the catalytic reaction is limited only by kinetics and not heat transfer limitations [1]. In our work, we developed structured nanocomposite catalysts for electrified magnetic catalysis, such as ammonia synthesis/decomposition, hydrogenation/dehydrogenation of LOHC etc. Those consist of CoNi nanoparticles (NPs) embedded within the alumina matrix [2] decorated with catalytic Ru NPs.

**Experimental/methodology.** Three different methodologies were used to prepare structured nanocomposite catalysts: i. The CoNi-A-Ru-I catalyst was prepared in a three-step process. In the first step, the CoNi mixed hydroxide-containing boehmite powder was synthesized by aqueous co-precipitation of Co and Ni cations followed by AlN hydrolysis [3, 4]. In the second step, the powder was arranged into a structured catalyst. After thermal treatment, Ru was deposited by impregnation in the last step. ii. The CoNi-A-Ru-P catalyst was also prepared by a three-step process. The first step is the same as described above. After thermal treatment (900 °C, 1 h, $H_2$ atmosphere), Ru was deposited by precipitation in the second step. And in the last step, the powder arranged into a structured catalyst. iii. For the synthesis of the A-CoNiRu catalyst in the first step, alumina powder was prepared by hydrolysis of AlN in the presence of colloidal silica, followed by thermal treatment (500 °C, 1 h, stagnant air). Then the powder was arranged into a structured catalyst. In the last step, catalytic and magnetic NPs were deposited on the catalyst. The catalysts were extensively characterized and tested for magnetic catalysis in a custom-made high-pressure reactor. As the AC power source, a high-frequency generator was used, to which a copper tube coil is attached. The reaction yield was determined by on-line gas chromatography and mass spectrometry.

**Results and discussion.** The $H_2$-TPR profile of CoNi mixed hydroxide-containing boehmite shows distinct temperature clusters at low (~300 °C) and high (~850 °C) temperatures, indicating a two-step reduction process. Structural analysis shows that heat treatment in $H_2$ atmosphere at 900 °C reduces the CoNi mixed hydroxides to a metallic CoNi alloy, while boehmite dehydrates to metastable γ-$Al_2O_3$. The size of the CoNi NPs ranges from 10 to 18 nm. Measurements of the temperature-dependent magnetic properties in $H_2$ atmosphere revealed that CoNi NPs exhibit high (> 940 °C) Curie temperature and soft magnetic properties, indicating their high potential for magnetic heating. Our best nanocomposite powder reached temperatures above 500 °C in less than a minute under magnetic heating while it cooled to ambient temperature in a few minutes when the field was shut down. The physical and chemical properties of the prepared structured catalysts will be presented.

**patrick.schuehle@fau.de*

**Theoretical background**

Renewable hydrogen is a promising energy carrier to decarbonise industrial, energy and mobility applications. Hydrogen can be stored and transported in liquid organic hydrogen carrier (LOHC) systems, allowing safe and loss-free $H_2$-handling and the use of the existing liquid fuel infrastructure [1]. $H_2$-storage is performed in an exothermic catalytic hydrogenation reaction of the used LOHC [1]. The endothermic dehydrogenation releases pure hydrogen that can be used at time and place of a $H_2$-demand [1].

Palladium based catalysts have been shown to possess high productivity in the hydrogenation of the LOHC system dibenzyltoluene/perhydro-dibenzyltoluene [2]. The same study also found that the $Pd/Al_2O_3$ catalyst still exhibits adequate activity when the used $H_2$ is contamined with CO [2]. To improve the efficiency of LOHC hydrogenation using hydrogen from different renewable and recycled sources, the productivity and CO-stability of Pd catalysts must be further optimised.

Phosphorous-modification has previously shown to positively effect transition metal catalyst performances. For instance P-doped $Pd/Al_2O_3$ showed increased activity and stability in anthraquinone hydrogenation [3]. This was attributed to an improved thermal stability, increased Pd dispersion and enhanced interaction between Pd and support, decreasing Pd-loss during the reaction [3]. Additionally, CO-TPD analysis by Chandler et al. showed that P-modification of transition metal catalysts weakens the binding strength between CO and metal and therefore increases CO-stability [4].

Inspired by this promising approach we herein pursue P-modification of Pd catalysts to improve LOHC hydrogenation with pure and impure hydrogen.

**Experimental procedure**

P-modification of a commercial $Pd/Al_2O_3$ powder catalyst with 5 wt.-% Pd is conducted by wet-impregnation with phosphorous acid at different molar P/Pd ratios. This is done in aqueous solution which is stirred at room temperature for 16 h. After solvent evaporation at 80 °C and 50 mbar the catalyst is reduced at different temperatures under diluted hydrogen for 2 h.

The prepared catalysts are tested in the hydrogenation of the LOHC system benzyltoluene (BT)/perhydro-benzyltoluene. Batch experiments are carried out at 200 – 250 °C, 30 bar $H_2$-pressure and 0.05 mol-% Pd. Liquid samples are drawn regularly and are analysed via GC-FID to determine the degree of hydrogenation (DoH) of BT, which is a measure of the hydrogen loading of the LOHC. The hydrogenation productivity *P* of the catalyst is calculated in the DoH-range of 30 to 50 %.

**Results**

Our results show that P-modification of $Pd/Al_2O_3$ catalysts can increase the productivity of the commercial catalyst by up to 60 % under pure hydrogen conditions. The variation of the molar P/Pd ratio suggests an ideal ratio of 2.0. Formation of by-products was not increased by P-modification despite the higher activity of these catalysts. Detailed results of the hydrogenation experiments, further material analysis and hydrogenation using impure hydrogen will be shown on the poster.

**Keywords:** m-cresol, perovskites, hydrogenation, cation B

**Introduction**. The importance of the lignocellulosic biomass valorization is constantly increasing due to its abundant availability in nature, low cost and it is a renewable carbon source, unlike petroleum derivatives. From the pyrolysis of the lignin of the biomass, 30 wt.% of phenolic compounds such as cresols, guaiacols, syringols and phenols can be obtained[1], which can be subjected to catalytic hydrotreatment (HDO) to improve their properties and obtain high added-value chemicals[2]. Recently, promising results have been found in HDO reactions using perovskite type structure [3]. In this work the catalytic evaluation of three pure ($ABO_3$) perovskite $LaCoO_3$, $LaNiO_3$, $LaFeO_3$ and three substituted ($AB_{0.5}B'_{0.5}O_3$) $LaFe_{0,5}Co_{0,5}O_3$, $LaFe_{0,5}Ni_{0,5}O_3$ and $LaCo_{0,5}Ni_{0,5}O_3$ previosuly reduced and passivated at 500°C perovskites in the HDO of m-cresol is reported.

**Experimental/methodology.** The pure and substituted perovskites were synthesized using the citrate method and characterized by X-Ray diffraction (XRD), $N_2$ physisorption at 77 K, thermal programmed reduction (TPR $H_2$) and thermal programmed desorption of $CO_2$ (TPD $CO_2$).The catalytic activity was evaluated in a semi-batch reactor in the m-cresol HDO reaction at 200°C and 50 bar of $H_2$ using the previously reduced catalysts.

**Results and discussion.**

The characterization results show that after reduction the $LaFeO_3$, $LaFe_{0.5}Co_{0.5}O_3$ and $LaFe_{0.5}Ni_{0.5}O_3$ perovskites did not show reduction of the structure, while the formation of metallic Co and Ni was found in the $LaCoO_3$, $LaNiO_3$ and $LaCo_{0.5}Ni_{0.5}O_3$ perovskites. With regard to the basic properties, in the reduced and passivated perovskites only the $LaCoO_3$, $LaNiO_3$ and $LaCo_{0.5}Ni_{0.5}O_3$ show basic sites formation. The $LaFeO_3$, $LaFe_{0,5}Ni_{0,5}O_3$ and $LaFe_{0,5}Co_{0,5}O_3$ did not present activity while the more active perovskite was $LaCo_{0,5}Ni_{0,5}O_3$ (Table) atributed to presence of Co and Ni metallic species which are active in the m-cresol conversion. The principal product detected on the active perovskites, with no Fe content in the B or B´cation was 3-methylcyclohexanol (3-MCXol) indicating that over these catalysts the reaction occurs by direct hydrogenation of the aromatic ring to 3-methyl-2-cyclohexenol (no detected) which is full hydrogenated to (3-MCXol). By tautomerization, 3-MCXol is converted in low amount to 3-methylcicloxenanone (3-MCXone), which is asocciated to the presence of basic sites. This route have been reported prevously, were is proposed that hydrogenation mechanism is atributed to presence of less oxophilic catalysts [4,5]

| Perovskite | Initial rate $r_0*10^4$ (mol/g*s) | Distribution of products at 40 % of m-cresol conversion | | | | |
|---|---|---|---|---|---|---|
| | | 3-MCXol | 3-MCXone | Others | Phenol | Toluene |
| $LaCoO_3$ | 18.9 | 85.4 | 4.2 | 8.1 | 3.2 | 2.0 |
| $LaNiO_3$ | 4.4 | 82.5 | 13.5 | 11.7 | 3.4 | 1.4 |
| $LaCo_{0,5}Ni_{0,5}O_3$ | 26.5 | 85.4 | 4.3 | 8.1 | 3.2 | 2.0 |

**Keywords:** heterogeneous photocatalysis, plasmonic catalysts, titanium nanorods, wastewater treatment

**Introduction.**
$TiO_2$ is one of the most studied catalysts for heterogeneous photocatalytic oxidation of organic pollutants dissolved in wastewaters, due to its strong oxidizing power, non-toxicity, long-term photostability, chemical stability, low cost, and insolubility in water. However, its inability to absorb light in the visible-light range severely limits its practical application. One way to overcome this disadvantage of $TiO_2$ is to combine it with noble metals (Au, Ag, Pt, etc.). The plasmonic properties of noble metals allow $TiO_2$ to have catalytic activity in the visible-light region. Therefore, there is a great interest in further research of $TiO_2$-based catalysts doped with noble metals to promote heterogeneous photocatalytic oxidation of organic pollutants in wastewaters under visible-light illumination [1,2]. The purpose of this work is to systematically investigate an influence of morphological and surface properties on performance of Au-$TiO_2$ catalysts in the process of visible-light trigerred photocatalytic oxidation of water-dissolved organic pollutants.

**Experimental/methodology.**
In this study, Au-$TiO_2$ catalysts were prepared using different $TiO_2$ supports. First, different $TiO_2$ nanorods (TNRs) were synthesized by alkaline hydrothermal synthesis, differing in their surface and structural properties. Once the TNRs were obtained, wet impregnation followed using an aqueous solution of $HAuCl_4 \cdot 3H_2O$ to infiltrate the TNRs with gold nanoparticles. Finally, calcination at 300 °C resulted in $TiO_2$ TNRs doped with elemental Au. Au-$TiO_2$ catalysts were further characterized using X-ray diffraction, SEM, $N_2$ physisorption, UV-VIS diffuse-reflectance (DR) spectroscopy, zeta potential, and solid-state photoluminescence (PL) techniques.

**Results and discussion.**
Different synthesis conditions allowed us to obtain TNRs with zeta potential between 3.9 and 5.9, and specific surface area ($S_{BET}$) between 87 and 111 $m^2/g$. The thermal stability of all the TNRs thus obtained was unchanged up to 300 °C, so calcination was performed at this temperature to obtain Au in the desired oxidation state. UV-VIS DR spectra show an additional absorption peak at approx. 550 nm, attributed to the presence of localized surface plasmon resonance (LSPR) effect, while solid-state PL spectra show the influence of the Schottky barrier at the $TiO_2$ support/Au ensemble junction on the rate of recombination of charge carriers. Both analyses confirmed the VIS activity of synthesized Au-$TiO_2$ catalysts. Several tests were performed with scavengers, such as ABTS and DPPH to investigate the production of “hot electrons” and reactive oxygen species. In addition, the photocatalytic activity of examined solids was evaluated using coumarin as a fluorescence probe molecule to selectively determine their ability regarding the formation of hydroxyl radicals. Catalytic tests with water-dissolved model organic pollutants (such as bisphenol A) and characterization using XPS and TEM analyses are in progress.

# Rationally designed bifunctional catalyst with metal incorporated core-shell silicalite-1 architecture

Urvashi Sharma[1†], Manjesh Kumar[1‡]

[1]*Department of Chemical Engineering, Indian Institute of Technology Delhi, New Delhi, India*
‡*manjeshkumar@chemical.iitd.ac.in,* †*urvashi.sharma@chemical.iitd.ac.in*

**Keywords:** Metal nanoparticle and cluster, core-shell zeolite, bifunctional catalyst

**Introduction.** A promising category of catalysts for a wide range of organic reactions and gas separation applications is represented by zeolitic frameworks loaded with diverse metal sites [1]. However, there are significant challenges to address, including diffusion limitations, catalyst lifetime, instability under harsh reaction conditions, and poisoning due to byproducts [2]. In this study, we present viable and environmentally friendly synthetic methods to create a bifunctional catalyst. This catalyst exhibits controlled topological distribution of metal sites and a core-shell architecture, effectively overcoming diffusion limitations. Our research offers valuable insights into the design of bifunctional catalysts with desired physicochemical properties, providing enhanced lifetime and activity.

**Experimental/methodology.** To obtain silicalite-1 crystals, a silica source combined with an alkaline structure directing agent (SDA) was stirred at room temperature, resulting in the formation of a viscous gel. The gel was then subjected to hydrothermal treatment within the temperature range of 100 to 200°C for a duration of 24 to 96 hours. This process yielded the desired silicalite-1 crystals. Subsequently, the obtained product underwent thermal treatment in an aqueous alkaline solution to achieve hollow zeolite crystals. To incorporate metal clusters and nanoparticles into the core-shell structure of silicalite-1, the metal complex was reacted with silicalite-1, enabling the integration of the metal clusters within the core-shell zeolite.

**Results and discussion.** Treatment of silicalite-1 with alkaline solution results in the formation of core-shell crystals, where the thickness of the shell ranges from 10 to 100 nm. For enhanced catalysis and stability, synthesizing core-shell zeolite crystals is highly desirable. We explored the new synthetic protocols here for obtaining silicalite-1 hollow crystals incorporated with metal clusters of Pd and Ag. Here, figure 1 (A), (C) and (F) show the hollow zeolite crystals with metal nanoparticles of size 2 to 10 nm inside the hollow domain. Whereas, figure (B), (D) and (E) shows that the small nanoparticles of the metal are dispersed on the surface of zeolite crystal. Similar trends are observed in the both the metals. We carried out numerous synthetic protocols to generate the zeolite crystals with controlled topological distribution of metal sites. The mechanistic studies and the detailed analysis results will be presented at the conference.

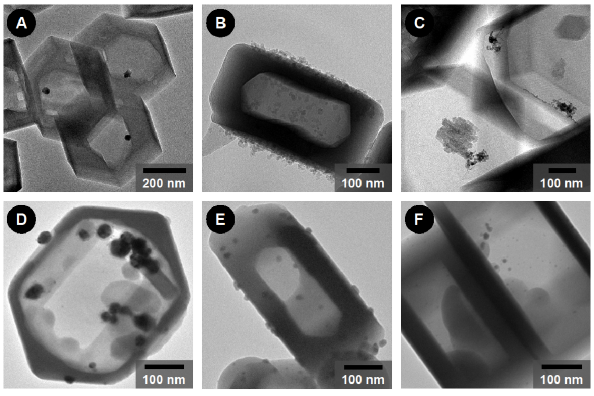

**Figure 1:** TEM images of the samples (A) Pd loaded silicalite-1 synthesized using a single step route, (B) Pd loaded silicalite-1 synthesized using a two-step route, (C) Pd loaded silicalite-1 synthesized using in- situ process, (D) Ag loaded silicalite-1 synthesized using a single step route, (E) Ag loaded silicalite-1 synthesized using a two-step route, (F) Ag loaded silicalite-1 synthesized using in-situ process.

**Keywords:** $CO_2$ hydrogenation, methanol synthesis, metal-support interface, heterogeneous catalysis, gas-phase clusters

**Introduction.** Supported Pd nanoparticles have demonstrated promising catalytic activity for the hydrogenation of $CO_2$ into methanol but the nature of the metal-support interface and its role in the reaction mechanism remains a topic of ongoing research [1-3]. We have produced model catalysts by depositing well-defined Pd and PdZn clusters directly onto ZnO and $SiO_2$ powders using the Cluster Beam Deposition (CBD) technology. Well defined Pd and PdZn catalysts will facilitate the investigation of the Pd-Zn and Pd-ZnO interface to unravel their structure-activity relationship.

**Experimental/methodology.** Pd and PdZn clusters of different compositions were produced in high vacuum using a magnetron sputtering-based CBD at Teer Coatings Limited, UK and deposited onto one gram of each pre-dried oxide powder placed in a vibrating cup for uniform deposition of size-controlled clusters containing 500 to 700 atoms. 0.1 wt% Pd clusters loading on oxide powders was confirmed using ICP-OES and the size of clusters deposited on TEM grid was found to be 3-4nm (figure 1). The samples were activated *in situ* in pure hydrogen at 120°C for 30 minutes before catalytic tests. Catalytic activity tests for $CO_2$ hydrogenation were performed at 210°C and 40 bar on 0.4 g of each sample loaded in a plug flow reactor in a 5 mL/min feed gas of $3H_2$:$1CO_2$.

**Results and discussion.** A very small concentration of Pd clusters (0.1wt%) on ZnO is found to promote the $CO_2$ hydrogenation to methanol and CO while only a very small activity is observed for $Pd/SiO_2$. A four-time increase of the $CO_2$ hydrogenation rate compared to sum of blank ZnO and $Pd/SiO_2$ is reported in Figure 1, confirming the excellent Pd-ZnO synergy in these model catalysts.

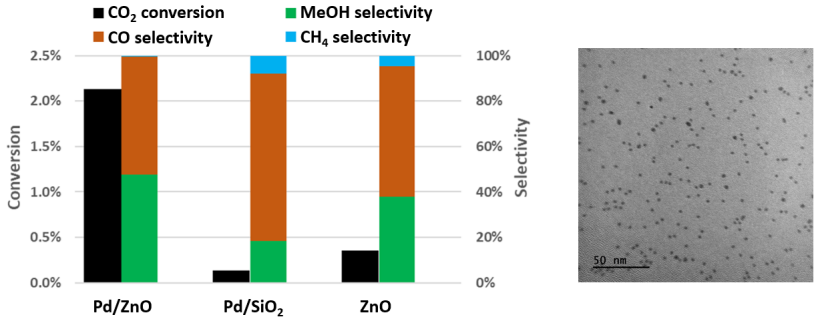

**Figure 1: (left)$CO_2$ conversion and product selectivity at 210°C ; (right) Image of $Pd_{604}$ clusters on a TEM grid.**

To investigate further the Pd-ZnO synergy and uncover structure-activity relationship, detailed structural investigation of Pd clusters on ZnO and PdZn clusters on $SiO_2$ under $CO_2$ hydrogenation conditions will be performed using in situ X-ray absorption spectroscopy and correlated to the catalytic activity.

# Non-oxidative Propane Dehydrogenation using Precious Metal-Free Chloride-Treated Metal Oxides

G. Celik[1*] and A. Bouziani[1]
[1]*Department of Chemical Engineering, Middle East Technical University, Ankara, Turkey*
[*]*gcelik@metu.edu.tr*

**Introduction.** Propylene production from nonoxidative dehydrogenation of propane (NPDH) is a well-recognized process. Yet, some downsides including toxicity of chromium and high-priced and low abundance platinum still need to be overcome. Metal oxides such as $TiO_2$-based or $ZrO_2$-based catalysts are promising alternatives having distinct bulk defects. For $ZrO_2$ based metal oxides, the literature has established that two neighboring coordinatively unsaturated Zr cations ($Zr_{cus}$) situated at the oxygen vacancies (OVs) are the active sites responsible for activating the C-H bonds of propane[1]. Regarding $TiO_2$, It was reported that the fourfold-coordinated Ti atoms surrounding oxygen vacancies (OVs) are the main active sites for PDH[2]. Hence, the OVs and defects are vital for the high activity of these metal oxides. Herein, we propose a chloride treated $ZrO_2$ (Cl-$ZrO_2$) $ZrO_2$ and (Cl-$TiO_2$) catalysts for the nonoxidative alkane dehydrogenation. Theoretically, the incorporation of anion into an oxide will lead to an increase in the surface basicity[3] and anions situated at the site of oxygen may generate more lattice defects, enhancing the activity of gaseous reactants and repressing deep dehydrogenation[4].

**Experimental/methodology.** Metal oxides were synthesized via sol-gel technique. HCl (1M, 4mL) was used as the $Cl^-$ source. The obtained catalysts were characterized by X-Ray Diffraction (XRD), laser Raman spectroscopy, X-ray photoelectron spectroscopy (XPS), $N_2$-physisorption, desorption of propene with diffuse reflectance infrared Fourier transform spectroscopy (DRIFTS), and DRIFTS of adsorbed $CO_2$. Finally, the Cl-$ZrO_2$ was tested for propane and n-butane nonoxidative dehydrogenation at 550°C.

**Results and discussion.** The characterization results showed that the chloride treatment resulted in changes of crystal phase, surface area, acidity and basicity. After the treatment, the $ZrO_2$-based catalysts had chloride doped into the structure and no detectable change in number of OVs, whereas $TiO_2$-based catalysts no chloride was found in the $TiO_2$ based catalysts. Interestingly, chloride treatment did not cause chloride doping, but increased the number and nature of oxygen vacancies. The type of OVs created by chloride treatment over $TiO_2$ was shown to be different and more active than the ones created by in-situ reduction under $H_2$, as evidenced by EPR and Temperature Programmed Reduction of CO, respectively. Furthermore, the DRIFT spectra taken after $C_3H_6$ adsorption displayed a weaker interaction of propylene with the catalyst surface after chlorine addition (Figure 1). Hence the desorption of propylene from Cl-$ZrO_2$ seen in TPD experiments was easier and may prevent undesired deep-dehydrogenation. The chloride treated catalysts improved the catalytic activity (more than three times per site) and improved the selectivity to ~99%. In conclusion, the results showed that chloride treatment of metal oxides during synthesis allowed us to tune important catalyst attributes such as basicity and desorption tendency of propylene, consequently altering its catalytic activity and preventing deep dehydrogenation in the nonoxidative dehydrogenation of alkane.

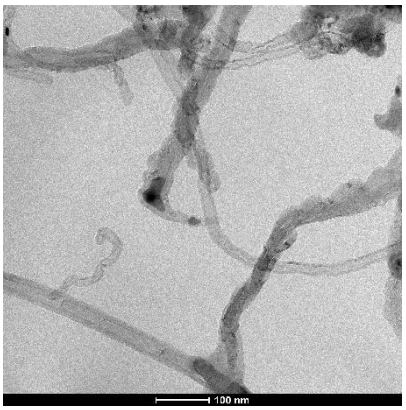
# Iron-based catalyst for production of hydrogen and CNTs through the catalytic decomposition of methane



S. Shekhar[1], K.K. Pant[1*], S. Roy[1], R. Joshi[2]
1.Department of Chemical Engineering, Indian Institute of Technology, Delhi, India
2.School of Materials Science & Engineering, University of New South Wales, Sydney, Australia

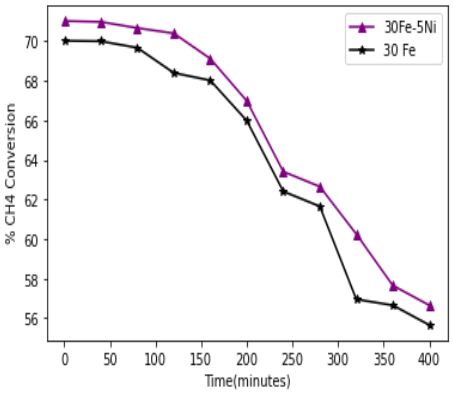
**Keywords:** Hydrogen, Catalytic decomposition of Methane (CDM), CNTs



**Introduction.** The promising technique of catalytic decomposition of methane (CDM) aims to produce hydrogen and valuable byproduct like CNTs without releasing greenhouse gas emissions [1]. However, a significant challenge in making this process commercially viable is the development of an appropriate catalyst that can maintain long-term stability, exhibit strong catalytic activity and be cost-effective. Nickel is the best catalyst for this process [2], but due to the rapid decomposition of nickel it is not suitable for the long run. Since iron-based catalysts performance is comparable with Ni catalysts because, Fe catalysts can survive temperatures of 700 °C and above, it is possible to achieve larger methane conversions with them than with Ni catalysts, leading to a favorable shift in the equilibrium. On the other side, greater temperatures hasten the catalyst's deactivation [3].

**Experiment /methodology.** Using incipient technique, monometallic and bimetallic catalysts were made, containing 30 wt% metal of Fe, 25Fe:5Ni. The calculated quantity of spherical Alumina (100–150 mesh) was dissolved in the metal salt solution that had already been prepared. Before the water was removed by rotary vacuum evaporation, the produced slurry was constantly agitated for two hours. The slurry was then put in the oven to dry for an entire night at 120°C. The resulting cake was then calcined in the furnace for 5 hours at a ramp rate of 3 °C/min from ambient temperature to 750 °C. Before each reaction, the catalyst was reduced in-situ using hydrogen and nitrogen gas (1:1 by volume) at a total flow of 40 mL/min at NTP.

**Results and discussion.** The experimental findings of methane conversion are shown in fig. The reaction was conducted at 800°C and an atmospheric pressure while the feed was kept at 4,000 mL $h^{-1}$ $g^{-1}$ cat. space velocity.

TEM Image of CNT

Conversion of methane

The figure illustrates that the addition of nickel (Ni) resulted in a slight increase in the conversion rate. However, the significant finding from the Raman spectroscopic is the quality of carbon nanotubes (CNTs) produced. It is evident that increasing the nickel content enhances the quality of CNTs, as the $I_G/I_D$ ratio is improved.

# The Effect of Vanadium Substitution into Cobalt Oxide Catalysts for Selective 2-Propanol Oxidation

Hauke Scheele[1], Nicolas Cosanne[1], Sharif Najafishirtari[1], Malte Behrens[1*]
[1]*Christian-Albrechts-Universität zu Kiel, 24118 Kiel*
[*]*mbehrens@ac.uni-kiel.de*

**Keywords:** 2-Propanol oxidation, Spinel Oxide, Cobalt, Vanadium

**Introduction.** Selective oxidation of 2-propanol to acetone is a probe reaction for redox and acid-base properties[1] and cobalt oxide with spinel structure showed high catalytic activity.[1] During the heating phase of a transient test, a first maximum of 2-propanol consumption rate was observed, i.e. a low-temperature channel, and attributed to $Co^{3+}$.[1] This maximum is not present during cooling due to poisoning by carbonaceous species like acetates and reduction of $Co^{3+}$ to $Co^{2+}$.[1,2] In this work, we studied the effects of partial substitution of the catalytic active $Co^{3+}$ ions by $V^{3+}$ on the catalytic behavior.

**Experimental/methodology.** The precursors were synthesized through the hydrothermal method and subsequently thermally decomposed to the spinel oxides in a muffle furnace at 400 °C under air atmosphere. 2-Propanol oxidation was carried out on the catalysts (100 mg, 250-355 µm) in a home-build setup with 0.18 % 2-propanol + 0.18 % $O_2$ balanced in nitrogen as dry feed gas or with the addition of 2 % water as wet feed after an oxidative pretreatment (TPO @ 300 °C) between the dry and wet runs.

**Results and discussion.** Needle-shaped cobalt hydroxycarbonate precursors $Co_6(CO_3)_2(OH)_8 \cdot H_2O$ were synthesized and calcined to the spinels with various V contents. EDX mapping shows a homogeneous distribution of Co, V and O, but with increasing V content, a crystalline $Co_3V_2O_8$ by-phase was obtained. Calculated from Pawley Fits, the spinel lattice parameter increases with V content, indicating the incorporation of V into the spinel structure. Within the selective catalytic oxidation of 2-propanol, the pure $Co_3O_4$ spinel shows the typical behavior as reported in the literature.[1] If V is present, the increase of the 2-propanol consumption rate changes significantly (Figure 1 a & d). During heating, there is a sigmoidal increase directly to the maximum without a distinct low-temperature path. Contrary to $Co_3O_4$, the acetone formation does not follow the 2-propanol consumption trend (Figure 1 b & e) but shows a maximum at around 200 °C. The acetone formation peak reappears during cooling, which is, however, shifted to higher temperatures. Above temperatures of 150 °C, propene is formed in significant amounts and becomes the main product at high temperatures (Figure 1 c & f). The propene formation indicates an acidic surface which is here introduced by the V sites. When water is present, propene formation is suppressed due to the competitive adsorption of water on these acidic sites. The incorporation of V in $Co_3O_4$ spinel thus offers a tool to tune the distribution of acidic sites affecting the selectivity.

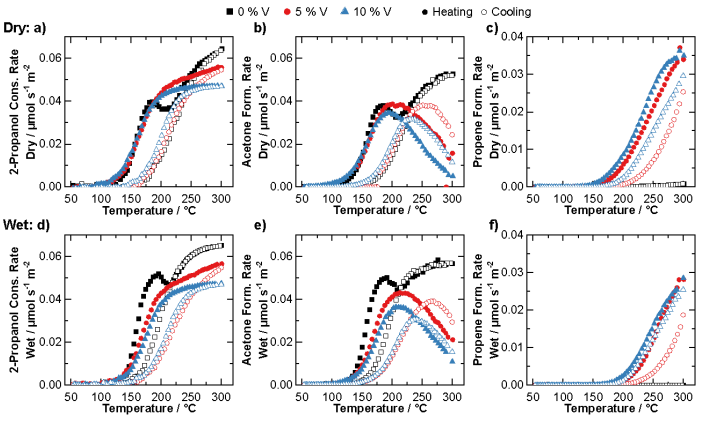

**Figure 1: Trends in 2-propanol consumption (cons.), acetone and propene formation (form.) rates with V-doping in selective catalytic 2-propanol oxidation in dry feed (a-c) and wet feed (d-f).**

**Keywords:** nanoparticle and cluster synthesis, noble metals, model catalysts, catalyst design, CO oxidation, exhaust gas treatment, continuous flow synthesis

**Introduction.** Nanosized transition metal particles are important materials in catalysis with a key role in academic research and in many industrial processes [1]. Pd- and Pt-based nanoparticles (NPs) supported on various metal oxides have been extensively employed as catalysts for various reactions, including emission control [2-4]. Due to their importance, there is a constant interest in optimizing their performance and reducing the noble metal loading. For their further development, relationships between catalyst structure and activity can only be revealed by studying well-defined catalysts. In the present study, mono- and bimetallic NPs with a narrow size distribution are prepared and used as precursors for catalysts in the oxidation of CO.

**Experimental/methodology.** The liquid-phase synthesis of well-defined, mono- and bimetallic NPs (Pt/Pd) is addressed in both batch and continuous processes. To prepare powder model catalysts, the particles are subsequently deposited on ceria. The NPs and catalysts are characterized, e.g. by electron microscopy (SEM, TEM, HAADF-STEM with elemental EDXS mapping), dynamic light scattering and atomic emission spectroscopy. The catalytic performance is investigated in CO oxidation, which is performed in a turbular reactor with a gas flow rate of 1 L $min^{-1}$ of 1000 ppm CO and 8 % $O_2$ in $N_2$ [5].

**Results and discussion.** The Pd- and Pd-Pt NPs were spherical and monodisperse and uniformly distributed on the $CeO_2$ support (Figs. 1a, b and c). In general, different CO oxidation activity profiles were obtained for the mono- and bimetallic catalysts. For monometallic Pd-based catalysts, containing noble metal NPs of about 5-6 nm, the light-off temperature for CO oxidation was around $T_{50}$~120 °C (Fig. 1c), while the bimetallic catalyst showed a lower light-off temperature. Additionally, the systematic investigation of such powder model catalysts with defined size, shape, and composition revealed high stability for all prepared catalysts during consecutive CO oxidation cycles (see Fig. 1c)

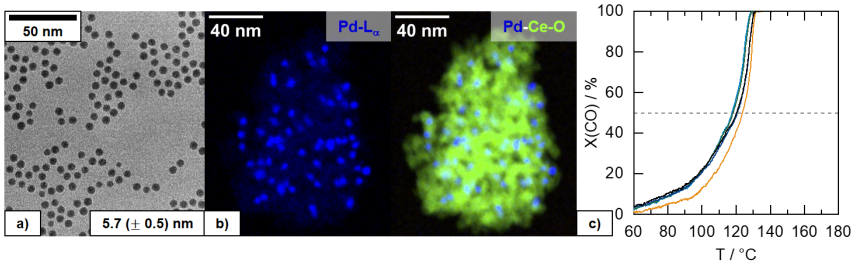

**Fig. 1:** a) TEM micrograph of Pd NPs; b) elemental EDS mapping of Pd and Ce and c) consecutive light-off curves of the $Pd/CeO_2$ catalyst during CO oxidation (1 L·$min^{-1}$; 1000 ppm CO; 8 % $O_2$ in $N_2$).

# Tandem Mixed-Metal Oxides/Zeolite Catalysts for $CO_2$ Utilization

C. Schroeder,[1] M. Palma,[1] N. Barrabés,[2] M. Sánchez-Sánchez[1],*

[1]*Institute of Chemical, Environmental and Bioscience Engineering, TU Wien, Austria*

**Introduction.** Direct catalytic $CO_2$ conversion into key chemicals is a promising field of research for sustainable processes. However, limitations exist for $CO_2$ utilization, i.e., its high activation energy. Tandem catalysts based on mixed metal oxides combined with zeolites ($MO_x$/zeolite) are suitable to combine $CO/CO_2$ hydrogenation on the metal/metal oxide function with the size selective C-C coupling catalyzed by acid sites within the zeolite micropores to produce highly demanded olefins.[1] In this work, we investigate the activation of $CO_2$ on selected $MO_x$/zeolite materials by testing their activity on the $CO_2$ conversion by reverse water gas shift reaction (rWGS, $CO_2 + H_2 \rightarrow CO + H_2O$). Oxygen vacancies on mixed-metal oxide surfaces are proposed to be relevant for the activity in both rWGS and $CO_2$ hydrogenation, therefore, we use the rWGS reaction as a proxy to evaluate the potential of the material for the tandem conversion of $CO_2$ into light olefins.

**Experimental/methodology.** Tandem $CuCeZrO_x$/SSZ-13 and $CuCeZrO_x$/ZSM-5 catalysts are either prepared by incipient wetness impregnation (IWI), or by co-precipitation (CP) in presence of sodium oxalate to prevent $Cu^{2+}$ introduction in the micropores of the zeolite. Catalysts are then analyzed by X-ray fluorescence spectroscopy (XRF), X-ray diffraction (XRD), and temperature-programmed reduction (TPR) to assess loading, dispersion, and redox properties of Cu species. The kinetics of rWGS on the catalytic materials is investigated at a $H_2$:$CO_2$ ratio of 4:1, adequate for the overall syn-gas to olefins conversion, in a lab-scale differential reactor. On-line gas analysis is performed with gas chromatography.

**Results and discussion.** Reaction rates for rWGS reaction are roughly doubled when the oxides are supported on the zeolites. Characterization by TPR shows that peak reduction temperatures are generally lowered by 10 to 90°C for $CuCeZrO_x$ supported on zeolites compared to unsupported $CuCeZrO_x$ (220°C), which indicates more easily reducible Cu as a result of higher dispersion and support interactions.[2] For catalysts synthesized by IWI, peak reduction temperatures are lowered down to 100-140°C, while also a large portion remains oxidized even at 400°C, which is attributed to ion-exchanged $Cu^{2+}$ on zeolite acid sites.[3] Oxalate in the co-precipitation method successfully prevents $Cu^{2+}$ ion exchange at the expense of higher peak reduction temperatures. We have observed a correlation between reducibility of Cu species and activity for rWGS, even though, at the reaction conditions in $H_2$-rich atmosphere, Cu species are stable in metallic state. This suggests that the nature of interaction of Cu with the $CeZrO_x$ and zeolite supports have an effect in the generation of active sites for rWGS.

In conclusion, directly supporting $CuCeZrO_x$ on zeolites significantly boosts activity for rWGS compared to unsupported $CuCeZrO_x$. Although catalysts by IWI show the highest activity per Cu in this study, catalysts synthesized by oxalate co-precipitation are expected to perform better in the tandem conversion of $CO_2$ and CO into light olefins, because the acid sites of the zeolite are not affected by Cu in the micropores.

# Influence of Oxidative Fluorination on Cu/ZnO Methanol Catalysts for Carbon Dioxide Hydrogenation

H. Schuster[1*], I. Krossing

[1]*Materials Research Center, University of Freiburg, Germany*
[2]*Institute of Inorganic and Analytical Chemistry, University of Freiburg, Germany*
[*]*henrik.schuster@fmf.uni-freiburg.de*

**Keywords:** heterogeneous catalysis, methanol synthesis, $CO_2$ conversion, fluorination

**Introduction:** Ongoing global warming and abandonment of fossil fuels and feedstocks require a restructuring of the energy carrier profile. Using Cu/Zn synergism[1], catalysts can be developed that are suitable for converting the greenhouse gas carbon dioxide $CO_2$ and hydrogen $H_2$ into methanol MeOH, with perspective to a sustainable $CO_2$ cycle. Methanol has a wide range of applications, as it is an excellent platform chemical (for *e.g.* formaldehyde) as a C-source.[2] Furthermore, oxidative fluorination is used in the research group of Prof. Krossing to increase activity for methanol synthesis from $CO_2$ and $H_2$.[3]

**Experimental/methodology:** Oxidative fluorination was used to synthesize a series of precatalysts differing in their synthesis conditions and resulting fluoride content. Properties of the catalysts were studied by infrared spectroscopy IR, thermogravimetric analysis TGA, ion chromatography IC, powder diffraction pXRD and surface area quantification method $N_2$ physisorption. To determine the activity of the catalysts, the catalysts were activated with $H_2$ and subsequently feedgas $CO_2$ and 3 $H_2$ were fed at 210 to 270 °C at 40 bar. Catalysis products were quantified by gas chromatography GC. In addition, feed gas composition was varied between gas mixtures of CO/2 $H_2$ and $CO_2$/3 $H_2$ to investigate feed gas compatibility of the catalysts.

**Results and discussion:** Investigation by TGA and IR particularly show that oxidative fluorination has effects on high-temperature carbonates. Fluorination corresponds to a chemical calcination, the metal carbonates thereby form metal fluorides by release of $CO_2$ and $O_2$. pXRD patterns of the highly fluorinated systems show more crystalline phases than those of low or non-fluorinated precatalysts. Fluorination leads to the formation of more active sites on the catalyst surface and significantly increases the catalysts activity.[3] Furthermore, the selectivity for $CO_2$-to-MeOH conversion is increased, supporting the revolution from fossil sources (CO-to-MeOH) to recycling of $CO_2$.

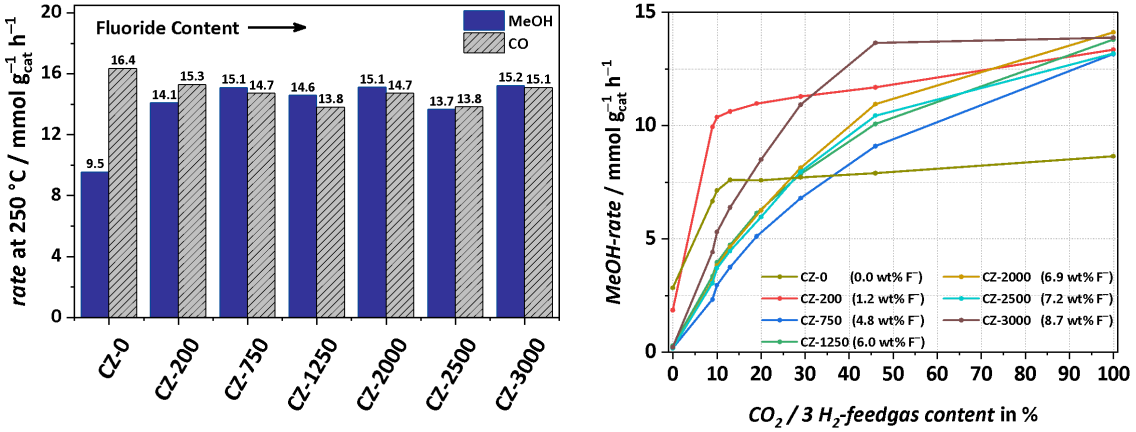

**Figure 1: Catalyst testing of fluorinated catalysts. On the left side, catalyst testing has been carried out at 250 °C, 40 bar and 33 mL min$^{-1}$. On the right side, feedgas composition was varied from 100 % $CO_2$ / 3 $H_2$ to 100 % CO / 2 $H_2$ at 250 °C, 40 bar and 33 mL min$^{-1}$ flow rate.**

**Keywords:** hydroisomerization catalyst, β-zeolite, fuel upgrading

**Introduction.** Finding an alternative fuel source to crude oil is a worldwide discussed topic.[1] Fischer-Tropsch (FT) process grants a route from carbon-rich solids to high-quality liquid fuel.[2] The drawback of FT process is a wide distribution of hydrocarbons chains length. The FT middle-distillate could be used as a diesel fuel; however, it contains high percentage of linear paraffines solidifying at low temperatures and cause a problem for its application during the winter season.

The aim of the research was finding a suitable catalyst that partially converts FT middle-distillates long-chained *n*-alkenes into branched *iso*-alkenes with limited hydrocracking. The desired upgraded product is characterized by improved cold flow properties (decreased CFPP value) and preserved cetane number above the standardized parameters.

**Experimental/methodology.** Serie of bifunctional catalyst samples based on a commercial β-zeolites and 0.5 % Platinum was prepared. The process of dealumination was applied on selected zeolites to adjust the silica-alumina ratio (SAR) and enhance the porous structure. Catalytic hydroisomerization testing was performed in a fix bed continuous flow reactor at constant WHSV and hydrogen flow. The effect of wide temperature range was investigated, followed by the evaluation of the optimal conditions for each catalyst sample.

**Results and discussion.** The goal of the project, to optimize CFPP value (up to -40 °C) of the fuel, was reached for several new catalysts.

**Keywords:** copper nanoparticles, aluminium oxide, catalytic combustion, propane

**Introduction.** The total combustion of volatile organic compounds is the most effective way to reduce their emission into the atmosphere. For this reason, the studies of the catalytic combustion of model compounds such as propane over economically and energetically inexpensive catalysts have also received considerable attention in green chemistry. In this regard, copper-based catalysts showed remarkable activity in the combustion of methane[1] and toluene[2]. In this work, the performance of two catalysts based on copper nanoparticles (Cu NPs) dispersed on nano, and bulk powder alumina supports in propane combustion to $CO_2$ was studied.

**Experimental.** The catalysts used for this study were prepared via wet impregnation of Cu NPs at 3 wt. % Cu loading on substrates of nano-$Al_2O_3$ (30-60 nm) and $Al_2O_3$ powder with pore size 580 nm. The prepared catalysts are therefore named Cu/nano$Al_2O_3$ and Cu/$Al_2O_3$, respectively. The catalysts were characterised *ex-situ* with TEM, SEM and EDX before and after the catalytic test, AAS was performed on the as-made catalysts. The catalysts were tested in a quartz plug-flow reactor using PID Microactivity Set-up equipped with GC for the on-line detection of the products. The reactant mixture of propene and $O_2$ diluted in He was introduced at atmospheric pressure.

**Results.** Fig.1 shows TEM micrographs of as-made catalysts, their conversion and corresponding selectivities during propane combustion. Cu NPs, around 4 and 8 nm in diameter, were dispersed on nano$Al_2O_3$ and $Al_2O_3$ supports, respectively. Both catalysts Cu/nano$Al_2O_3$ and Cu/$Al_2O_3$ produce mainly $CO_2$ and propene, with the fraction of the latter dropping fast with increasing temperature, and Cu/nano$Al_2O_3$ showing both higher conversion as well as higher combustion to $CO_2$ in comparison with Cu/$Al_2O_3$. Small amounts of ethane and ethylene were observed at 550 °C, with approximately 2 % methane and 3 % ethylene on Cu/nano$Al_2O_3$, and 2 % methane and 6 % ethylene on Cu/$Al_2O_3$.

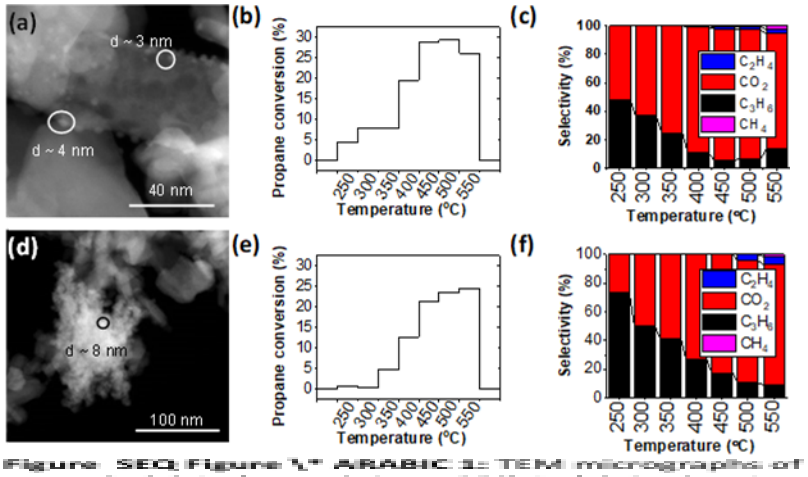

Figure SEQ Figure * ARABIC 1: TEM micrographs of as-made (a) Cu/nano$Al_2O_3$ and (d) Cu/$Al_2O_3$ showing the Cu NPs, and their (b,e) conversion and (c,f) selectivity.

**Keywords:** catalytic oxidation of *n*-octane, ON bidentate ligands, crystal structures

**Introduction.** One of the most challenging areas of catalytic research in both academia and industry is the direct functionalization of C-H σ bonds of chemically inert linear alkanes[1-2]. Selective oxidations of linear alkanes is at the forefront of research to catalitically convert linear alkanes to value-added products. Biocatalytic systems, such as the heme-based cytochrome $P_{450}$, exhibit substrate specificity, regio and stereo selectivity and operate under mild conditions [3]. These systems have served as biomimetic inspiration for homogeneous catalytic selective oxidation of *n*-octane. In this study pyridinyl alcoholato ligands were coordinated to Ru and Cu and employed as catalysts in the oxidation of *n*-octane. Pyridinyl alcoholato ligands are bidentate ligands that bind to the metal centre via N and O donor atoms with the deprotonation of the O atom. This ligand imparts strong donor properties that can stabilize high oxidation states of metals and prevent ligand decomposition. These ligands can withstand harsh oxidizing conditions because they are tertiary alcohols[4-6].

**Experimental/methodology.** The combination of a solution of the respective ON ligands, in methanol with a solution of either copper or ruthenium chloride in a mixture of methanol and acetone resulted in the formation of neutral complexes, shown in scheme 1.

Scheme 1: The synthesis and coding of ON complexess

**Results and discussion.** The synthesised complexes were fully characterised. In the selective oxidation of *n*-octane the ruthenium complexes gave yields of 2-7 % to C8 oxygenates in 6 hours and selectivities of up to 70 % to C1-C4 alcohols, with $H_2O_2$ as oxidant. The copper catalysts gave yields up to 25% with predominant selectivity to C2-C4 ketones.

**corresponding author: omvir10011995@gmail.com, bsarkar@iip.res.in,*

**Keywords:** Renwable aromatics, composite, zeolite, MOF.

**Introduction**

Aromatic production using bio-derived alcohols is desirable for various reasons. BTX from bio-derived alcohols is indistinguishable from traditional sources; therefore, the demarcation of end products is not required. In addition, the production of $C_2$–$C_5$ alcohol through sugar fermentation is high and continuously growing worldwide.1 Therefore, producing BTX from these alcohols provides a sustainable approach to promoting domestic resource consumption and foreign energy independence.

In this study, we designed a Zn-based MOF-zeolite composite by using an IRMOF-1 with a typical formula of Zn4O(BDC)3 and MFI type zeolite ZSM-5. The hybrid composite prepared from ZSM-5 and IRMOF-1 exhibits an Al/Zn ratio of ∼4 showed a dual distribution of ZSM-5 particles of ∼40-80 nm encapsulated within the MOF matrix and ZSM-5@IRMOF-1 particles of ∼40-50 nm located on the external surface of the composite. This composite features a combination of Nano pores and mesoporous, which may accelerate the mass transfer to enhance the aromatic yield compared to commercial ZSM-5. Our adopted strategy enhanced the Lewis acidic sites dispersed Zn-MOF composites paves the way for their evaluation as a durable aromatization catalyst.

**Experimental/methodology.**

The ZSM-5@IRMOF-1 composite was synthesised using a double-solvent strategy, where Zn $(NO_3)_2 \cdot 6H_2O$ (0.78 g, 3 mmol) and 1,4-BDC (0.165 g, 1 mmol) were dissolved in DMF (2 mL) as precursors for IRMOF-1. Subsequently, ZSM-5 (0.1 g) was suspended in dry n-octane (20 mL) as a hydrophobic solvent, and the mixture was stirred for 30 min. The hydrophilic precursor solution (0.1 mL) was added dropwise for 30 min with vigorous stirring. The resulting solution was continuously stirred at 120 °C for 24 h. After the solution cooled to room temperature, the supernatant was removed, and the solid deposited at the bottom of the flask was collected. The solid obtained was washed with DMF and dried overnight at 120 °C. The activity of aromatisation reactions was investigated in a fixed bed and continues down-flow reactor. 1 g of the palletised catalyst (40–60 mess) was placed between SiC beds into the reactor at 250–350 °C. Isopropyl alcohol (IPA) (feed) was introduced using a syringe pump at a flow rate of 0.5–4 $h^{-1}$ (liquid hour space velocity, LHSV) and atmospheric pressure. The He gas was used as the carrier, and gas hour space velocity (GHSV) was maintained at 1200 $h^{-1}$. The product stream was separated through a glass condenser, and the gas was analysed using gas chromatography–refinery gas analyser (GC–RGA), Agilent Technologies equipped with an HP-PLOT Q column. Liquid hydrocarbons were analysed using the detail hydrocarbon analysis (DHA), Varian Inc., according to the ASTM D6730 test method.

**Results and discussion.**

Zn-composite materials and Zn-MOF have high surface area and coordinated unsaturated open metal sites, which may be useful for aromatisation. Table 1 presents the detailed product distributions of IPA to aromatics for different catalysts. In the presence of composite catalysts, aromatic hydrocarbons, mainly benzene, toluene, xylenes and ethylbenzene increased compared to Zn-supported ZSM-5 zeolite. This phenomenon may be correlated with the increase in the surface area, which can lead to the enhancement of metal dispersion on the catalyst surface. Another reason for enhanced aromatic selectivity may be the increased surface acidity with the modification of B/L ration caused by the replacement of BAS by Zn ions

(represents Lewis site) of MOF. Among these, Zn-composite provides the highest aromatic yield. Zn Comp. accounts for 92.3% conversion of IPA with 38.2% aromatic selectivity at 350°C, where the end product contain 4.8% benzene, 18.5% toluene, 11.3% xylene, and 3.6% EB.

Figure 1 presents the XRD patterns of IRMOF-1 (Zn-MOF), IRMOF-1@ZSM-5 (Zn-composite), and Zn-ZSM-5 (Zn/Z). The XRD patterns of crystalline IRMOF-1 shows the characteristic peaks at 2θ of $6.8^0$, $9.6^0$, and $13.7^0$ that corresponded to (200), (220), and (400) crystal planes. This observed pattern agreed with the XRD diffractogram of IRMOF-1 reported by Luan et al.2 The XRD pattern of ZSM-5 in Zn/Z shows peaks at 2θ of 7.9, 8.9, 15.2, 17.2, and 19.4 corresponding to (011), (200), (501), (422), and (133) planes, indicating the crystalline hexagonal symmetry framework of the zeolite (JCPDS no. 49-0657, 2002 database).3 ZnO peaks appearing at 2θ of 34.4, 36.2, and 47.5 correspond to the (002), (101), and(102) planes of the hexagonal framework (JCPDS no. 36-1451, 2002 database)4. Incorporation of IRMOF-1 crystals in the ZSM-5 matrix, the XRD pattern showed distinct characteristics of both IRMOF-1 and ZSM-5, indicating the co-existence of IRMOF-1 on ZSM-5 channels.

The Zn composite (Zn-MOF supported ZSM-5) appeared as raspberry-like particles, where the outer shell is covered with needle-like spikes. The raspberry-like composites with a diameter of 1–1.5 µm exhibit a fluffy appearance compared with the morphology of ZSM-5 described in our previous studies. The HR-TEM analysis revealed (Figure 2) the presence of inter-grown 2-dimensional crystals of MOFs with a highly ordered rod-like structure having the size of a few hundred nanometres. Rare particles with the hexagonal ZSM-5 morphology were scattered inside the cavity but were not found on the outer surface. The image shows unclear fringes, which resulted from the collapse of MOF crystals during irradiation with high-energy X-ray used in TEM. The double solvent strategy is effective in incorporating mesopores in Zeolite@MOF composites, resulting in hierarchal materials.

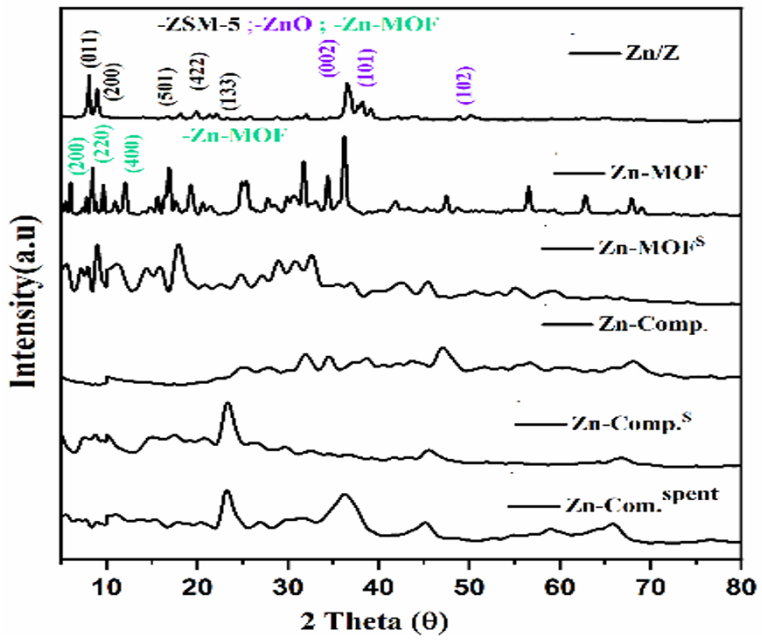

**Figure 1: Powder XRD pattern of Zn-ZSM-5, different Zn-MOF and Zn-composite catalyst**

**Reaction condition: Catalyst wt.-1 g (mesh size 50-70); reaction temp.-250-350°C; LHSV-2 $h^{-1}$; GHSV-1200 $h^{-1}$; time-after 6h**

In summary, a catalytic Zn-based MOF-zeolite composite with tunable acidity, pore structure and better stability established for the first time. Different zinc composite materials using Zn-MOF with various zeolites were prepared using the double-solvent strategy. The systematic distribution of Zn sites in the MOFs framework led to an increase in the metal dispersion of the composite material. This large amount of exchanged Zn2+ species in IRMOF-1 enhanced the stability of the Zn-composite and increased its Lewis acidity. With the desired acidity and pore geometry, the new composite was found very active for isopropyl alcohol to aromatics. Based on activity data, the relationship between the catalytic activity and the features of a distinct increase in BET surface area, surface acidity and distribution of active sites in the framework have been investigated systematically. We anticipate that highly dispersed Zn on the composite exhibited a higher cyclodehydrogenation activity through isopropyl alcohol protonation and showed better performance than zeolites or MOFs. The present study might cover a new research method on interdisciplinary for Zeolite@MOF composite and other applications of these composites such as hybrid catalysis and enhanced gas adsorption.

**Keywords:** Single atom catalysis; flow reactors; heterogeneous catalysis; process intensification

**Introduction.** In recent years, the merging of photoredox chemistry and transition metal catalysis has attracted the attention of a growing number of researchers [1]. Unfortunately, most of the homogeneous (photo)catalysts and photoactive complexes to conduct these transformations (i.e., Ir and Ru-based complexes) suffer from sustainability issues, such as difficult purification of the mixtures, materials toxicity and costs, and catalyst recyclability. To bypass these challenges, we report herein a heterogeneous single-atom catalyst, merging peculiar features of homogeneous and heterogeneous analogues. The catalyst features single-atom Ni on mesoporous carbon nitride (Ni@mpg$CN_x$) for the direct coupling of alkyl halides and α-aminoacids. The intrinsic features of our optimally designed microreactor ensure improved homogeneity of light irradiation, that is always an issue for batch photocatalyzed protocols due to the limited contact between light, reactants, and catalyst.

**Experimental/methodology.** The catalyst was prepared following a three-step procedure. In brief, cyanamide, LUDOXTM, and $NiCl_2$ were mixed. The obtained solid was heated at 550 °C for 4 h. For flow experiments, different reactor geometries have been adopted. The solution was pumped by a syringe pump into the reactor irradiated using the PhotoCube reactor, with varying residence time values. For the comparative photocatalytic batch reactions, the bromo-derivatives and α-aminoacid were mixed in MeCN solvent and irradiated with white LED light at 40 °C (Photoreactor, ThalesNano) under a $N_2$ atmosphere. Isolated products were analyzed by $^{1}H$ and $^{13}C$ NMR, while conversions were monitored via HPLC.

**Results and discussion.** The catalyst characterization has been performed by combining a battery of analytical techniques, which confirmed the single-atom nature of the material. The catalyst was first tested in batch mode for the coupling of alkyl halides with α-aminoacids, in order to conduct a systematic study, and rationalize the effect that the wavelength of light, type of base, and solvent have on the kinetics of the system. The key driver behind the implementation of continuous flow technologies was the need to allow for a uniform radiation distribution inside the reactor, as dictated by the Beer-Lambert Law, which would maximize the efficiency of the photochemical process. For this reason, the optimal reactor design was based on a packed-bed architecture, which allowed for: (i) increased surface area-to-volume ratio, to satisfy homogeneity in the photon distribution, (ii) immobilization of both the solid photocatalyst and the base, by plugging these materials within the irradiated reactor zone. The presence of packing material made of borosilicate glass beads were deemed essential for separating the catalyst particles from one another (and improve light absorption), while simultaneously not being able to compete for incident visible-light photons. Such design alterations to the reactor allowed for an improvement of 20-25% in isolated yield relative compared to batch operation. Time-on-stream analysis confirmed the stability of our reactor configuration, and of the catalyst activity, while a scaled-up experiment performed at optimized conditions (white LED, T = 40 °C, τ = 20 min), elucidated the robustness of our protocol, and allowed to synthesize gram amounts of precursor compounds that have a direct relevance to the pharmaceutical industry.

**Keywords:** Ni-Co-Mn mixed oxides, sol-gel, supported catalysts

**Introduction.** Transition metals-containing oxides are widely used in heterogeneous catalysis as catalysts for various reactions such as dehydrogenation, selective oxidation, selective reduction, removal of volatile organic compounds (VOC) and electrocatalysis [1]. The performance of metal oxide-based catalysts depends on the methods and conditions of preparation. The sol-gel reaction is advantageous for the preparation of mixed oxide coatings combining various catalytically active components. The process involves the formation of a stable colloidal suspension (sol) by hydrolysis and partial condensation of reactants to form metal-oxygen-metal bonds [2]; products with a fine and homogeneous distribution of components are formed. The prepared sol can be deposited on substrates to obtain supported catalysts. The deposited gel contains relatively large amount of liquid and, after drying and calcination, oxide materials with a large surface area are obtained. The aim of this work was preparation of supported catalysts with catalytically active oxide coatings combining Ni, Co, and Mn components deposited on stainless steel supports. The precursors preparation by sol-gel method, their depoisition on supports, and thermal treatment were optimized to obtain homogeneous mixed oxide coatings with good adhesion to the stainless steel supports and good catalytic activity in VOC total oxidation.

**Experimental/methodology.** Ni-Mn, Ni-Co and Ni-Co-Mn mixed oxides coatings were prepared by sol-gel method. The salts (typically chlorides) of metals mentioned above were dissolved in distilled water together with complexing agent (tartaric acid) and water-soluble polymer (gelatin). The reaction mixture was stirred for several hours at 85-90 °C to evaporate water and obtain a desired volume of the mixture. The formed sol was deposited on the stianless steel substrates (sheets and meshes) by dip-coating method, dried in a controlled manner and finally calcined for 4 h at 500 °C in air. The obtained mixed oxides on the supports were characterized by powder XRD, Raman spectroscopy, and TPR and tested as catalysts in the total oxidation of ethanol, which was chosen as a model VOC.

**Results and discussion.** The combination of Ni, Co, and Mn chlorides, tartaric acid and gelatin in the reaction mixture for the sol-gel reaction led to the formation of a sol precursor suitable for deposition on the supports and obtaining of homogeneous oxide coatings after calcination. The adhesion of catalytically active mixed oxides to stainless steel sheets and meshes was improved by pre-coating them with $SiO_2$ interlayer and repeated dip-drying cycles before calcination. The deposited Ni-Mn coatings contained a mixture of Ni-Mn mixed oxides ($Ni_6MnO_8$ and $NiMnO_3$), whereas the spinel-type mixed oxides were found as a major component in the Co-containing samples. The supported mixed oxide catalysts with Co:Mn, Ni:Mn, and Ni:Co:Mn molar ratios of 4:1, 1:1, and 1:1:1, respectively, showed good catalytic activity in the ethanol deep oxidation.

**Keywords:** Reactive oxygen species, o-phenylenediamine, oxidation, oxide catalysts

**Introduction.** The formation of reactive oxygen species (ROS) via the decomposition of hydrogen peroxide is associated with a cascade of reactions involving active redox centers of Fenton-like catalysts or acid-base functional groups of non-Fenton, amorphous surfaces of metal oxides that mediate electroprotic reactions [1]. These two catalytic functions can be achieved by combining two types of oxides, crystalline redox active oxides, and amorphous non-redox oxides, into one material. Such composite materials could be potentially used as catalysts in advanced oxidation processes (AOP), which are highly efficient and promising methods for the detoxication of wastewater. The present study aims to investigate the role of the reactive oxygen species in o-phenylenediamine (OPD) oxidation as a model AOP reaction.

**Experimental/methodology.** The composite oxide catalysts used in the study were synthesized using a hydrothermal method and characterized using XRD, XRF, zeta potential measurements, and Raman spectroscopy. The formation of ROS was monitored with Raman (peroxo species) and EPR (superoxide anions, hydroxyl radicals) techniques. Singlet oxygen was detected indirectly via oxidation with TEMP substrate (2,2,6,6-tetramethylpiperidine) into paramagnetic TEMPO and its detection with EPR. The chemical reactivity of the obtained materials was tested in the oxidation of OPD by using UV-vis absorption spectrometry.

**Results and discussion.** In this work, we have tested several oxide materials based on $Nb_2O_5$, CuO, $CeO_2$, combined into mixed, multiple oxide phases or composites with enhanced activity toward $^1O_2$ or radical ROS. We found this activity dependent on doping with phosphates or selected redox oxide nanocrystals. We have evaluated the role of hydroxyl radicals in OPD oxidation as well as the possible direct involvement of superoxide radical anions and singlet oxygen. Since oxidation of OPD is considered a test reaction for evidencing a peroxidase-like activity (oxidation with hydroxyl radicals) [2], we have concluded on the selectivity of OPD oxidation toward particular ROS substrates. For this purpose, the test reactions have been carried out for the mixtures containing catalyst suspension in water, OPD, $H_2O_2$, and typical quenchers of the individual ROS (alcohols, 1,4-benzoquinone, $NaN_3$).

**Keywords:** single atom catalysts, heterobimetallic, catalyst design

**Introduction.**
Atomically dispersed single, double, and cluster catalysts are receiving intense research interest as class of catalyst that bridges the easy separation of heterogeneous catalysts with the tunability and single-site nature of homogeneous catalysts.[1],[2] However, their synthesis can be challenging, and limited options exist for the controlled formation of *heterobimetallic* or mixed-metal sites.[3] This leaves a gap where the fascinating reactivity of homogeneous bimetallic catalysts is difficult to explore in its atomically dispersed cousins.[4]
In this work, heterogeneous catalyst design and synthesis is linked with techniques from coordination chemistry to develop routes that install defined heterobimetallic sites on a support material.

**Experimental/methodology.**
Mixed palladium-platinum complexes were synthesised and a range of encapsulation and polymerisation techniques investigated to disperse the PdPt sites across support materials. The resulting materials were characterised by methods such as HAADF-STEM, XPS, ICP.

**Results and discussion.**

Coordination polymers and dispersed metal atoms were produced, resulting in mixed clusters and discrete double atom sites. These features were investigated by high resolution STEM. The catalysts were assessed in the electrochemical hydrogen evolution and $CO_2$ reduction reactions.

**Keywords:** Catalytic purification of $H_2$, deoxo-catalyst, $H_2$-$O_2$ recombination

**Abstract**

In complex and sophisticated devices using hydrogen as an energy source, the presence of impurities in hydrogen can cause fatal defects in the device. In particular, oxygen is an impurity that must be removed to ensure stability because there is a risk of explosion if more than 4% is present in the hydrogen stream. In this paper, we compared the performance of removing oxygen from the hydrogen stream using hydrogen-oxygen recombination reactions(eqn. 1) with various single metal catalysts.

$H_2 + ½\ O_2 \rightarrow H_2O$ ($\Delta_R H$) = - 242 kJ/mol (1)

The results of a study aimed at determining the feasibility of using catalytic deoxo-reaction to scavenge oxygen nearly zero from main gas stream. A series of experiments were conducted to assess the catalytic recombination characteristics and the catalyst that showed the highest performance was a catalyst using Pd. The result was that the oxygen concentration of 2% could be remarkabley lowered to about 5 ppm or less with metal loading of 0.1 wt.%. Furthermore, it was found that the catalyst maintained its performance even in a continuous reaction for 150 hours.

**Keywords:** Heterogeneous Catalysis, $CO_2$ Reduction, Coordination Compounds, Platinum.

**Introduction.**

Pt and $TiO_2$ present a dynamic interaction that can be understood by the strong metal support interaction mechanisms, which encompass (i) charge transfer at the interface between the metal and oxide; (ii) encapsulation, when a non-stoichiometric $TiO_x$ layer cover the metallic nanoparticle; and (iii) alloy formation, when the system is over-reduced and Ti atoms are incorporated into Pt lattice [1]. We aim to employ organic complexes in the heterogenization of Pt on $TiO_2$ and evaluate how these precursors impact the dynamics of Pt/$TiO_2$ and the final catalytic performance in RWGS (reverse water gas shift).

**Experimental/methodology.**

The complexes were synthesized as described in Figure 1(a) [2]. They were impregnated on $TiO_2$ by wet impregnation and total Pt loading of 1 wt%. The pre-catalysts were pyrolyzed under $N_{2\,(g)}$ (500 °C for 1 h). XAFS (X-ray absorption fine structure) data were collected at BioXAS beamline (Canadian Light Source). For the RWGS reaction, 5 mg of catalyst mixed with a diluent was placed in a fixed bed tubular reactor. The RWGS reaction was performed with 2% $CO_2$, 8% $H_2$, and 90% He (total flow of 100 ml.min$^{-1}$, 500 °C for 1h).

**Results and discussion.**

Figure 1 (a) shows the synthesis of selected complexes. These compounds differ in their carbon content, and electronic structure, in which C2 and C3 have more carbon atoms, and C3 is an example of π-extended system. Figure 1(b) depicts the XAFS spectra of the complexes heterogenized on $TiO_2$ and pyrolyzed at 500 °C. The catalysts showed an intermediate electronic state, between $Pt^{2+}$ and $Pt^0$ standards, indicating that pyrolysis reduced the samples but kept a certain degree of electron deficiency, with C1/$TiO_2$_P500 being the most reduced and C2/$TiO_2$_P500 the least. This difference had a clear impact on the catalytic activity for $CO_2$ conversion to syngas through the RWGS ($CO_{2\,(g)} + H_{2\,(g)} \rightleftharpoons CO_{(g)} + H_2O_{(g)}$), with C2/$TiO_2$_P500 having the highest conversion rate and C1/$TiO_2$_P500 the smallest one. We demonstrated that the design of molecularly defined precursors can be a promising strategy for modulating properties, such as metal speciation, particle size, and metal-support interaction. Complementary characterizations to XAFS and evaluation of other activation conditions ($O_2$, $H_2$) helped to understand the metal support interactions that take place among the complexes and $TiO_2$, we were able to identify a strong interaction through charge transfer and $TiO_X$ formation at soft conditions (pyrolysis 350 °C), and its evolution under harsher treatments.

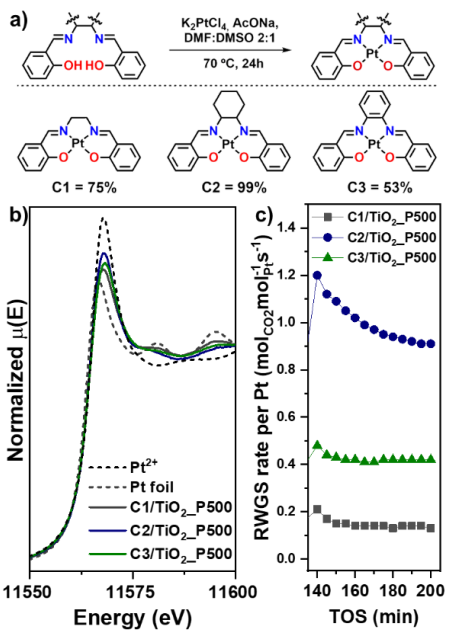

**Figure 1.** (a) Complexes' synthesis and yield; (b) XAFS spectra; (c) RWGS rate.

**Keywords:** AuPdPt, Hydrogen peroxide, Peroxygenase, Cyclohexane, Oxidation, Cascade

**Introduction.** Combining an evolved unspecific peroxygenase, from *agrocybe aegerita* (PaDa-I variant), and 1 wt.% $Au_xPd_yPt_z/TiO_2$ chemo-catalysts in a one-pot system is demonstrated to be highly effective towards the selective hydroxylation of cyclohexane to cyclohexanol. The metal catalyst provides a continuous supply of $H_2O_2$ to PaDa-I via direct combination of $H_2$ and $O_2$. It is demonstrated that Pt alloying into AuPd nanoparticles (NPs) promotes the rates of $H_2O_2$ production, relative to the bimetallic analogue, leading to significant enhancement in process efficiency.

**Experimental/methodology.** Au-Pd-Pt/$TiO_2$ catalysts were prepared by a conventional wet impregnation procedure.[1] Cyclohexane oxidation cascade experiments were performed in a one-pot system under conditions conductive to enzyme stability.

**Results and discussion.** Incorporating Pt at dopant levels into AuPd NPs enhances the rate of $H_2O_2$ production, relative to Pd and AuPd analogues. Due to the rate limiting nature of *in-situ* $H_2O_2$ production when compared to the rate of enzymatic turnover, it is found that dopant levels of Pt enhance the activity of the oxidation cascade relative to the AuPd analogue, as shown in Figure 1A. An optimum Pt loading is found at 0.02 wt%, above which the rate of $H_2O_2$ production decreases. Notably,the high selectivity of PaDa-I towards the formation of cyclohexanol is preserved when the rate of $H_2O_2$ production is increased.

tion of chemo-enzyme oxidation cascade at 2 h reaction
ng in the $Au_1Pd_1Pt_x/TiO_2$ catalysts, and related to the initial
he catalysts under low-pressure conditions. **B)** AC-STEM
$_1Pd_1$-0.02%/$TiO_2$ catalyst.

Figure 1B shows AC-STEM and X-EDS imaging of the $Au_1Pd_1$-0.02%Pt sample and reveals the nature of Pt speciation, which exists almost exclusively in the AuPd alloys, resulting in the formation of trimetallic nanoalloys with size range 5 – 20 nm. The presence of well-dispersed monometallic Pd (~ 3 nm) is also observed, analogous to the AuPd sample. Through extensive characterisation it is demonstrated that the enhanced performance of the AuPdPt/PaDa-I system resutls from the electronic modification of the Pd species, as a result of Pt incorporation. These pbservations represent a considerable advance on previous works with this burgeoning field.

# Dimethyl ether as hydrogen carrier: Development of catalysts for DME steam reforming

R. Stöber[1], F. Seidl[1], P. Schühle[1*]

[1]*Institute of Chemical Reaction Engineering, Friedrich-Alexander Universität Erlangen-Nürnberg, 91058 Erlangen, Germany*

[*]*patrick.schuehle@fau.de*

Green hydrogen will play a key role in the defossilization of the global energy system. Hydrogen production from electrolysis, however, is economically only attractive where renewable electricity is available at low cost. Consequently, the locations for future large-scale electrolysis operations will in most cases not coincide with the hydrogen consumption sites, making the long-range transport a problem to be solved. Due to the low volumetric energy density of gaseous compressed hydrogen, conversion into easily liquefiable hydrogen carrier molecules like dimethyl ether (DME) is considered a solution [1]. While there are already commercial routes for the synthesis of DME, the reverse hydrogen release by DME steam reforming (SRD) still needs significant advances. The reaction proceeds over two steps, namely the acid catalysed hydrolysis of DME to Methanol, followed by methanol steam reforming (MSR) to $CO_2$ and $H_2$. For both individual reactions a variety of different heterogeneous catalysts finds application in literature [2]. For the first reaction step solid acids, such as H-zeolites or γ-$Al_2O_3$, are reported, while Cu/ZnO/$Al_2O_3$ or spinell-type catalysts are used for the MSR step [1]. However, coking and/or active metal sintering contribute to deactivation of these catalysts, especially when both reactions are combined in one setup [2]. Therefore, further catalyst development is required.

**Figure 1: DME conversions of H-ZSM-5, γ $Al_2O_3$ and $Zr(HPO_4)_2$ over 8 h at 320°C**

In this work, SRD catalyst studies were conducted in a continuously operated fixed-bed reactor (1 bar(g), 260-350 °C, $H_2O$:DME:$N_2$ of 5:1:2). In the first set of experiments, the stability of three different commercial acidic hydrolysis catalysts (H-ZSM-5, γ-$Al_2O_3$ and $Zr(HPO_4)_2$) was determined, without addition of a MSR system. To study the deactivation behaviour, catalyst masses (0,5 g of H-ZSM-5, 3 g of γ-$Al_2O_3$ and $Zr(HPO_4)_2$) were adjusted to avoid operation at the thermodynamic equilibrium. As can be seen from Figure 1, the HZSM-5 catalyst shows the highest (mass related) DME conversion at the beginning of the experiment, but deactivates over 8 h TOS. In contrast, the less acidic γ-$Al_2O_3$ and $Zr(HPO_4)_2$ show remarkable stability. Due to the best compromise of stability and activity, γ-$Al_2O_3$ was chosen for the combination with a reforming catalyst in subsequent studies.

A commercial Cu/ZnO/$Al_2O_3$ and self-synthesized supported Pd and PdZn catalysts (1 wt.% of Pd) were used for the screening of the reforming component. The materials were prepared by wet-impregnation of metal precursors on γ-$Al_2O_3$, followed by calcination and reduction. The catalysts were characterized by X-ray diffraction, ICP-AES and $N_2$-physisorption measurements before and after testing. A comparison of the investigated catalysts is given in Figure 2 (48 h TOS, 350 °C). Cu/ZnO/$Al_2O_3$ is the most selective of the screened materials, while the Pd catalysts favor CO formation. Higher hydrogen yields are observed with the Pd and PdZn systems. The addition of the Zn-Phase enhances the $CO_2$ selectivity of the Pd catalyst and

**Figure 2: Hydrogen yields (△) and $CO_2$ selectivities (□) of the tested Pd/$Al_2O_3$ (blue), PdZn/$Al_2O_3$ (red) and Cu/ZnO/$Al_2O_3$ (grey) catalysts.**

slightly improves catalyst stability, leaving room for further catalyst optimization.

**Keywords:** layered double hydroxides, mixed oxide catalysts, methane combustion, VOC abatement.

**Introduction.** Different industrial processes produce flue gases containing volatile organic compounds (VOC) leading to air pollution and harmful effects over the environment, requiring treatment for VOC removal before release [1]. The most effective abatement process is catalytic combustion, whereas catalyst materials based on transition metal mixed oxides prepared from layered double hydroxides (LDH) precursors have shown great promise in this application [2]. We have previously shown that ex-LDH CoCeMgAlO mixed oxides are effective catalysts for the complete oxidation of methane, used as a VOC model molecule. The best composition was 40 at. % Co, 10 at. % Ce and Mg/Al atomic ratio of 3 [3]. Thus, in this work, two series of M-promoted CoCeMgAlO mixed oxides (M = Cu, Fe, Mn, Ni) were obtained from LDH precursors and tested for methane complete oxidation: a series of M(x)CoCeMgAlO mixed oxides with M content *x* = 3 at. %, and another series of Fe(x)CoCeMgAlO mixed oxides with various Fe contents *x* ranging from 1 to 9 at. % with respect to cations, while keeping constant in both cases 40 at. % Co, 10 at. % Ce and Mg/Al atomic ratio of 3.

**Experimental/methodology.** The mixed oxide catalysts were prepared *via* thermal decomposition at 750 °C of their corresponding LDH precursors obtained by coprecipitation. Their physico-structural properties were investigated with several techniques, such as XRD, SEM-EDX with elemental mappings, ICP-AES, XPS, $H_2$-TPR and nitrogen adsorption at -196 °C. They were tested in a fixed bed reactor for methane complete oxidation with a gas feed of 1 vol.% methane in air.

**Results and discussion.** XRD analysis revealed in all the samples the coexistence of $Co_3O_4$ crystallites with periclase-like and ceria phases, with no separate M-based oxide phase. All the cations are homogeneously distributed in the mixed oxide as suggested by EDX measurements and elemental mappings of the samples. The metals contents were determined by EDX and ICP-AES and were in accordance with the theoretical values set for the preparation of the catalysts. The redox properties studied by $H_2$-TPR, along with the surface composition determined by XPS have provided information to elucidate the catalytic behavior of the investigated materials. The catalytic tests have shown that all the M-promoted CoCeMgAlO mixed oxides are more active than their M-free counterpart. The highest promoting effect was observed for Fe. The Fe(x)CoCeMgAlO mixed oxide sample, with *x* = 3 at. % Fe, displayed the highest catalytic activity for methane combustion with a temperature corresponding to 50 % methane conversion, $T_{50}$, of 489 °C, which is ca. 40 °C lower than that of the unpromoted catalyst. This was attributed to its superior redox properties and lowest activation energy among the studied catalysts, likely due to a Fe-Co-Ce synergistic interaction. In addition, long term tests of Fe(3)CoCeMgAlO mixed oxide has been examined showing a good stability over 60 h on-stream. On the other hand, the addition of water vapors in the feed led to textural and structural changes of the Fe(3)CoCeMgAlO system affecting its catalytic performance. At the same time, the catalyst recovered its catalytic activity as soon as the water vapors were removed from the feed.

**Introduction.** Understanding how to tune the properties of metal oxides, e.g. controlling and manipulating defects and catalytic sites, and establishing a clear understanding of metal-support interactions is essential for developing catalysts with enhanced activity, selectivity, and stability. Reducible metal oxide supports, that associate redox and acid properties, in combination with a metallic phase, can result in promising catalytic systems for different reactions. The hydrodeoxygenation (HDO) reaction is one of the main biomass-derivate upgrading processes to obtain biofuels and deals with the selective cleavage of C-O bonds under a hydrogen-rich atmosphere combined with a solid catalyst, reducing the oxygen content to produce hydrocarbons as the main products. Here, Ti-Nb mixed metal oxides were explored to address the impact of acidity in HDO reaction.

**Experimental/methodology.** Ti-Nb mixed metal oxides with various Nb at.% contents were synthesized using a hydrothermal methodology. Pt-supported catalysts were obtained through the wet impregnation method over 0 at.% Nb and 25 at.% Nb supports. Vapor phase acetone HDO reaction was conducted in a plug-flow tubular reactor equipped with a quartz tube. Textural, structural, and electronic characterizations of the catalysts were conducted using various techniques.

**Results and discussion.** The formation of Ti-Nb mixed metal oxides was achieved up to 25 at.% Nb (Ti:Nb), where morphological and structural modifications were verified upon Nb insertion into the $TiO_2$ anatase crystal lattice, according to SEM, XRD, and short- and medium-range order PDF analysis. Py-FTIR and $^{31}$P NMR of adsorbed TMPO demonstrated that Brønsted/Lewis (B/L) acid sites ratio increased along with the Nb content (Figure 1a). The acid site distribution per accessible area in all mixed oxides presented similar values, between 0.28 and 0.41 sites per nm$^2$. The impact of the acidity modulation of these materials was evaluated using Pt-supported catalysts in the acetone HDO reaction. While the dominance of Brønsted acid sites led to 60 % of deoxygenated products (DOD - degree of deoxygenation) along 20 h on stream, the dominance of Lewis acid sites led to a DOD about 3 times smaller (Figure 1b). XPS measurements of pre- and post-reaction Pt-supported catalysts indicated that the Pt dispersion and Pt species differed depending on the support. The presence of Nb led to more oxidized Pt species and better dispersion. These oxidized Pt species decreased the coke deposition, resulting in more stable metallic sites. The catalytic performance demonstrated that Pt-supported catalysts with selective C-O bond cleavage could be designed through the modulation of catalytic sites of the support. We also demonstrated that the acidity modulation of the support led to significant changes in the metal-support interaction (MSI), affecting both the nature and stability of the catalytic sites. A better understanding of the correlation between acidity and MSI effects of Pt-supported over metal oxides could be provided, along with a correlation with the catalytic performance.

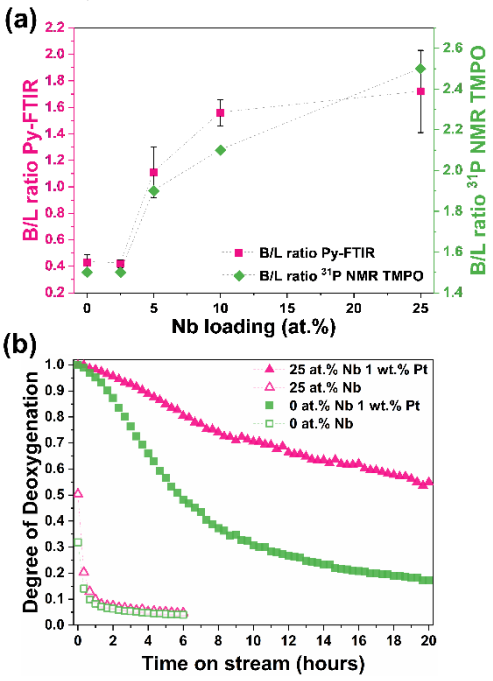

**Figure SEQ Figure * ARABIC 1: (a) B/L acid sites ratio measured by Py-FTIR and $^{31}$P-NMR of adosrbed TMPO; (b) DOD over TOS for the Pt-supported catalysts and their bare supports.**

# Synergistic Catalysis between Fe Single Atoms and $Fe_3O_4$ Nanoparticles to Generate Reactive Oxygen Species for the Oxidative Trifluoromethylation of Olefins

Tianyue Su, [1] Chun Cai [1*]

[1] School of Chemistry and Chemical Engineering, *Nanjing University of Science & Technology, Nanjing, China*

**Keywords:** Fe single atoms; $Fe_3O_4$ nanoparticles; synergistic effect; reactive oxygen species; the oxidative trifluoromethylation.

**Introduction**

In recent years, the α-trifluoromethylated ketone compounds have been well considered as valuable building blocks for the construction of fluorinated products. The traditional synthetic strategy using olefins as substrates and $CF_3SO_2Na$ as $CF_3$ source is photoredox catalysis, but it's limited by the light source, high price, toxicity or large-scale application etc. Therefore, the development of thermal-driven heterogeneous methodology to obtain α-trifluoromethylated ketones under mild conditions is highly imperative.

**Experimental/methodology**

The addition of aniline and ammonia during the synthesis of Fe-ZIF-8 precursors can effectively adjust its morphology, crystallization rate and the particle size. Besides, the BAN-Fe@NC catalyst by ball milling method have a better catalytic performance than the general Fe@NC catalyst and the reaction condition which is carried at 80 ℃ for 12 h under 1 atm $O_2$ atmosphere is green and sustainable.

**Results and discussion**

We discovered the coexistence of $Fe_3O_4$ nanoparticles with Fe single atoms on the N-doped porous carbon nanotube could significantly improve catalytic performance for the oxidative trifluoromethylation of olefins using $O_2$ as the oxidant (Figure 1). The optimal BAN-Fe@NC catalyst has exhibited a high efficiency with a broad substrate scope under mild conditions. Furthermore, it could be easily recovered because of its magnetic properties and reused 5 run without appreciable loss of activity. Experimental measurements and mechanistic studies revealed that both the superoxide radicals ($O_2^{\cdot-}$) and the singlet oxygen ($^1O_2$) were the main reactive oxygen species (ROS), and this catalyst structure has a great influence on the absorption of $O_2$ and the ability of thermally-driven generating ROS, which are attributed to the "synergistic effect" between $Fe_3O_4$ nanoparticles and Fe single atoms. It not only offers a simple method in the design of Fe catalysts but also opens up a heterogeneous pathway for the oxidative trifluoromethylation of olefins *via* radical mechanism.

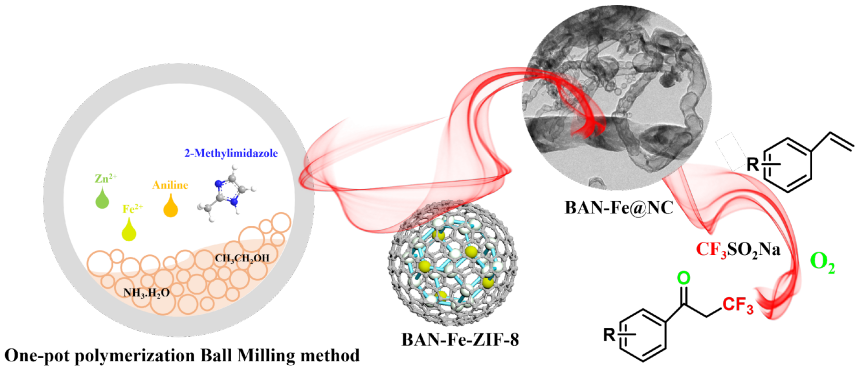

**Figure 1. the preparation of BAN-Fe@NC and its catalytic application in the oxidative trifluormethylation of olefins (B is ball-milling method; A is aniline; N is ammonia).**

**Keywords:** Palladium, Nickel, Bimetallic Nanoparticles, H/D Exchange, N-Heterocyclic Carbene

**Introduction**.

Deuterated amino-acids have gained importance in recent years due to their application in deuterated proteins production. The smart way to obtain these molecules is through direct H/D isotopic exchange by means of C-H bond activation. Although nanocatalysts based on Ni, Ir, Ru, Pd and Pt have shown good performance on this reaction, aromatic amino-acid reduction is a common undesired process.[1] In order to overcome this drawback, we present here PdNi-based nanoparticles (NPs) stabilized by a hydrophilic (**IMesPrSO$_3$**) N-Heterocyclic Carbene (Figure 1) as nanocatalysts for H/D exchange. We have found that **PdNi@IMesPrSO$_3$** selectively deuterate aromatic amino-acids such as L-phenylalanine and L-tyrosine without reduction of the aromatic ring in an enantiospecific fashion thanks to a synergetic Pd-Ni effect.

**Experimental/methodology.**

Mono- and bi-metallic NPs of Pd and Ni were synthesized by the organometallic approach method using $Pd_2(dba)_3$ and $Ni(COD)_2$ as metal precursors and **IMesPrSO$_3$** as stabilizing agent (Figure 1).[2] The NPs were characterized by state-of-the-art of techniques (TEM, HR-TEM, XRD, XPS, ATR-FTIR, SS-NMR) and used as nanocatalysts in H/D exchange over L-phenylalanine (PhAla) and L-tyrosine (Tyr).

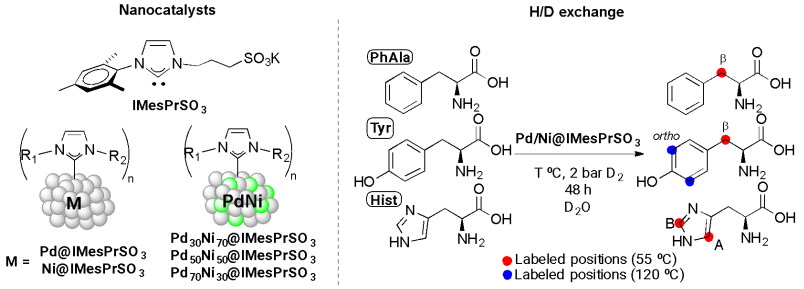

Figure 1. Pd, Ni and PdNi NPs stabilized by **IMesPrSO$_3$** and their use as nanocatalysts in HIE reactions.

**Results and discussion.**

Solid-state NMR and XPS techniques allowed us to confirm the NHC coordination to the PdNi NPs surface, which explains their high colloidal stability found in water. In addition, we were able to confirm the bimetallic nature of the PdNi NPs by XRD, STEM-EDX and ATR-FTIR techniques. Regarding the catalytic activity, while monometallic Pd and Ni NPs displayed low deuteration values, bimetallic PdNi NPs (**Pd$_{70}$Ni$_{30}$@IMesPrSO$_3$**) showed great deuterium incorporation values (up to 98.5%) at the $CH_2$-β position of PhAla without aromatic reduction. This behavior is explained by a Pd–Ni synergetic effect. On the contrary, Tyr showed a different behavior and the selectivity of the deuteration was found to be temperature-dependent. These results together with the enantiospecificity found for the first H/D exchange in PhAla and Tyr will be also discussed.[3]

**Introduction.** Imogolite ($(OH)_3Al_2O_3SiOH$) is a naturally occurring aluminosilicate clay mineral possessing a nanotubular structure, typically having a diameter of 2 nm with a length of several hundred nanometers. Limited study has been performed on characterising and the application of this material. It is currently proposed that imogolite could find success as a molecular sieve or by reinforcing polymers through formation of a nanocomposite material [1]. It has also been proposed the imogolite could find application as a catalyst due to the gibbsite structure of the outer wall displaying acidic and basic properties [2]. Investigations into imogolite as a catalyst for glucose to fructose isomerisation has proved successful [3]. DFT studies have also suggested it would make a successful photocatalyst. Imogolite has shown versatility with several possible modifications explored. Germanium and iron have both been substituted into the structure while both the inner and outer surface of the nanotube has been functionalised [3]. This work aims to investigate a methods of synthesizing germanium-imogolite and its suitability as a catalyst.
**Experimental/methodology.** A stock solution of aluminium nitrate nonahydrate and germanium ethoxide was refluxed for 4 days with the solution subsequently dialysed and dried to give a powder. The material was characterized primarily using electron microscopy, porosimitry, and acidity measurements. Catalytic testing was performed through liquid-phase acetalization of benzaldehyde with methanol.
**Results and discussion.** Ge-imogolite types were successfully synthesised using this method. Unlike previous studies into this material where a mixture of nanotube lengths were seen often reaching 100 nm, microscopy identified a very regular length of 8 nm. This was consistent across syntheses and reflux times identifying this as a technique to synthesise nanotubes with reliable and expected properties. Porosimitry was performed identifying a double-walled nanotube with an inner diameter of 2 nm and outer diameter of 4 nm. Material acidity was also gauged via $NH_3$-TPD and pyridine DRIFTs showing a high number of acid sites, especially when compared to other aluminosilicates. Initial catalytic testing investigated the Ge-imogolite for the acetylisation of benzaldehyde with methanol showing high conversion after 1 hour at ambient temperatures. This suggests that Ge-imogolite could find use as an active catalyst. Further study into Ge-imogolite's catalytic capabilities along with its use as a support for metal nanoparticles is in progress.

**Keywords:** chlorinated VOC, dichloromethane, catalytic oxidation, titania-ceria, titanyl sulphate

**Introduction.** Emissions of volatile organic compounds (VOCs) into air and water from processes and products are considered as serious environmental problem [1,2] . According to the classification of the International Agency for Research on Cancer some of widely used VOCs belong to the three most serious groups; group 1 (carcinogens, *e.g.* formaldehyde, vinyl chloride), group 2A (probable carcinogens to humans, *e.g.* halogenated VOCs such as dichloromethane, perchloroethylene) and group 2B (possible carcinogens to humans, *e.g.* acetaldehyde, halogenated VOCs such as chloroform) [3]. Emitted VOCs can also react with other gases and particulates, forming secondary air pollutants being even more harmful, moreover, complicating their abatement. Catalytic combustion is a well-accepted and reliable technology for industrial VOCs abatement in environmentally and economically acceptable manner.

**Experimental/methodology.** A set of $Pt/CeO_2$, $Pt/TiO_2$ and $Pt/TiO_2$-$CeO_2$ catalysts with various molar composition (Ti:Ce – 9:1, 7:3, 5:5, 3:7) was prepared by co-precipitation method using titanyl sulphate as Ti precursor, impregnation and calcination. Catalytic oxidation experiments were carried out on a laboratory apparatus consisting of a flow-through tube reactor with a fixed catalyst bed located in the furnace, injection of dichloromethane (500 ppm) with water (1.5 wt.%) and an on-line FTIR analyzer. The efficiency of catalysts in oxidation of dichloromethane was studied in the range of 100−500°C, under the SV of 70 $m^3 \cdot kg_{cat}^{-1} \cdot h^{-1}$.

**Results and discussion.** Over all investigated catalysts 100% conversion of dichloromethane was reached. $Pt/TiO_2$ and $Pt/Ti_{0.7}Ce_{0.3}O_n$ showed the best catalytic activity. $Pt/TiO_2$ showed also the highest HCl selectivity. It was found out that catalysts prepared from titanyl sulphate precursor contain sulphates, which affected the acidity of the catalysts, being a determing property in the first adsorption step within dichloromethane oxidation. Increased reducibility of catalysts due to present Pt species was reflected to improved $CO_2$ selectivity.

**Keywords:** gold catalysts, Cu-Ce mixed oxide; complete benzene oxidation

**Introduction.** Nowadays, the increased levels and detrimental effects of volatile organic compounds (VOCs) on air quality and human health have become a serious global concern from environmental point of view. A variety of technologies is applied to decrease harmful emissions from various chemical industries. Among them, complete oxidation to $CO_2$ and water at relatively low temperature is one of the most effective and environmentally-friendly approach for VOCs removal. Rational design of catalytic materials with high effectiveness in the destructive elimination of VOCs is one of the scientific challenges. It has triggered a substantial interest in the field of environmental catalysis because efficient catalysts should combine high activity and economic profitability. Currently, two major types of catalysts, namely noble metal-based and transition metal oxides are the most intensively studied to meet demanding environmental regulations. The aim of the present work is to study complete benzene oxidation (CBO) over $Al_2O_3$-supported CuO-$CeO_2$ mixed oxide promoted by gold. The investigation is focused on the effect of various Cu/Ce molar ratios on benzene conversion. Benzene molecule is the most stable among the aromatic hydrocarbons with toxic and often carcinogenic effect known as BTEX (benzene, toluene, ethylbenzene, and xylenes) owing to the symmetry and stability of the benzene ring.

**Experimental.** Wet impregnation of γ-$Al_2O_3$ with solution of $Cu(NO_3)_2.3H_2O$ and $Ce(NO_3)_3.6H_2O$, properly mixed to guarantee Cu:Ce molar ratio of 2:1 and 1:5 in the composition (20 wt.% active phase in total) was used for sample preparation. Synthesis of gold-containing (2 wt.%) samples on water suspended carriers by using ultrasound was performed by deposition-precipitation. Analysis of the impact of support composition in benzene oxidation was based on sample characterization by textural measurements, PXRD, EPR spectroscopy, and TPR technique.

**Results and discussion.** Complete oxidation of benzene as a probe reaction for VOCs elimination over alu-mina-supported CuO-$CeO_2$ mixed oxide promoted by gold was studied. The effect of various Cu/Ce ratios, namely 2:1 and 1:5, and the role of supported gold nanoparticles were investigated. Catalytic activity was greatly influenced by sample composition. Catalytic tests demonstrated that the Cu-Ce 1:5 configuration outperformed the catalytic behavior of the single-component counterparts in the whole temperature interval, while Cu-Ce 2:1 exhibited such behavior above 250 °C. Incorporation of Cu ions into the ceria lattice was proven by a small shift of the ceria main XRD peak in the patterns of all Cu-Ce containing samples evidencing defect formation, in particular $Ce^{3+}$ ions and oxygen vacancies. Promotion by gold provided additional benefits to the benzene conversion. Gold on alumina-supported binary oxide catalysts exhibited a substantially higher activity than promoted supported monometallic oxides. Our findings revealed a crucial role of highly dispersed CuOx for benzene oxidation activity. The highest concentration of paramagnetic $Cu^{2+}$ ions and the best dispersion of CuO in Cu-Ce 1:5 and Au/Cu-Ce 1:5 correlate well with best performance among alumina-supported oxides and gold-containing catalysts, respectively. Gold nanoparticle availability contributed to enhanced mobility of oxygen in ceria surface layers, thus facilitating the process of oxygen vacancy formation and replenishment. Au/Cu-Ce 1:5 achieved stable total oxidation to $CO_2$ and water by 94 % benzene conversion at 250 °C, thus implying the potential of this composition in developing efficient catalytic materials for atmospheric pollutant abatement.

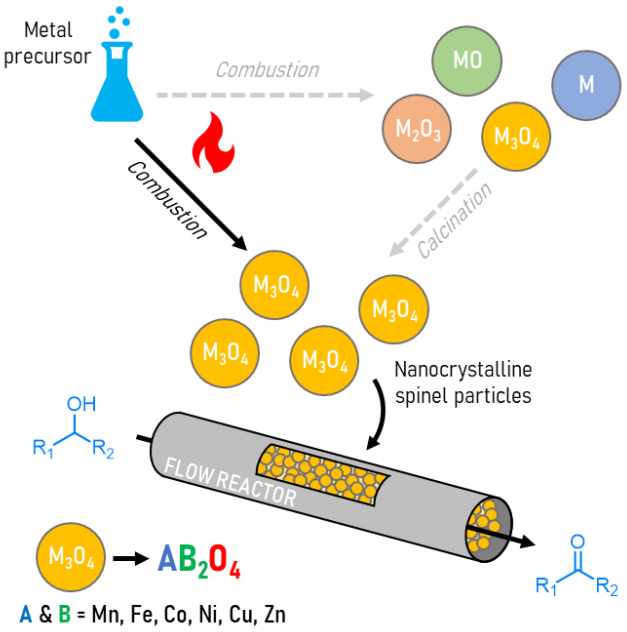
# Liquid-phase catalytic oxidation of alcohols over spinel oxides



A. Tampieri[1], F. Romanelli,[1,2] T. Lederer[1], M. Pittenauer[1], K. Föttinger[1*]

[1]*Institute of Materials Chemistry, Technische Universität Wien, Vienna, Austria*
[2]*Polytechnic University of Milan, Milan, Italy*
[*]*karin.foettinger@tuwien.ac.at*

**Keywords:** Spinel oxides, alcohol oxidation, nanocrystals, flow reactor, solid-liquid interface.

**Introduction.** The selective oxidation of alcohols is an important synthetic tool in the portfolio of the chemical industry. Even though the oxidation of small alcohols such as methanol to formaldehyde are established processes, the selective transformation of higher alcohols is more challenging; moreover, the mechanistic understanding of these reactions over heterogeneous catalysts is still poor, especially about the phenomena taking place at the solid-liquid interface [1]. Besides, the most active catalysts are based on noble metals [2]; metal oxide catalysts are more complex and comprise less defined active sites, but they are based on more earth-abundant metals and are less susceptible to leaching. Therefore, the surface study and design of more active and selective oxide catalysts are important matters in light of the green transition. In this regard, oxides of the spinel type proved to be outstanding catalysts in liquid-phase aerobic oxidations [3].

**Experimental/methodology.** A library of nanocrystalline spinels based on Mn, Fe, Co, Ni, Cu and Zn was prepared using the combustion method followed by calcination. The obtained solids were characterised by XRD, FT-IR, SEM-EDX, $N_2$-physisorption, and XPS. The catalysts were tested in the liquid-phase oxidation of 2-propanol and -butanol in a flow reactor, and the collected liquid and gas samples were analysed by GC-FID.

**Results and discussion.** Every spinel with a different elemental composition produces a different type of combustion, which is reflected in the different morphology and phase composition of the solids. While the as-synthesised Mn, Co and Ni ferrites are pure, the rest of the combinations required calcination, each with a different temperature, atmosphere and cooling. The temperature stability of each material was tested to assess the suitability of different pretreatments, as well as the crystal growth during those. The catalysts were tested in a flow reactor, in the presence of water and $O_2$, to study the effect of the catalyst composition on the activity and selectivity, together with the impact of the presence of a normal-vs-inverse spinel configuration and a cubic-vs-tetragonal structure. Finally, the stability of the catalyst to water and to the reaction conditions was also assessed.

**Keywords:** Dispersion enhancement, Catalytic activity, Stability of catalyst, Complexation, Adsorption

**Introduction.** High catalytic activity, desired selectivity and long-term stability are key features associated with the effective catalyst in the context of heterogeneous catalysis. For a targeted reaction, these features strongly depend on the reaction conditions and multi-way interactions between reactants, active sites and support material. Therefore, active sites on catalyst must be designed and optimized to increase catalytic performance. In this study, a synthesis strategy for dry impregnation (DI) method is proposed to enhance active metal dispersion and stability on support material via $Ni/Al_2O_3$ catalyst example.

**Experimental/methodology.** Effect of support type, precursor compound, impregnating solution and calcination temperature were analyzed to enhance metal dispersion level on $Ni/Al_2O_3$ catalyst by DI method. Point of zero charge (PZC) values of supports were measured and used to predict the pH at maximum adsorption by a simplified physical adsorption model [1]. Surface of impregnated supports were analyzed by Raman spectroscopy. Three different calcination temperatures (500, 700, 900°C) were applied. $H_2$ chemisorption was used to determine Ni dispersion levels. Selected samples and supports were characterized by their BET surface area, pore volume, pore size distribution, XRD and Raman spectroscopy.

**Results and discussion.** Since nickel is a low oxidation state metal and can be accommodated in $Al_2O_3$ spinel by absorption on surface, theoretical adsorption model is not suitable for $Ni^{2+}$ [2]. However, complexes of nickel show high stability and are mainly adsorbed on support surface that makes possible to apply physical adsorption model. Theoretical equilibrium calculations and UV–vis spectroscopy evidenced the formation of targeted Ni complexes (EDTA, NTA, citric acid, ammonia) in impregnating solutions. Nickel-ammonia complexes have lower dispersion levels from theoretical calculations because of the $Ni(OH)_{2(s)}$ formation at high pH levels. As shown in Figure 1, catalysts prepared by using Ni-EDTA complex shows higher dispersion at 900°C while citric acid and NTA addition results with significantly higher dispersion levels at lower calcination temperatures.

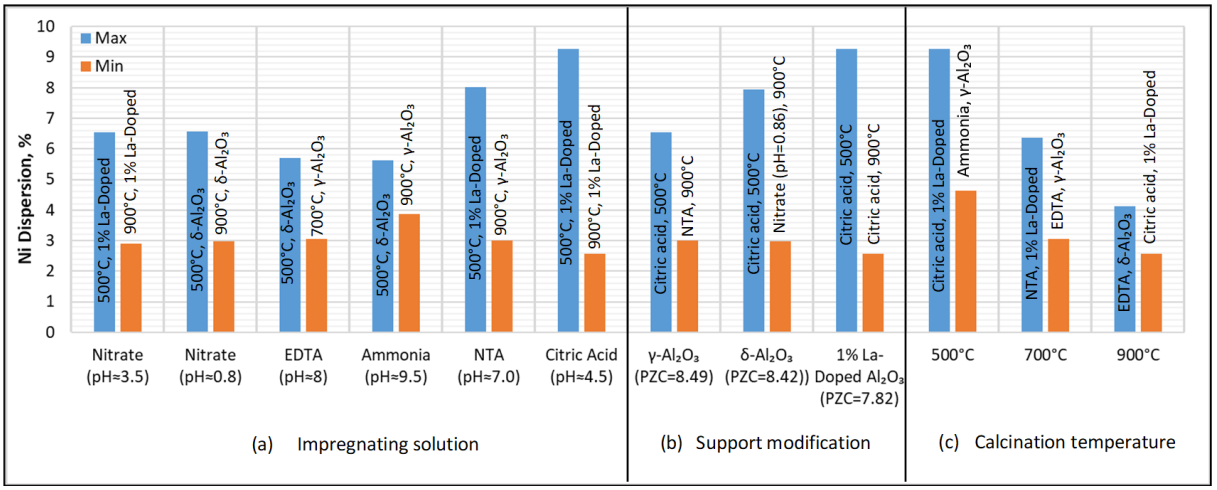

**Figure 1.** Maximum and minimum dispersion levels of manufactured catalysts.

# Diastereoselective Synthesis of Novel Phosphine-Phosphoramidite Ligands and their Performance in Asymmetric Catalysis

Simon Teeuwen[1], Giancarlo Franciò[1*], Walter Leitner[1,2]

**Keywords:** asymmetric synthesis, asymmetric catalysis, hydroformylation, hydrogenation

**Introduction.** From pharmaceuticals and agrochemicals, over flavors and fragrances to material sciences, asymmetric synthesis plays a crucial role for accessing a plethora of chiral organic molecules.[1] We endeavor to enlarge the catalyst availability through easily accessible and effective chiral ligands. Herein, we present a route to diastereoselectively synthesize novel phosphine-phosphoramidite ligands. Those ligands are then used in two of the largest homogeneously catalyzed reactions, i.e. the Rh-catalyzed asymmetric hydrogenation (AH) and hydroformylation (AHF).[2]

**Experimental/methodology.** Starting from simple 2-(diarylphosphino)benzaldehyde, a first stereocenter is introduced into the ligand structure by a facile condensation reaction with a chiral amine (see Figure 1). The presence of a stereocenter acting as directing group allows the diastereoselective functionalization of the imine upon addition of an organometallic reagent and the generation of a second stereocenter in a controlled manner. This strategy permits to largely overcome the challenging separation of diastereomers formed in equimolar amounts during synthesis, as it was the case for the related Quinaphos ligands.[3] Addition of an organometallic reagent and introduction of the desired phosphoramidite moiety could be conveniently done in a one-pot synthesis for some derivatives. Alternatively, the phosphine-amine (or the corresponding hydrochloride salt) can be isolated and then functionalized with the phosphoramidite moiety.

**Results and discussion.** Through this methodology, a mini library of chiral imines and phosphine-phosphoramidite ligands have been synthesized varying both R* and R' and achieving diastereoselectivities of up to 99 % during imine functionalization. The phosphine-phosphoramidite ligands have then been used in asymmetric hydrogenation, as well as asymmetric hydroformylation of benchmark substrates. The results obtained will be presented.

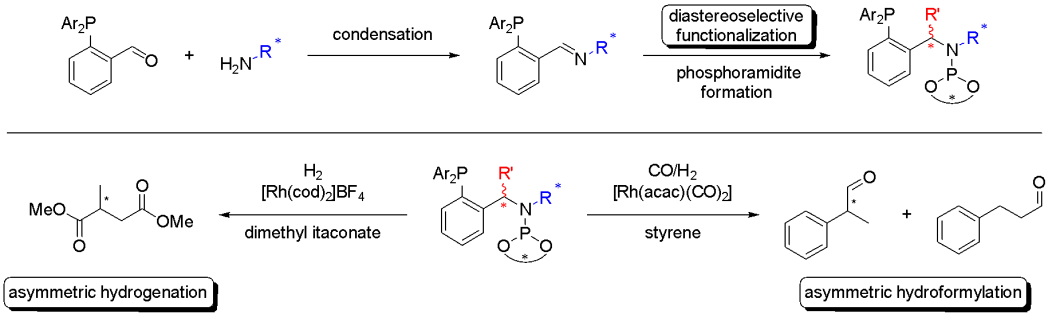

**Figure 1: Synthesis of chiral phosphine-phosphoramidite ligands (top) and their application in asymmetric catalysis (bottom).**

# Highpressure pulse experiments and cofeeding of ethylene: Insight into the active sites of a prussian blue analoguederived Mn-Co catalyst in the CO hydrogenation to higher alcohols

P. Telaar[1], P. Schwiderowski[1], P. Diehl[1], M. Muhler[1]

[1]*Laboratory of Industrial Chemistry, Ruhr University Bochum, Bochum, Germany*
[*]*Corresponding author: muhler@techem.rub*

**Keywords:** higher alcohol synthesis, prussian blue analogues, carbonylation, hydroformylation, steadystate kinetics, highpressure pulse experiments

The heterogenously catalyzed hydrogenation of carbon monoxide to higher alcohols has attracted substantial attention in the last decades due to the possibility of decreasing the dependence on fossil fuels. Therefore, the application of climateneutral fuels obtained by higher alcohol synthesis (HAS), shown in Equation 1, is an important factor to mitigate the global $CO_2$ emissions in the next decades.[1]

$$n\,CO + 2n\,H_2 \rightarrow C_nH_{2n+1}OH + (n-1)\,H_2O \; n\,CO + 2n\,H_2 \rightarrow C_nH_{2n+1}OH + (n-1)\,H_2O \quad (1)$$

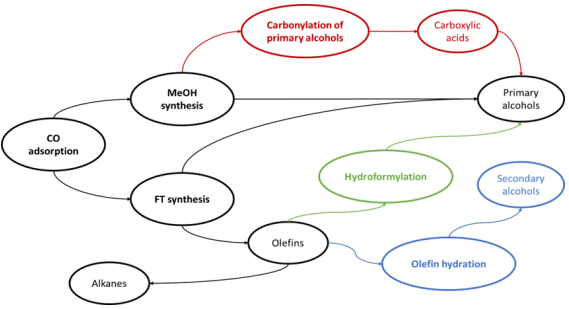

**Figure 1.** Proposed schematic reaction network for the HAS using PBA based catalysts.

This work further investigated the reaction network, shown in Figure 1, of a Cobased catalyst derived from a prussian blue analogue (PBA).[2-3] During our previous work, the pyrolysisbased synthesis of the catalysts was further improved resulting in a Cobased catalyst promoted with $Mn^0$, but no longer with K.[3] Here, the most promising approach was the implementation of a washing step, leading to increased CO conversion and a higher total oxygenate selectivity.[3] Consequently, the steadystate kinetics as well as transient kinetics of this $Mn_{1.0}Co_{10.6}$ catalyst were further investigated in this study. Highpressure pulse experiments with MeOH and $NH_3$ were performed to gain deeper insight into the interplay of the carbonylation of primary alcohols, reductive hydroformylation of olefines as well as the olefin hydration. In addition to the established variation of reaction temperature, pressure, residence time and partial pressures of CO and $H_2$, a cofeeding experiment was performed. While maintaining a CO:$H_2$ ratio of 1, ethylene was constantly added to the feed gas to investigate the influence of the hydroformylation reaction pathway. The performed kinetic study gave deeper insight into the interplay of presumably two active sites present in Cobased catalysts derived from PBAs. The cofeeding experiment showed that the increased partial pressure of ethylene resulted in an increased formation of 1PrOH, while no increased formation rate of the longerchain primary alcohols was observed, suggesting that in addition to the *in situ* formed $Co_2CCo$ interface embedded in the highly functionalized carbon matrix, another active site for the oxygenate formation is present. Based on recent studies,[4] this active site can be assumed to be an *in situ* formed Co carbonyl hydride complex. The necessary stability is ascribed to the presence of the nitrogen and oxygenfunctionalized carbon matrix, resulting in an efficient anchoring of this labile complex. However, further studies are needed to fully understand the nature of the active sites using PBAbased catalysts. *In situ* DRIFTS and *in situ* XPS are currently performed to investigate the surface transformations taking place under reaction conditions.

**Introduction**

The doping of supported heterogeneous catalysts can significantly affect their physicochemical properties which, in turn, can dramatically influence their catalytic performance.[1] Herein, a series of Si-doped $TiO_2$ metal oxide materials were synthesized using a sol-gel technique and used as supports for Pt nanoparticles, which were deposited by chemical vapour impregnation (CVI). We demonstrate that the incorporation of Si into the lattice of the $TiO_2$ support can drastically influence the activity and stability of the supported Pt particles in the total oxidation of propane under wet, industrially relevant conditions.

**Experimental/methodology.**

$Si_x$-$TiO_2$ (x = 0 – 16 *wt.*%) materials were prepared by a sol-gel method and used as catalysts and supports for Pt nanoparticles. For the latter, 1 wt.% of Pt was deposited by chemical vapour impregnation (CVI). Phase purity and crystallinity measurements were determined by X-ray diffraction. Support surface area and porosity measurements were determined by $N_2$ physisorption. Acidity measurements were acquired from $NH_3$ temperature programmed desorption (TPD) and diffuse reflectance infrared Fourier transform spectroscopy (DRIFTS) experiments with pyridine. Data relating to the Pt particle size and dispersion, in fresh and used catalysts, was acquired from CO chemisorption and transmission electron microscopy (TEM) experiments. The catalytic performance of the materials prepared in this study were acquired from experiments conducted in a continuous flow fixed bed reactor, under wet and dry conditions. A premixed cylinder of 1000 ppm propane in 10% $O_2$ in $N_2$ was used, a gas hourly space velocity (GHSV) of 50,000 $h^{-1}$.

**Table 1**. Temperature of propane conversion at $T_x$ x = conversion, Pt dispersion based on CO chemisorption, BET surface area measurements.

| Catalyst | $T_{20}$ | $T_{50}$ | Dispersion (%) | BET Surface Area ($m^2/g$) |
|---|---|---|---|---|
| $Pt/TiO_2$ | 209 | 236 | 33 | 68 |
| $Pt/Si\text{-}TiO_2$ (1%) | 217 | 243 | 90 | 149 |
| $Pt/Si\text{-}TiO_2$ (2%) | 210 | 240 | 75 | 222 |
| $Pt/Si\text{-}TiO_2$ (4%) | 204 | 228 | 59 | 235 |
| $Pt/Si\text{-}TiO_2$ (8%) | 183 | 220 | 46 | 255 |
| $Pt/Si\text{-}TiO_2$ (16%) | 237 | 291 | 6 | 342 |
| $Pt/SiO_2$ | 213 | 250 | 6 | 798 |

**Results and discussion.**

The incorporation of Si into the lattice of the $TiO_2$ supported Pt catalysts had a profound effect on their catalytic activity towards total propane oxidation. Low loadings of Si promoted Pt dispersion, which was confirmed by TEM and CO chemisorption. On the contrary, higher Si loadings increased Pt dispersion and was collectively, confirmed as a key activity descriptor for the reaction (**Table 1**). Importantly, the incorporation of Si was also found to influence the stability of the $Pt/Si\text{-}TiO_2$ catalysts and influenced their resistance to $H_2O$. Ammonia TPD and In-situ DRIFTS experiments using pyridine, CO and propane as probe molecules were employed to uncover important features relating to the reaction mechanism, which confirmed that the C-H bond activation was rate determining.

**Keywords:** Yttrium aluminium garnets, exsolution, dry reforming of methane

**Introduction.** Synthesis gas (syngas) can be produced by several industrial processes, e.g., steam reforming of hydrocarbons or partial oxidation. An alternative is the highly endothermic dry reforming (DRM) in which an equimolar syngas product in obtained [1]. Ni and Co are promissing active metals in DRM catalysts, nevertheless, deactivation caused by sintering needs to be prevented. Hence, complex oxide structures, e.g., spinells or perovskites were investigated [2]. Here, we report the synthesis of complex mixed-oxides by two routes, from which the active metal can be extracted via exsulution. The phase pure Ni- and Co-substituted Y-Al-garnets (YAG) as DRM catalysts.

**Experimental/methodology.** YAG catalysts were prepared via the conventional Pechini and polymer-analogue Flocculant route acording to [3]. Fresh and spend catalysts were characterized by e.g. XRF, $N_2$ sorption and TPR. By means of XRD and TEM-EDX, the phase purity of the obtained garnets and the effect of activation was studied. The catalytic activity was investigated in the DRM for 15 h time on-stream (TOS). After activation (1 h, 10 vol.-% $H_2$ in Ar at 1123 K), catalytic studies at ambient pressure under conditions of $n(CH_4)/n(CO_2) = 1$, T = 1023-1123 K and GHSV = 6000 $h^{-1}$ were conducted.

**Results and discussion.** Phase pure Ni- and Co-substituted YAGs were synthesized. Here the applied route had a significant influence on, e.g., crystalinity and catalytic activity. The ocurance of crystalline side phases was observed not only depending on the synthesis route, but also on molar composition and calcination temperature. In general, applying the Flocculant route led to an increased phase purity of YAGs as well as an enhanced porosity compared to the conventional Peccini based catalysts. Applied in DRM, Ni-based YAGs were found to be more active (Fig. 1 right) and less prone to carbon depositions then their Co-containing analogues. $Ni^0$ sites were found to be the active phase since reduction prior to DRM caused an exsolution of Ni from the crystal structure. It should be noted, that the activity of Co-YAGs was found to be higher, if no activation in $H_2$ was conducted. Hence, oxidic cobalt seems to play a significant role regarding catalytic activity and coke resistance.

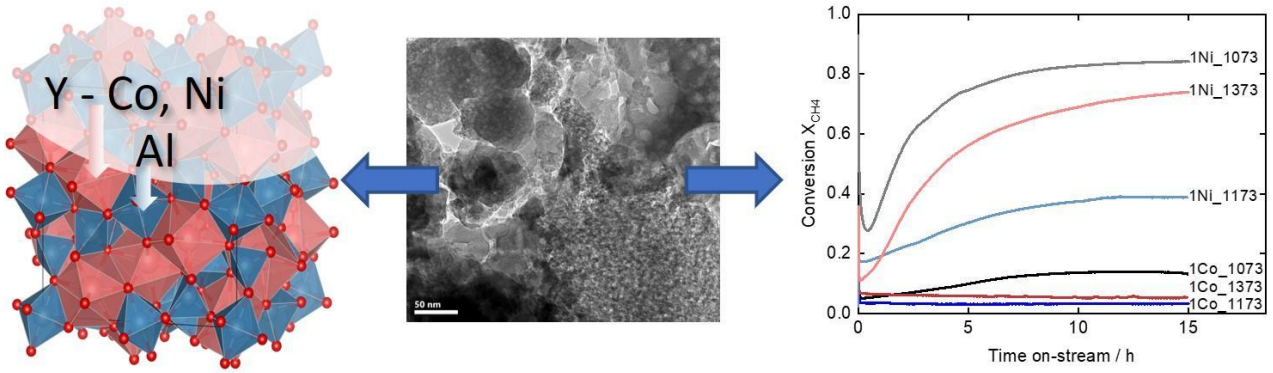

**Figure 1. Graphical abstract displaying the YAG structure (left), a TEM image of phase pure YAG (middle) and the activity in DRM with the conversion $X_{CH4}$ versus time on-stream for 1 mol-% Ni- and Co-substituted YAGs calcined at different temperatures (right).**

**Introduction**

Structured catalysts with high porosity and low pressure drop are particularly suitable for industrial processes carried out at high space velocities. One of these processes is catalytic total oxidation of volatile organic compounds, which is economically feasible and environmentally friendly way of emission abatement. Noble metal catalysts are typically preferred due to high activity and stability. Designing catalysts with low amount of active phase is important for industrial applications [1]. Herein we report the preparation of thermally stable electrospun mat, which can be used as a support for platinum catalysts.

**Experimental**

Electrospun polybenzimidazole support was impregnated with platinum(II) acetylacetonate.

**Results and discussion**

The morphology of the support allowed to prepare catalysts with high porosity and low mass transfer limitations. Moreover, by tuning the preparation conditions, it was possible to obtain catalysts with different Pt loading and particle size. The Pt active sites were deposited on the surface of nanofibers (Fig. 1) and were readily accessible to the reactants. As a result, the catalyst containing only 0.08 wt.% of Pt was able to reach a high conversion (90 %) of model VOCs (ethanol, acetone, toluene) at moderate temperatures (229 °C, 271 °C, and 334 °C, respectively).

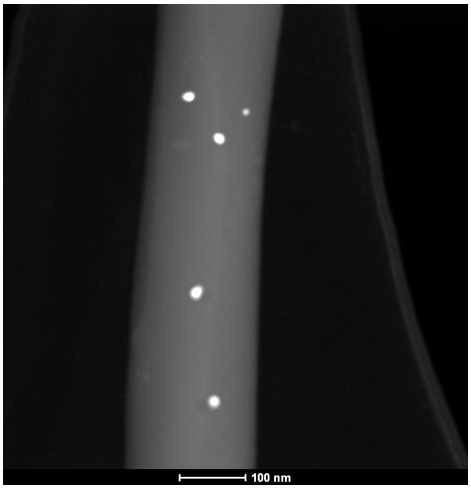

**Fig. 1. STEM image of Pt nanoparticles supported on polybenzimidazole nanofiber mat.**

Furthermore, we have shown that the TOF depends on the size and type of Pt nanoparticles. The catalysts with Pt particle sizes 1.5 nm and 26 nm exhibited lower catalytic activity than that with Pt particle size of 12 nm. The catalysts with Pt particle size 1.5 nm and 12 nm were prepared by equilibrium adsorption and the higher catalytic activity of the latter catalyst can be explained by the decrease of the Pt–O bond strength with the enlargement of the Pt particle size, which led to more reactive adsorbed oxygen on Pt sites. On the other hand, the catalyst with Pt particle size 26 nm was prepared by solvent evaporation method and contained polycrystalline platinum. Thus, although the Pt particle size determined by TEM was 26 nm, the size of single coherent domains was lower, which correlated with the lower catalytic activity of this catalyst.

**Keywords:** Additive manufacturing, carbon materials, heterogeneous catalysis, ozonation

**Introduction.** Additive manufacturing, also known as 3D printing, in catalysis has been the target of several studies because it allows to transform powder catalysts into 3D structures that are adaptable for different operation conditions, easy to manipulate and optimize the processes of mass transfer [1]. Catalysts based on carbon materials, such as multi walled carbon nanotubes (MWCNT) and activated carbon (AC) have been studied to reduce different types of environmental pollutants in liquid and gas phases due to their excellent textural and mechanical properties [2-4]. Their application is generally studied in suspensions in the effluents to be treated and/or fixed beds, making the introduction in large-scale processes difficult. In this study, macro structured catalysts of MWCNT and AC through the direct writing technique were developed to be applied in the ozonation of oxalic acid in the liquid phase.

**Experimental/methodology.** The macro-structured catalysts were developed by direct writing printing. Sodium carboxymethyl cellulose (CMC) was used as a binder to prepare the inks, and deionized water was used as a solvent. Briefly, the carbon materials were mixed with CMC using ball milling equipment (at low frequency). Then the resulting mixture was wetted drop by drop and stirred until a workable rheology for printing was obtained. The mixture was immediately inserted into a syringe, and the printing process was carried out by applying controlled pressure. Macrostructures of AC and MWCNT with 20 wt.% of CMC (AC_20CMC and MWCNT_20CMC, respectively), and thermal treated MWCNT_20CMC at 250 and 500 $^{0}$C (MWCNT_20CMC_250 and MWCNT_20CMC_500, respectively) were prepared and tested in oxalic acid ozonation in a semi-batch system.

**Results and discussion.** Stable structures were obtained for all the prepared inks demonstrating that CMC is a viable binder for this purpose. Moreover, the manufactured thin MWCNT structures exhibited high flexibility, whilst the AC structures collapsed when some light pressure was applied. Thermogravimetric analysis confirmed the two selected temperatures for CMC degradation, and at 500 $^{0}$C, almost all CMC was degraded. In addition, the textural properties were determined, and $S_{BET}$ of MWCNT_20CMC (136 $m^2$ $g^{-1}$) increased with the temperature of the applied thermal treatments. The kinetics were determined at 30 min of oxalic acid ozonation reaction, and the catalyst MWCNT_20CMC_250 obtained the most promising results, followed by MWCNT_20CMC and lastly, MWCNT_20CMC_500. It was evidenced that 250 $^{0}$C is the optimal temperature to improve the catalytic properties, likely due to an optimal compromise between morphology and binder degradation. The AC structures crumbled into powder during the reaction, which is not feasible for the intended application of this work.

# Porous Tin-Organic Frameworks as a Selective Epimerization Catalysts for the Synthesis of Rare Monosaccharides

V. Toussaint[1*], T. Röper[1], L. Pavlis , I. Delidovich[1].

[1]*Institute of Chemical, Environmental and Bioscience Engineering, TU Wien, Vienna, Autria.*
[*]*valerie.toussaint@tuwien.ac.at*

**Keywords:** Porous organic frameworks, epimerization, isomerization, saccharides, aqueous solution.

Nowadays, the interest in biomass valorization in technological areas such as chemical, fuel and food industry is rapidly increasing. In this regard, the conversion of abundant into rare monosaccharides with significant application potential in medical and pharmaceutical industry is of great interest. [1]

Element-organic frameworks are a young class of nanoporous inorganic-organic hybrid materials. Recently, catalytic activity for epimerization of monosaccharides of Lewis acidic porous tin-organic frameworks (Sn-OF) was uncovered.[2a]

A few Sn-OFs were synthesized *via* corresponding lithium intermediates as summarized in Figure 1a starting from the linkers shown in Fig. 2b. The synthesized materials were characterized by elemental analysis, low-temperature $N_2$ physysorption, $^{1}H$, $^{13}C$, and $^{119}Sn$ MAS NMR, EXAFS, XANES, IR spectroscopy, and SEM. We currently work on elucidating structure performance relations of the Sn-OFs.

High reaction rates were achieved for epimerization of monosaccharides, i.e. glucose and xylose, whereas transformation rate of lactose dissacharides was two orders of magnitude lower. We explain this result by inaccessibility of the active sites located in micropores.The Sn-OFs were applied to convert readiliy available monosaccharides into rare and expensive products. The epimerizations of D-glucose to D-mannose, L-ribose to L-arabinose, D-xylose to D-lyxose, D-galactose to D-talose, and L-rhamnose to L-quinovose were explored. The conversion for Sn-OF-1 was in the range of 12-36% with a selectivity for the epimerization product of 77-90% at 100 °C after 1.5 h (Figure 1c). [2] The rare monosaccharides are highly demanded as precursors in pharmaceutical and food industries.[4]

Development of an efficient product recovery presents a key element of process design. We work on product separation *via* adsorption, focusing on elaborating materials with high affinity towards the desired products. For instance, D-mannose is selectively adsorbed on CaY zeolite from D-glucose-D-mannose, with separation factor up to 4.2, owing to complexation of the eq-ax-eq motive of D-mannose with $Ca^{2+}$ ions.

The results of this project will provide a knowledge-driven basis for manufacture of rare saccharides.

**Keywords:** ammonia decomposition, electric field, ruthenium

**Introduction.** Ammonia is regarded as a promising hydrogen carrier for on-site use as it has high $H_2$ content (17.6 wt%) and can be easily decomposed into $H_2$ and $N_2$ without liberating $CO_x$ and other impurities.[1] However, $NH_3$ decomposition requires high temperatures (> 500°C) even in the presence of catalysts. Ruthenium is by far the only catalyst that can give significant conversions at temperatures below 500°C, but full conversions at lower temperatures are still unattainable.[2] On the other hand, the application of an external electric field (EF) has been reported to lower temperatures and enhance catalyst activity for several reactions. In this study, we present the synthesis of Ru nanoclusters on $CeO_2$ via a facile support precipitation and impregnation route and investigated the effect of applying an EF on catalyst performance towards $NH_3$ decomposition.

**Experimental/methodology.** The $RuCeO_2$ catalysts were synthesized via a modified oxalate precipitation and impregnation route.[3] Catalytic tests were carried out on a fixed bed reactor equipped with stainless steel electrodes that are connected to a DC power supply. Effluent gases were then analyzed by GC-TCD.

**Results and discussion.** Catalysts with Ru loadings of 1, 2.5, and 4 wt% were synthesized and characterized, from which it was found that the catalysts possess high surface areas, small particle sizes, and good dispersion. The catalysts were then evaluated for $NH_3$ decomposition at GHSVs of 30,000 and 3,000 $mL_{NH3}/gcath$ with and without EF. As seen from Figure 1, significant increase in conversions at all temperatures were obtained upon applying an EF of 5mA current. Interestingly, considerable conversions were obtained at low temperatures in the presence of EF. Notably, $NH_3$ conversions reached a value of > 60% at T = 450°C and 30,000 $mL_{NH3}/g_{cat}h$, and > 90% at T=350°C and 3,000 $mL_{NH3}/g_{cat}h$, which are much higher than previous reports at the same temperatures. Moreover, catalyst conversion further improves with decreasing GHSVs, allowing the $4RuCeO_2$ catalyst to exceed equilibrium values at T = 250°C.

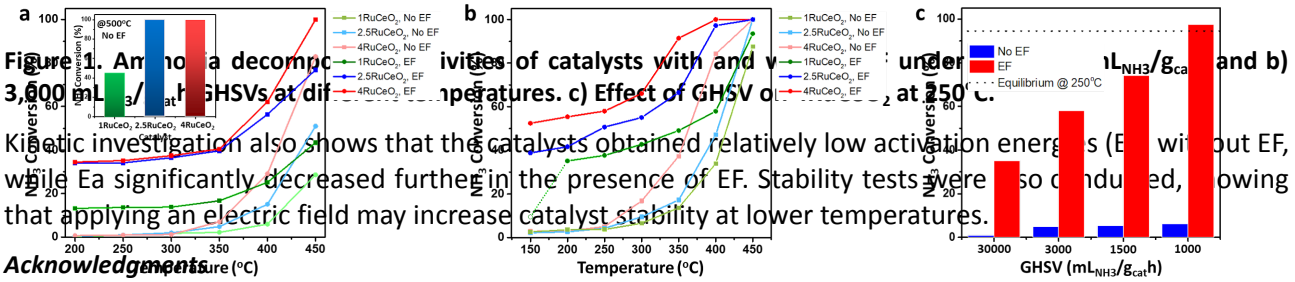

**Figure 1. Ammonia decomposition activities of catalysts with and without EF under $mL_{NH3}/g_{cat}$ and b) 3,000 $mL_{NH3}/g_{cat}h$ GHSVs at different temperatures. c) Effect of GHSV on $NH_3$ conversion at 250°C.**

Kinetic investigation also shows that the catalysts obtained relatively low activation energies (Ea without EF, while Ea significantly decreased further in the presence of EF. Stability tests were also conducted, showing that applying an electric field may increase catalyst stability at lower temperatures.

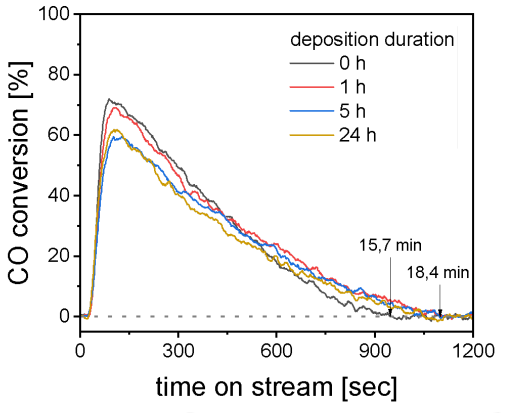
**Keywords:** CO oxidation, non-noble metal, moisture resistance, surface modificaton



**Introduction.** Oxidation catalysts for user-friendly air purification have the special requirement to be applicable at ambient conditions. This is especially challenging for catalytic materials in gas-mask applications because of highly humid conditions. A common catalyst for CO gas masks is e.g. the non-noble mixed metal oxide Carulite®, which suffers from deactivation from environment and breath humidity resulting in a decreased durability.[1] To improve the moisture resistance of catalysts various approaches use the hydrophobicity of carbon materials to prevent the adsorption of water on the catalysts surface.[1–3] The carbon modifications are carried out by pyrolysis of carbon precursors or attachment of carbon nanofibers. Here, we demonstrate the non-destructive polymerization of hydrophobic aromatics on the catalysts surface as new method for improved moisture resistance.

Schematic depiction of the VOC saturated dissicator

**Experimental/methodology.** The modification was carried out using Carulite® in a dissicator under saturated volatile organic compound (VOC) atmosphere for different durations. To remove unpolymerized VOC, the catalyst was dried over night at 150 °C. For screening the hydrophobicity and moisture-resistant catalytic activity, InfraSORP techniques were used to resolve the thermal response of heat of reaction and adsorption. Furthermore, 100 mg of the moisture resistant catalyst was tranfered into a reactor tube and activated at 120 °C for 30 min in synthetic air. The CO conversion was tested with 0.7 % CO in a 60 mL $min^{-1}$ synthetic air stream with 75 % relative humidity (r.h.). To determine the catalytic lifetime, the CO and $CO_2$ concentrations were measured and evaluated. $H_2O$, $N_2$-physisorption and elemental analysis were carried our for every sample while the most promising samples underwent closer characterization.

**Results and discussion.** First experiments revealed a simple and reproducible method to create humidity resistance at room temperature. The modified catalyst exhibits a smaller water uptake while it highlights a prolonged CO oxidation lifetime at 75 % r.h. and room temperature. The deposited carbon by CHNS analysis seems to be of no significant amount while TEM images could not reveal the morphology of deposited coke, yet. Further investigations are focussed on the The applied modifications on the catalyst and the influence of different VOCs.

CO removal over TOS at 75 % r.h. with commercial and modified Carulite®

**Keywords:** Zeolite, NaY, carbon, composite, microcrystals, nanocrystals, $CO_2$ adsorption.

**Introduction.** The continuous expansion of civil society, with the change in lifestiles and resources use, leads necessarily to an higher impact of the industrial facilities on the surrounding environments. As it is well known, nowadays $CO_2$ emissions are still one of the major effects of industrial pollution. The aim of this work is to show that composites zeolite/carbon materials could act as useful $CO_2$ adsorbants in the field of environmental preservation. Examples of such materials are widely used for the most diverse application, ranging from stabilizers for electrochemical batteries to enhance in thermal energy storage, or also for treatment of industrial waste water [1]. Usually, the approach that is used to obtain such composites is to disperse a precise amount of carbon from different sources (palm oil, coal, rice hulls, …) directly on the zeolite support.

**Experimental/methodolgy.** Here we propose a direct synthesis of the NaY zeolite with 3 different carbon sources (activated carbon - AC, carbon black - CB and graphite - GP) by hydrothermal method aimed at obtaining microcrystal-sized and nanocrystal-sized samples. In general, all ours samples have been characterized by SEM, FT-IR, XRD, TGA, $N_2$-physisorption and TPD techniques.

**Results and discussion.** Similar approaches already showed enhanced $CO_2$ adsorption properties in the case of carbon black composite with a zeolite 13X [2], while carbon black itself usually needs to be activated by surface modification (or coating) with an adequate $CO_2$ adsorbant [3]. This is consistent with ours result, as the pure carbon phases that have been used for the composites didn't show any $CO_2$ adsorption property at the investigated temperature before being coupled with the NaY zeolite. After confirming the Faujasite crystalline phase of each composite by XRD, SEM pictures showed an higher average diameter of the NaY-AC with respect to the other samples. However, TPD measurements of this sample exhibits amounts of adsorbed $CO_2$ that are quite comparable to the pure NaY zeolite, while in the case of the other composites this increase showing higher $CO_2$ adsorption performances for the NaY-CB and finally the best for the NaY-GP composite.

**Keywords:** nanoalloys, size selected clusters, subnanometer clusters, oxidative dehydrogenation

**Introduction.** Supported single atoms and subnanometer clusters of transition metals proved to be promising catalysts in various reactions, including dehydrogenation processes that belong to the most important ones in the chemical industry for the synthesis of olefins and aromatic intermediates for the production of fine chemicals or polymers. With their high surface-to-volume atomic ratio, and most of the atoms being undercoordinated and therefore very reactive, subnanometer size clusters open new avenues for the design of new classes of high-performance catalysts with their activity and selectivity controllable at the atomic level [1].

**Experimental/methodology.** The synthesis of atomically precise $Cu_{4-n}Pd_n$ ($0 \leq n \leq 4$) clusters of select atomic compositions was performed in molecular beams in the gas phase and clusters of single size and composition deposited on commercially available ultrananocrystaline diamond (UNCD) support as well as on silicon wafers coated with thin layers of $ZrO_2$ and $TiO_2$ using atomic layer deposition. Catalytic tests were performed in a custom reactor under a continuous flow of a reactant mixture containing 0.3 % cyclohexene and 0.3 % oxygen seeded in helium at a pressure of 1.1 bar, in a temperature range from 25 °C to 400 °C and products analyzed on a mass spectrometer.

**Results and discussion.** The results show that by altering the composition of the cluster in an atom-by-atom fashion in synergy with the effect of support leads to significant changes in catalytic reactivity and selectivity, up to switching the selectivity between the main dehydrogenation products benzene and cyclohexadiene, and that as much to totally suppressed combustion to $CO_2$. For instance, to just illustrate the size, composition, and support effects, titania-supported monometallic Cu and bimetallic CuPd tetramers exhibit 100 % selectivity towards benzene. UNCD-supported $Pd_4$ clusters are highly active without any combustion to $CO_2$ despite the known potency of Pd as a combustion catalyst. Central results are shown in Figure 1, which shows a gradual change in the selectivity of zirconia-supported tetramers when changing the atomic ratio between Pd and Cu in an atom-by-atom fashion, ultimately switching selectivity from benzene to cyclohexadiene on the way going from $Pd_4$ to $Cu_4$.

**Figure 1:** Selectivity for benzene, cyclohexadiene and $CO_2$ at 400 °C for all tetramers $Cu_{4-n}Pd_n$ on $ZrO_2$.

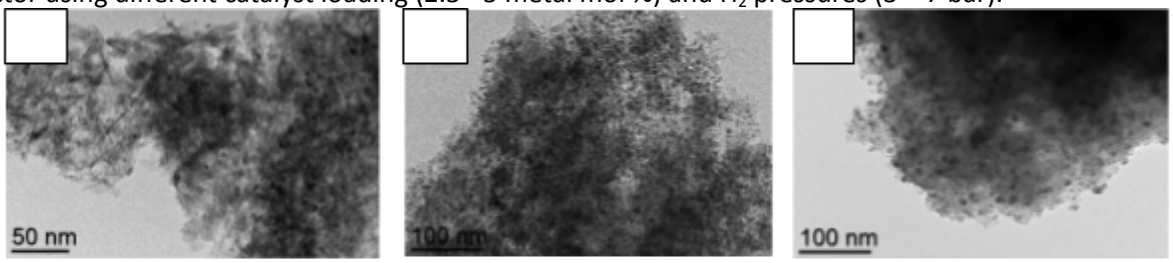
**Keywords:** hydrogenation, hydrodechlorination, polymers, ruthenium, nickel, palladium.

**Introduction.** Polymeric structure modification is a well-known methodology providing novel materials with tailored physical properties, thereby increasing the application range of the original polymer.[1] In particular, aromatic polymer hydrogenation catalyzed by Pd and Pt catalysts has been widely used to alter the polymeric chain.[2] On the other hand, Ni and Pd catalyst are commonly used in hydrodechlorination reactions under hydrogen atmosphere for small organic molecule modification[3]. However, in the case of polymers, these catalysts remain unexplored and radical-based reactions are preferred[4]. Those two strategies were applied to modify commercial polymers in the work herein presented.

**Experimental/methodology.** Supported Ru, Ni & Pd NPs (5-10 wt%, figure 1) were prepared by thermal decomposition of Ru(COD)(COT), $Ni(COD)_2$ or $Pd_2(DBA)_3$ in the presence of different supports (Carbon, Mesoporous Carbon, SiRAlOx, $TiO_2$). The synthesis was carried out under $H_2$, at temperatures ranging from RT to 150 $^0$C. Reactions over several polymers (PS, PPO, VDF-CTFE copolymer) were carried out in a glass FP reactor using different catalyst loading (2.5 - 5 metal mol %) and $H_2$ pressures (3 – 7 bar).



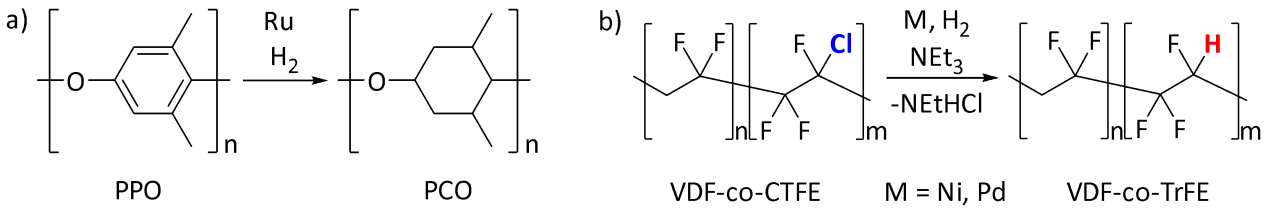


***Figure 1.*** *TEM pictures of selected Ru (a), Pd (b) and Ni (c) supported catalyst.*

**Results and discussion.** Ru NPs (Figure 1a) have been found to be active in aromatic polymer hydrogenation (PS, PPO), with low hydrogenolysis level (scheme 1a). Remarkably, different semi aromatic polymers could be obtained by modifying reaction temperature and support selection. Moreover, Pd and Ni NPs (Figure 1b and 1c, respectively) achieved selective hydrodechlorination (up to 80%) of VDF-CTFE, without affecting the fluorine moieties (scheme 1b). All these reactions were carried out under mild conditions (3 - 7 bar of H2, 423 K as maximum temp.).

**Introduction.** The necessity to diversify our resources and the general trend of reducing our $CO_2$ footprint has opened opportunities to produce chemicals, materials, and fuels from renewable feedstocks.[1] In this context, the sugar platform is now the subject of intense investigations. Gluconic acid is a highly valuable chemical used as a platform molecule in many industrial processes. Nowadays, its synthesis is achieved via the enzymatic oxidation of D-glucose, which has many disadvantages, such as poor productivity and wastewater generation. Precious metals have also been extensively tested for this process, but their practical applications are impeded by low selectivity, large energy consumption and high cost. Therefore, the development of more effective and cheaper processes should be a promising strategy for traditional technologies. In this context, photocatalysis has been developed and some authors reported the use of graphitic carbon nitride (g-$C_3N_4$) as semiconductor material, but giving low selectivity to the desired products.[2] In this work, a highly defective g-$C_3N_4$ was synthesized, to which different Fe quantities were incorporated by a solvothermal method. The solids were successfully used as photocatalysts in the oxidation of glucose in the presence of $H_2O_2$. In addition, cellulose degradation to glucose and subsequent oxidation to the main products, was also carried out in the presence of $H_2O_2$ or air. Reaction conditions: catalysts loading, substrate and oxidant concentration and time were optimized.

**Experimental/methodology.** Catalysts were synthesized by a solvothermal method in a controlled air atmosphere using different precursors ratio (urea and guanidine chloride (GnCl)) and various Fe wt%. The catalytic reactions were performed in a glass reactor under irradiation between 280 and 380 nm, using the optimized concentration of $H_2O_2$, [sustrate]=0.5 g/L, and 15 wt% of catalysts. The reaction medium withdrawal was characterized by HPLC-RI using a ROA-sugar as column. Catalysts were fully characterized by XRD, SEM, TEM, XPS, ICP, BET, Raman and elemental analysis before and after reaction.

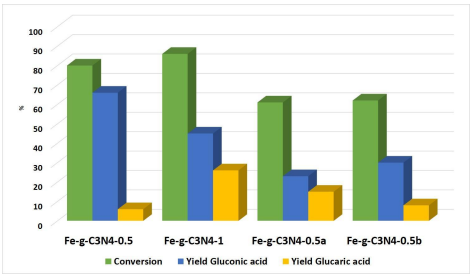

**Figure 1.** Catalytic oxidation of glucose. Reaction conditions: time=120 min, catalyst=15% w/w ,[Glucose]=0.5 g/L $VH_2O$=5 mL, irradiation=280-380 nm, [$H_2O_2$]=30% a. 4% of Fe; b. Cellulose was used as substrate

**Results and discussion.** Figure 1 shows the main results of the oxidation of glucose to gluconic or glucaric acid. The catalysts synthesized with a ratio 1Urea:0.5GnCl (Fe-g-$C_3N_4$-0.5) show the best selectivity to gluconic acid, 82%. Changing the precursor ratio (1:1;Fe-g-$C_3N_4$-1) shifts the reaction's selectivity, making gluconic acid selectivity decrease to 50% and glucaric acid increase to 30%. A more defective solid might enhance selectivity to gluconic acid, which also increases the BET surface area, suggesting that structural changes may have caused more effective oxidation. Additionally, the amount of Fe plays an important role in catalytic activity, with solids containing at least 2% Fe having the highest activity and selectivity. When high quantities of Fe are used, the dispersion of this Fe is less effective, which results in a lower conversion. Excitingly, gluconic acid was also produced by degrading cellulose to glucose and then oxidizing it to gluconic acid using the most active catalyst, achieving an excellent yield and outlining the potential of this catalytic system. Additionally, air as oxidant was tested, but conversion and yield decreased considerably. After 5 consecutive runs, the optimal catalyst shows high recyclability and a slight decline in conversion as well as an increase in selectivity toward the main products. There will be a discussion of the features of the catalysts, SEM and XPS mainly, and the hypothesis as to why such a good yield of gluconic acid can be achieved. This work opens the possibility of obtaining valuable gluconic acid from solid waste such as cellulose using a new catalytic process.

# MOF-Derived Co/N Doped Carbons for the Nitroarene Hydrogenation Reaction

**D. Villalgordo Hernández[1], E.V. Ramos Fernández[1], J. Narciso[1]**

*[1]Instituto Universitario de Materiales (IUMA), Inorganic Chemistry Department, University of Alicante, Alicante, Spain*
*[*]dvh5@gcloud.ua.es*

**Keywords:** MOFs, doped carbons, heterogeneous catalysis, nitroarene hydrogenation.

**Introduction.**

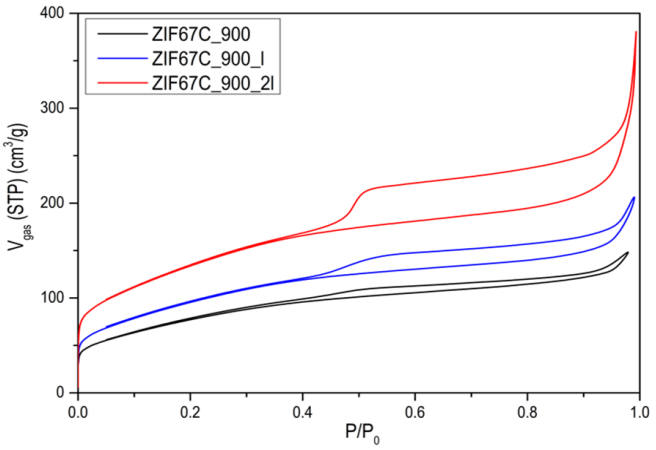
Reduction of nitroarenes is an efficient route for the production of functionalized anilines which are widely used in several chemical industries including pharmaceuticals, agrochemicals, dyes and polymers. Conventional processes applied in industry consist of non-catalysed reactions generating great amounts of waste products. There has since been an intensive research on heterogeneous catalysts towards the efficient and selective transformation of nitroarenes with various reducing sites into functionalized anilines. Supported metal catalysts such as platinum supported nanoparticles appear as a highly efficient option for this reaction. However, its lack of chemoselectivity and high cost raise the need for an alternative. Co-N-C are found to be extremely active and selective in nitroarene hydrogenation. Thus in this work a series of ZIF-67 (a Co and N containing MOF) derived carbons, with high content in Co and N have been obtained.

**Experimental/methodology.**

A simple room temperature synthesis has been carried out to obtain ZIF-67. Once the MOF is obtained it is pyrolized at various temperatures between 600-1000 °C in $N_2$ atmosphere. In some cases a Co leaching step has been performed.

**Results and discussion.**

A series of activated carbons have been obtained by pyrolisis of a Co and N containing MOF such as ZIF-67 in order to obtain a highly doped carbon material with a high density of active sites of the type Co-N which allow for the activation of the nitro group by means of the N sites as well as $H_2$ by the Co ones. A varying N content has been observed with its decrease as the carbon's porosity develops. Also a cobalt leaching process with 0'1 M HCl has beed tested to study carbons with a lesser content of Co which will be much more dispersed in the carbon structure. The greater dispersion of this theoretical active site appears to have a direct impact on its efficiency, as can be seen in Figure 1.b), reaching a complete conversion with a 100 % selectivity in half the time than its more concentrated counterpart.



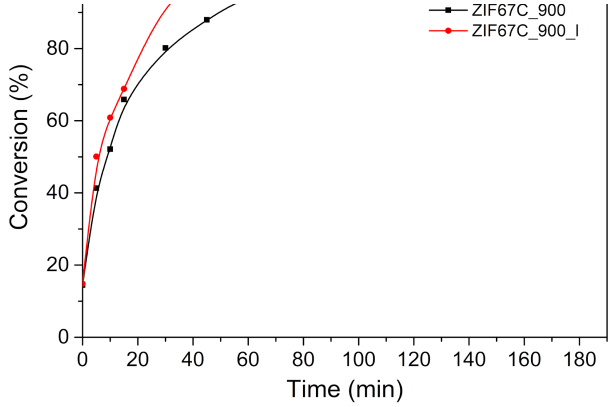


**Figure 1. a) $N_2$ adsorption isotherm for a series of ZIF-67 derived carbons, b) conversion rate of 4-Chloronitrobenzene for two carbonized ZIFs with varying Co content.**

# Pickering interfacial catalysis on the particles-stabilized foams

M. Pera-Titus[1*], K. Wang[1], S. Zhang[2], D. Dedovets[2],

[1]*Cardiff university institution, Cardiff University, Cardiff, United Kingdom*
[2]*Laboratoire du Futur (LOF), UMR 5258 CNRS-Solvay-Université Bordeaux, Pessac Cedex, France.*
[*]*PeraTitusM@cardiff.ac.uk*

**Keywords:** Pickering foams, Interfacial catalysis, POSS, Janus particles

**Introduction.** Gas-liquid-solid (G-L-S) reactions are widespread in the chemical industry. State-of-the-art G-L-S reactors are affected by the low gas solubility in liquids and mass transfer limitations due to low G-L and L-S specific interface areas. In practice, high pressure is often required to boost the gas solubility and promote mass transfer. A way out of these shortcomings is to engineer G-L-S reactors based on particle-stabilized microbubbles for conducting catalytic reactions at near-ambient pressure. This requires surface-active heterogeneous catalysts able to adsorb and self-assemble at the G-L interface (**Figure 1a**).
Herein, we rationally designed three particle designs bearing flurionated chains and Pd nanoparticles to generate non-aqueous catalytic foams (**Figure 1b**): (1) organosilicas with randomly distributed fluorinated chains; (2) amphiphilic 'Janus' organosilicas including oleophobic (or gasphilic) and oleophilic hemispheres, and (3) polyhedral oligomeric silsesquioxanes (POSS) combined with particles in (1).

**Experimental/methodology.** Fluorinated organosilicas (364 nm) (1) were synthesised by the Stöber method using 1H,1H,2H,2H-perfluorodecyltriethoxysilane (PFDTES), (3-mercaptopropyl-triethoxysilane (MPTES) and tetraethylorthosilicate (TEOS) precursors, with MPTES/PFDTES and TEOS/PFDTES molar ratios of 1 and 4, respectively.[1] The Janus silica particles (250 nm) (2) were synthesized by sequential grafting of PFDTES and MPTES in each hemisphere using the emulsion template method. Finally, the POSS particles (1-3 nm) (3) were synthesized by hydrolytic condensation of triethoxylphenylsilane in basic conditions, and were further functionalized with trichloro(1H,1H,2H,2H-perfluorooctyl)silane.[2] Pd nanoparticles (1 wt%) were selectively deposited by wet impregnation (1) and sol-immobilization (2). The foaming and catalytic properties of the different particles were surveyed for the benzyl alcohol - xylene - air system. The particles were characterized by TGA, FTIR, and $^{13}C/^{29}Si$ MAS NMR.

**Results and discussion.** The different particles exhibited a divergent catalytic performance in the aerobic oxidation of benzyl alcohol in xylene (1:1 v/v) at near-ambient pressure, which was correlated to the foamability. Fluorinated organosilicas (1) exhibited high activity at a stirring rate >750 rpm by generating foams with intermediate stability. Janus particles (2), with much lower fluorine content (7.8% vs 33%), displayed comparable foamability and activity. However, these particles required xylene to generate foams. In contrast, particle system (3) exhibited high foamability for pure benzyl alcohol, increasing the green footprint of the system. Foams could be generated for a broad library of organic solvents with different surface tension by simply tuning the ratio of Pd-containing fluorinated organosilica and POSS particles, which expands the utility and flexibility of the strategy.
In conclusion, the design of surface-active particles plays a crucial role in stabilizing non-aqueous foams and affects accordingly the catalytic activity for benzyl alcohol oxidation at near-ambient pressure.

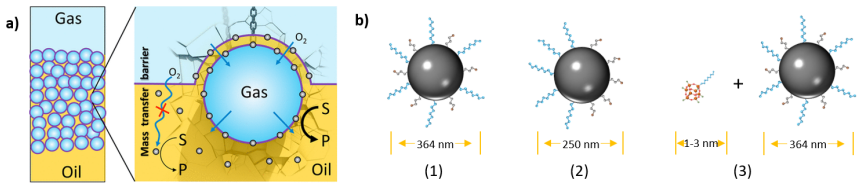

**Figure 1. a) Schematic of G-L-S reaction on the Pickering foams. b) Sketch of three particles; (1) Fluorinated organosilica; (2) Janus particle; (3) POSS particles + Fluorinated organosilica.**

# The Confinement Effect of $CeO_2$ Nanotubes Loaded Pd in $CO_2$ Hydrogenation to Methanol Reaction

Fengying Gao[1], Ning Wang[1*], Biaohua Chen[1]

[1]*Faculty of Environment and Life, Beijing University of Technology, Beijing 100124, China*
[*]*Corresponding Author's E-mail address: ning.wang.1@bjut.edu.cn*

**Keywords:** $CO_2$ hydrogenation, methanol, $CeO_2$ nanotubes, confinement effect

**Introduction.** The confinement effect of nanotubes loaded metal in catalytic reaction has increasing attention. By now, the confinement effect of $CeO_2$ nanotubes (NTs) loaded Pd in $CO_2$ hydrogenation to methanol reaction has still few reports.

**Experimental/methodology.** The of $CeO_2$ nanotubes with three different tube diameters was synthetized by adjusting the concentration of urea and NaOH solution. The catalysts of Pd in $CeO_2$ NTs and Pd out $CeO_2$ NTs were synthesize by ultrasonic-assisted vacuum impregnation method and direct impregnation method, respectively.

**Results and discussion.** In this study, the average inner diameter of $CeO_2$ nanotubes was 13nm,11nm and 9nm, respectively. The size of Pd particles in $CeO_2$ NTs was smaller than out through CO pulse adsorption because of the effect of tubal confinement effect. The results of HAADF-Mapping and XPS could be indicated that the solid solution $Pd_xCe_{1-x}O_{2-\delta}$ formed on the $CeO_2$ nanotubes loaded Pd after calcining. This solid solution $Pd_xCe_{1-x}O_{2-\delta}$ was confirmed to promote $CO_2$ adsorption in $CO_2$ hydrogenation to methanol reaction[1]. The performance evaluation are shown in Fig. 1. We can find the $CH_3OH$ selectivity showed an inverted U-type trend as the inner diameter of $CeO_2$ NTs decreases and the $CH_3OH$ selectivity of Pd in $CeO_2$ NT were higher than that of Pd out $CeO_2$ NT, simultaneously, the $CH_3OH$ selectivity of Pd in $CeO_2$ NT 12nm was the highest value (42%). However, the $CO_2$ conversion showed the opposite trend. And the $CO_2$ conversion of Pd in $CeO_2$ NT were lower than that of Pd out $CeO_2$ NT. We could tentatively speculate using these results that the smaller particle size promoted the improvement of methanol selectivity and the higher $CO_2$ conversion was because of the higher amount of $Pd^{2+}$ in the solid solution $Pd_xCe_{1-x}O_{2-\delta}$ of Pd out $CeO_2$ NTs. This work provides new insights into the confinement effect of metal oxide nanotubes.

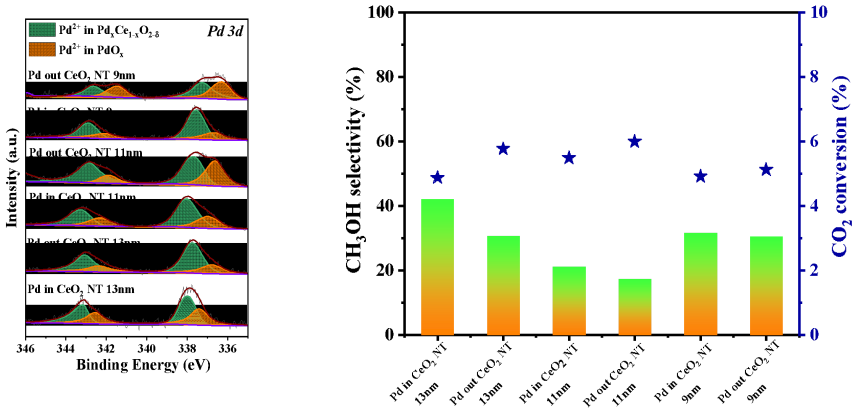

**Fig. 1.** XPS of $Pd/CeO_2$ NTs and the comparison of the catalytic performance of $Pd/CeO_2$ NTs in $CO_2$ hydrogenation to methanol reaction. Reaction conditions: 200mg catalyst,240°C, 3 MPa, $CO_2$:$H_2$:$N_2$=22:66:12, 10 mL $min^{-1}$, WHSV=3000 mL $g_{cat}^{-1}$ $h^{-1}$

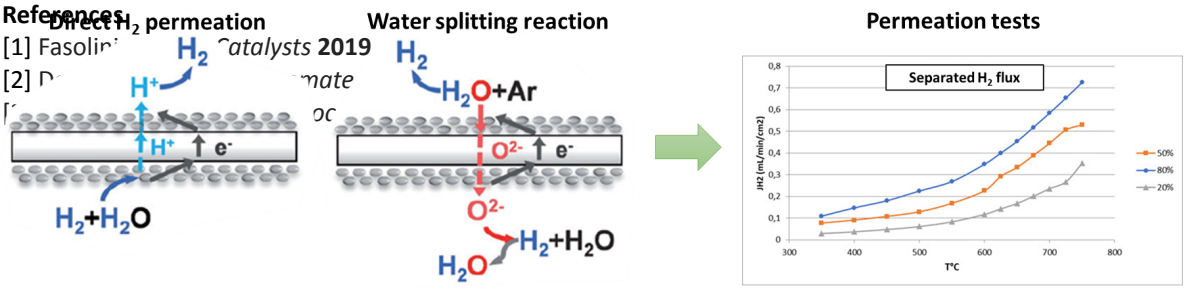
**Keywords:** Hydrogen, Water splitting, Pt deposition, ceramic membranes, $H_2$ purification

**Introduction.**

Hydrogen economy development is becoming a priority among the EU countries and is needed to fulfill the clean energy transition. However, the immediate availability of large amounts of green $H_2$ is hold back by scale up issues and the production and utilization of blue hydrogen is needed to speed up the development of the $H_2$ infrastructure. Blue hydrogen refers to fossil based hydrogen integrated with carbon dioxide sequestration in processes such as hydrocarbon reforming or catalytic partial oxidation [1,2].



Here, gas separation is a crucial step to yield pure hydrogen. In this context, ceramic hydrogen permeation membranes are a breakthroiugh system able to operate at the high temperatures used in the hydrogen producton processes (>500°C) unlocking the possibility of processes intensification. These membranes is based on a composite forming a thin dense ceramic layer allowing the permeation of $H^+$, $e^-$ and $O^{2-}$. The dense layer can be thinned by the production of a porous matrix (asimmetric membrane) that ensure the mechanical stability of the membrane system, allowing a higher permeation flux [3]. Here asimmetric dense ceramic membranes have been produced, to be applied, after the deposition of a Pt catayst, in the separation of hydrogen at high temperature.

**Experimental/methodology**

BCZY-GDC ($BaCe_{0.6}5Zr_{0.20}Y_{0.15}O_{3-\delta}$ - $Gd_{0.2}Ce_{0.8}O_{2-\delta}$) membranes with a porous-dense architecture were obtained by tape casting or freeze casting process with screen-printing. Pt was deposited over the membrane by impregnation, the membrane morphological properties were characterized and the hydrogen permeation tests were carried out in a double chamber reactor feeding a mixture of $H_2O$, He and $H_2$ at one side of the membrane and Ar and $H_2O$ as sweep gas at the other side.

**Results and discussion.**

The performances of the produced membranes were investigated modifying the operative conditions with particular attention to $H_2$ concentration and the operative temperature. The hydrogen permeation through the dense layer was postively affected by temperature and partial pressue and was related to two main phenomena: (i) the permeation of hydrogen as proton and electrons and (i) the possibility of occurrence of water splitting to produce hydrogen with inverse permeation of $O^{2-}$ and their reaction with $H_2$ at the hydrogen rich side of the membrane and thus producing as reactions sum the transfer of hydrogen from retentate to permeate (WS). The latter mechanism became predominant above 650°C allowing to push the hydrogen separation. From a catalytic point of view water splitting was highly affected by Pt distribution along the membrane. Here, its deposition was optimized and resulted in increased WS and $H_2$ permeation.

# Waste to Wealth: Fluid Catalytic Cracking Catalyst Synthesized from Solid-Waste Coal Gangue Minerals

Ruoyu Wang, Ye Song, Xue Yang, Wei Lin*

*SINOPEC Research Institute of Petroleum Processing Co., Ltd., Beijing, China*
**linwei.ripp@sinopec.com*

**Keywords:** coal gangue, Y zeolite, solid waste, self-combustion-depolymerization, FCC catalyst.

**Introduction.**

Globally, explorating efficient utilization technologies for coal gangue, a notorious hazardous solid waste, is one of the most important issues among current sustainable development topics. Herein, a green and energy-efficient self-combustion-depolymerization (SCD) approach is proposed to activate coal gangue into highly reactive silica and alumina species for in-situ crystallization of fluid catalytic cracking (FCC) catalysts[1-3].

**Experimental/methodology.**

FCC catalysts (SCD-Y) bearing in-situ generated Y zeolites can be readily fabricated via hydrothermal synthesis. In addition to conventional analytical characterization techniques, temperature-distance profiles acquired by a lab-scale drop-tube furnace (DTF) was used to evaluate the self-combustion behavior and the obtained SCD-Y were analyzed by X-ray micro-computed tomography (μ-CT).

**Results and discussion.**

Taking advantage of the heat released by the self-combustion of coal residue, the SCD activation of kaolin-type CG can be achieved at a medium temperature much lower than that required by natural kaolinite. Using microspheres mainly composed of SCD-CG as zeolization precursors, FCC catalysts bearing in-situ generated Y zeolites (SCD-Y) have been synthesized under hydrothermal conditions, and the zeolite crystals are fully exposed on its external surface. The as-prepared SCD-Y has a high crystallinity of ca. 50 % and a well-developed intraparticle macro-, meso- and microporosity, as revealed by BET, Hg intrusion and μ-CT. A comprehensive dissolving-crystallization microscopic model corresponding to the SCD-Y zeolitization process is proposed on the basis of kinetic study. Significantly, SCD-Y exhibits superior catalytic performance for cracking and prominent anti-deactivation properties for heavy oil conversion, demonstrating a gasoline boosting effect while suppressing dry gas and coke formation. Remarkably, the overall energy consumption (Etot) using this SCD approach (1429.65 kgce/t product) is 33.5% lower than that of the conventional semi-synthesis route (2151.37 kgce/t product). The green synthesis of FCC catalyst can be successfully achieved following this proposed SCD approach, which opens a broad field for energy-saving and high-efficient ultilization of solid-waste coal gangue minerals.

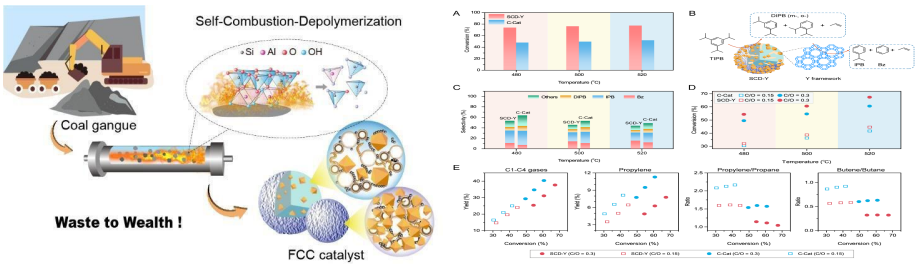

Fig.1 Schematic illustrations of the SCD approach proposed in this work using solid-waste coal gangue as the starting material. Fig.2 Catalytic cracking performances of SCD-Y and C-Cat

**Keywords:** Zeolite, Pd@ZSM-5/SiC, Monolith catalyst, Solvent-free synthesis

**Introduction**

Zeolite-based catalysts are localized in fixed-bed reactors in the form of powdered microgranules or extrudates, which are extensively used in the current practical processes, but the mass transfer on these catalysts still needs to be improved. In most reactions, temperature differences in the reactor caused by limited heat transfer is also known to lead to unsatisfactory catalytic performance. In order to overcome these problems, we investigate a promising strategy in which zeolite crystals are coated onto a monolith support. In pioneering studies, coating zeolite-based catalysts onto an SiC matrix were generally synthesized using the conventional hydrothermal route. This strategy is not very effective due to the production of undesirable wastes.

**Results and discussion.**

Here, we report a solvent-free crystallization process to coat ZSM-5 zeolite crystals on a monolithic SiC foam with a honeycomb structure (ZSM-5/SiC), as shown in Fig.1. Characterizations of the ZSM-5/SiC by scanning electron microscopy, $N_2$ sorption, and X-ray diffraction indicate that the zeolite sheath has been ideally coated on the surface of the SiC foam with high purity and crystallinity. Fixing Pd nanoparticles within the ZSM-5 zeolite crystals delivers a bifunctional Pd@ZSM-5/SiC catalyst, which exhibits high activity and selectivity toward diesel range paraffins in the hydrodeoxygenation of methyl oleate, a model molecule for biofuel. In comparison to the powder Pd@ZSM-5, the Pd@ZSM-5/SiC monolith catalyst shows more efficiency, which is attributed to the fast mass transfer and high heat conductivity on the honeycomb SiC structure. The durability test indicates that the Pd@ZSM-5/SiC catalyst is stable under the reaction and high-temperature regeneration conditions.

**Keywords:** Chemical hydrogen storage, LOHC, dehydrogenation, bimetallic, platinum, rhenium

**Introduction.** Hydrogen is considered a game changer in the global energy transition. However, while the gravimetric storage density of $H_2$ with a lower heating value (LHV) of 33.3 kWh $kg^{-1}$ is excellent, the volumetric storage density at ambient pressure is as low as 0.003 kWh $L^{-1}$. In consequence, existing technical storage solutions either compress $H_2$ to high pressures of up to 850 bar or store it in its liquid state at -253 °C.[1] Liquid organic hydrogen carriers (LOHCs) represent an emerging alternative and highly attractive way to chemically store and release $H_2$, which avoids transportation and storage of molecular $H_2$. For example, benzyltoluene (H0-BT) can reversibly bind 6 mol of $H_2$ yielding perhydro benzyltoluene (H12-BT). Such storage and transportation of $H_2$ in form of diesel-like liquids allows for utilization of existing infrastructure for liquid fuels. H12-BT is non-flammable, has a wide liquid range and a storage density for $H_2$ of 6.2 wt%.[1,2] However, up to 30% of the LHV of the released $H_2$ must be expended to provide sufficient heat for the dehydrogenation step if no external heat streams are available. First demonstrations plants for $H_2$ release operate at temperatures exceeding 300 °C.[2] Lowering the temperature of $H_2$ release during dehydrogenation is of utmost importance to increase the overall efficiency. Here, the generally slower reaction rates and other challenges, such as product desorption, demand novel catalyst materials, which may strongly differ from existing commercial solutions.[2,3]

**Experimental/methodology.** Herein, bimetallic Pt-Re/$Al_2O_3$ catalysts with various Pt:Re ratios were prepared and characterized to study the low temperature liquid phase dehydrogenation of H12-BT. The catalysts were analyzed by means of temperature programmed reduction (TPR), high-resolution scanning transmission electron microscopy coupled with energy-dispersive X-ray spectroscopy (HRSTEM-EDX), and *in situ* X-ray absorption spectroscopy (XAS) during catalyst activation in $H_2$.

**Results and discussion.** The bimetallic Pt-Re catalysts exhibited a superior performance during dehydrogenation of H12-BT at low temperatures (Fig. 1). Here, optimization of the Pt:Re ratio is crucial, while calcination and reduction temperature have little influence. Sophisticated *in situ* characterization of the catalyst suggests mostly structural promotion of Pt by Re resulting in a robust catalyst with a significantly enhanced activity when compared to a monometallic Pt/$Al_2O_3$ catalyst. The preparation of the bimetallic catalyst was scaled-up and shaped supports were employed to bridge lab-based catalyst development and commercial application of this novel dehydrogenation catalyst. Lastly, selective sulphur poisoning[3] was successfully demonstrated to suppress side reactions combining an accelerated $H_2$ release in with high yields of H0-BT.

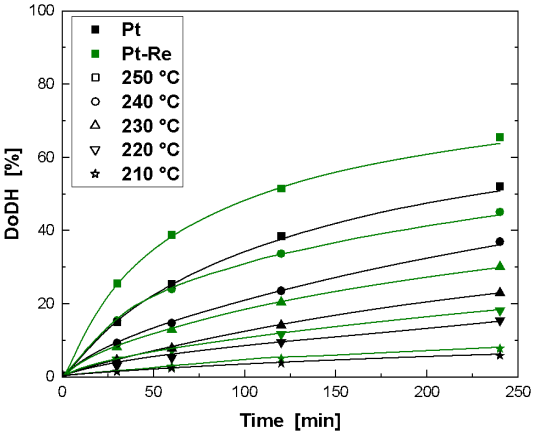

Fig. 1: Degree of dehydrogenation (DoDH) during semi-batch dehydrogenation of H12-BT at 1 bar using an optimized Pt-Re/$Al_2O_3$ catalyst in comparison to a Pt/$Al_2O_3$ catalyst.

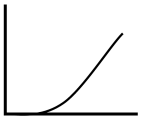
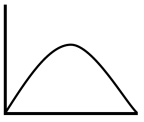
**Introduction.**





A potential key monomer in the industrial production of PET,[1] FDCA, can be produced *via* the full oxidative dehydrogenation of HMF utilising supported Au and Pd bimetallic catalysts. Recently, the separation of Au and Pd in supported bimetallic catalysts was demonstrated to enhance catalytic performance in such reactions through the coupling of separate redox reactions; an effect known as cooperative redox enhancement (CORE).[2] This effect differs from conventional synergistic interactions exhibited by Au-Pd bimetallic catalysts as the individual metallic properties, crucially, are unaltered. Deriving kinetic models based on our understanding of CORE, we can provide further evidence and acquire deeper understanding for CORE effects exhibited by bimetallic Au-Pd catalysts.

**Experimental/methodology.**

All the catalysts used in this study were prepared by the sol-immobilisation (SI) method, using polyvinyl alcohol as a stabiliser and carbon as the support. Catalysts were tested in glass reactors for the aqueous phase oxidation of HMF under $O_2$ (3 bar). Particle size distribution of the catalysts were determined using transmission electron microscopy (TEM) and metal oxidation states were probed by X-ray photoelectron spectroscopy (XPS). Au and Pd loadings were determined through catalyst digestion and Inductively Coupled Plasma Mass Spectrometry (ICP-AES).

**Results and discussion.**

TEM of the Au/C and Pd/C catalysts confirmed that the SI method was effective, with both catalysts exhibiting narrow particle size distributions of 3.0 and 4.3 nm, respectively. XPS analysis of the Au*4f* region and Pd*3d* region was conducted over the respective catalysts, confirming the metallic nature of the Au present. For the fresh Pd/C catalyst, a small proportion of $Pd^{2+}$ was observed with a $Pd^0$ /$Pd^{2+}$ at % ratio of 6.33. However, it is not anticipated that the proportion of $Pd^{2+}$ present in the fresh Pd/C catalyst will influence the rate of reaction, due to the consideration that the electron transfer between both metals are non-limiting. Microwave digestion of the solid catalysts followed by ICP-AES analysis confirmed both Au/C and Pd/C had an accurate loading of 1.0 wt%. The catalysts were subsequently assessed for the aqueous phase oxidation of HMF, enabling the derivation of kinetic models. The Au monometallic system conforms to the kinetic model at low Au masses, showing evidence for coupling between DH and ORR half-cells, where an above-linear enhancement arises. At high masses of catalyst and throughout the Pd data set, a linear the relationship between activity and metal moles is overserved. When the combination of both catalysts in a physical mixture occurs, the activity exceeds the sum of the two monometallic systems and therefore illustrating the significant enhancement which is driven by the CORE effect.

# Gold(III)-Crosslinked Single-Chain Nanoparticles as Sonogashira Reaction Recyclable Homogeneous Catalytic

Haonan Xiang,[1] Wenbin Yi[1*]

[1]Nanjing *University of Science and Technology, Nanjing, P.R. China*
[*]*Corresponding Author's E-mail: yiwb@njust.edu.cn*

**Keywords:** Homogeneous Catalysts, Single-Chain Nanoparticles, Recyclable Catalysts.

**Introduction.** Chemical catalytic systems for industrial and laboratory use are of fundamental importance in our daily lives. Catalysts not only activate inert starting materials but also improve reaction conditions and product selectivity. However, there is a constant need for further development and improvement of homogeneous catalytic systems due to its higher catalytic activity but difficult to separate and tend to remain in the final product.[1] Indeed, such an extraordinary system already exists in nature: enzymes.[2] Driven by a carefully selected sequence of building blocks, the sulfur-containing macromolecular chains are a group of attractive modern materials, due to their fascinating properties such as metal coordination ability.[3] Therefore, the development of sulfur-containing single-chain nanoparticles to ligand precious metals to achieve recyclable homogeneous catalysis effect is highly imperative.

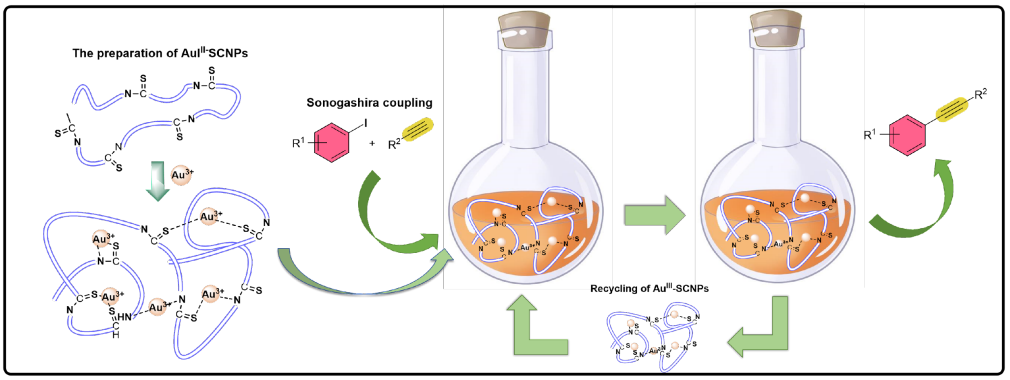

**Figure 1.** the preparation of gold(III)-SCNPs and its application in the Sonogashira coupling reaction

**Experimental/methodology.** Prepration of gold(III)-SCNPs: In a 10 mL aqueous solution of $AuCl_3$, ([$Mn^+$] = 100 mg/L, with 5 wt% $HNO_3$), 10 mg polythioamide was added respectively. After stirring at room temperature for 2 h, the suspensions were centrifuged for 10 min with a spin rate of 10000 r/min, and the solid gold(III)-SCNPs was filtered by a filter membrane with an aperture of 0.22 m.
Sonogashira coupling reaction: Iodobenzene, alkyne and $K_3PO_4$ were added in a Schlenk tube under $N_2$. Gold(III)-SCNP dissolved in dry DMF were subsequently added. The reaction mixture was stirred for 12 h at 120 ℃. The product yield was calculated by GC.

**Results and discussion.** In this work, benefit by the good solubility of the polythioamides prepared by secondary amines, the gold$^{III}$-SCNP can be the homogeneous gold catalyst in polar solvents and to bridge the gold catalyst gap between homogeneous activity and heterogeneous recyclability. To develop the practicality of this type of catalyst, Sonogashira coupling reaction can be realized with nearly 80% yield. To our delight, amplified gram-scale reaction and a wide range of Iodobenzenes and alkynes both participate in this gold catalys cross-coupling. Finally, we demonstrate that our current system allows for post-catalytic isolation and reuse of the gold$^{II}$-SCNP by precipitation in methanol and the activity of the recovered gold complexes was investigated in a second cycle of Sonogashira cross-coupling. With 1,2-diphenylethyne conversion of approximately 77%, the catalyst retains high catalytic activity, thus confirming them to be a recyclable homogeneous catalyst, obtaining high conversions while applying only 10 mol % of catalyst.

# Controlling the chemoselectivity of 3-nitrostyrene hydrogenation by modification of the interface of Pt catalysts

Lifeng Xiao[1*], Rongsheng Cai[2], Sarah Haigh[2], Meenakshisundaram Sankar[1*]

[1] *Cardiff Catalysis Institute, Cardiff University, Cardiff, UK*

**Keywords:** selective hydrogenation, strong metal-support interaction, interfacial site

**Introduction.** The hydrogenation of 3-nitrostyrene (3-NS) is a model reaction to probe the industrially relevant chemoselective reduction of a vinyl (C=C □ C-C) or nitro group ($NO_2$ □ $NH_2$) over a catalyst. Hutchings[1] and Corma[2] have proposed that strong metal-support may influence chemoselectivity towards 3-vinylaniline (3-VA) during this reaction. This work investigates how the interaction between metal (Pt) and support affects the chemoselectivity of this reaction between different supports ($TiO_2$ and $Nb_2O_5$). To further identify the active site for chemoselectivity, the interaction between metal and support was modified by preparing a catalyst using the sol-immobilization (sol-im) method and utilising further heat treatments to invoke changes in the interaction between metal and support. We found that interfacial sites played an important role in controlling chemoselectivity in this reaction.

**Experimental/methodology.** A series of 0.2wt%Pt/$TiO_2$ and 0.2wt%Pt/$Nb_2O_5$ catalysts were prepared wet-impregnation and sol-im method using PVA as stabiliser. A further heat treatment was applied Pt/$TiO_2$ sample to obtain the sample without PVA on the catalyst surface. The catalytic activity test was performed at 40 ℃ and 3 bar $H_2$. A comprehensive high-resolution microscopy (HAADF-STEM) study was applied to investigate these sample in morphology. CO-DRIFTS, XPS, XAFS and DFT experiments were also performed.

**Results and discussion.** Figure 1 shows that the chemoselectvity of Pt/$TiO_2$ is towards to 3-VA and keeping at high selectivity even at high conversion, whilst for Pt/$Nb_2O_5$, 3-NS hydrogenation is chemoselective to 1-ethyl-3-nitrobenznene (3-ENB). CO-DRIFTS and HAADF-STEM of these two catalsyts shows that the Pt particle structure is same. According to our further characterization by XPS, XAFS and DFT, the diference in the interfacial site between these two catalsyts determines whether the adsorption of nitro or vinyl group is more favourable, leading to an inversion in the chemoselectivity. To further demonstrate the site responsible for chemoselectivity, Pt/$TiO_2$ catalysts were prepared by sol-im and tested as-prepared and after a calcination step. STEM analysis revealed PVA was blocking the interaction of Pt with the support for the as-prepared catalyst. However, in the catalyst that underwent a further heat treatment, the Pt particle was observed to be in direct contact with the support with no residual PVA stabiliser around Pt particle using STEM imaging. As shown in Figure 2A, the catalyst prepared by Sol-im method and has no contact with the support, the selectivity is towards to 3-ENB. Whereas, the catalysts prepared without PVA or are subjected to further heat treatment to remove resiudal PVA, the selectivity is reversed to 3-VA. Our conclusion, combining the results of catalytic performance, is that the PVA blocked the interface of metal and support, which lead to the difference in chemoselectivity between these two samples and demonstrates the importance of the Pt/$TiO_2$ interface for the selective reduction of the 3-NS to 3-VA.

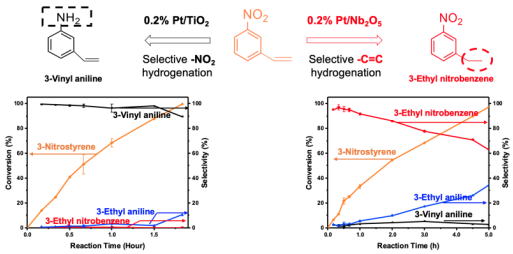

**Figure 1.** Catalytic performance of sample prepared by wet-impregnation with different supports.

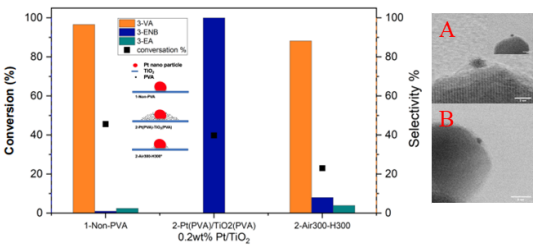

**Figure 2.** Catalytic performance of sample prepared by sol-im sample and sol-im with further heat treatment and wet-impregnation.

**Introduction.** Flame aerosol synthesis (FAS) is an established method of synthesizing nanoparticles. It remains to account for the production of the majority of commercial nanoparticulate products including but not limited to carbon black, fumed silica, and the benchmark photocatalyst, P25 $TiO_2$.[1,2] FAS is a continuous flow process where precursor vapors or micro-droplets are fed to a flame, pyrolyzed, and form nanoparticles as an aerosol.[3] The recovery of the particles from the aerosol is less energy consuming than separation of a slurry due to the difference in viscosity, and the waste treatment is simpler because with properly selected precursors, the exhaust of FAS is hardly different from that of a gas burner. In laboratory studies, the high reaction temperature of FAS (typically >1500 °C) and the tunable redox environment provide a versatile platform that has facilitated the synthesis of almost all nonradioactive metal oxides and noble metal nanoparticles.[3] They have found a wide range of applications in thermo- and photocatalysis.[4-7] Moreover, by aiming a particle-laden flame at a substrate, nanostructured films can be prepared without separating the particles, which is an attractive synthesis strategy for electrochemical devices.[8]

**Experimental/methodology.** In our lab, we have fabricated various catalysts using the FAS method,[5,6,9,10] including NiFe-P for electrochemical oxygen evolution, Cu for $CO_2$ electrochemical reduction and $NiO_x$-$SiAlO_x$ for oligomerization of ethylene.

**Results and discussion.** We have shown that FAS is a promising alternative method for fabrication of nanocatalysts with controllable properties.

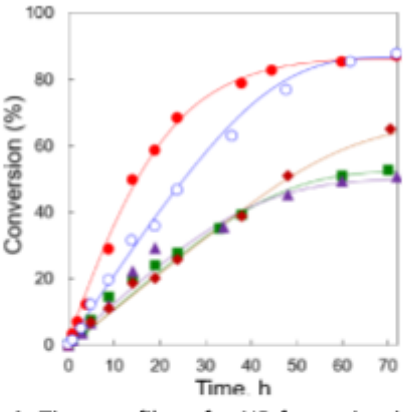
**Keywords:** pesticide, insecticide, europium, terbium

**Introduction.** Residual organophosphates after using pesticides and insecticides found in soils, irrigation, and air should be removed to prevent adverse effects on human health. The residual organophosphates are usually removed by suitable adsorbents such as activated carbon, however, those at high concentrations cannot be removed entirely due to the limited capacity of the adsorbents. Some metal ions including lanthanoid ions ($Ln^{III}$; Eu, Tb, etc) have been reported to act as homogeneous catalysts highly active for the hydrolytic reaction in an aqueous solution. Heterogenization of the metal ions is strongly demanded for easy handling, high robustness, and facile separation after the catalytic reactions. However, the heterogenization often results in reducing the catalytic activity due to the limited diffusion of substrates and specific adsorption of products on the catalyst surfaces. We report herein how to heterogenize $Ln^{III}$ ions in various matrices without losing catalytic activity for *p*-nitrophenyl phosphate (*p*-NPP) hydrolysis. The heterogenization of $Ln^{III}$-ion catalysts was examined by three methods, i.e., preparation of lanthanoid oxides ($Ln^{III}_2O_3$), immobilization of the $Ln^{III}$ ions on silica-alumina (Al-$SiO_2$) by the cation-exchange ($Ln^{III}$/Al-$SiO_2$), and cyano-bridged heterometallic coordination polymers containing $Ln^{III}$ ions ($[Ln^{III}(H_2O)_x]_y[M^C(CN)_6]$, Ln = Tb or Eu; $M^C$ = $Fe^{III}$ or $Ru^{II}$; $x \geq 2$) [1]. A class of cyano-bridged coordination polymers have been reported to exhibit high catalytic activity for the reaction.

**Experimental.** $[Ln^{III}(H_2O)_x]_y[M^C(CN)_6]$ complexes were synthesized as precipitates by mixing $K_a[M^C(CN)_6]$ and $Ln^{III}$ ions in aqueous media. *p*-NPP hydrolysis was performed in a mixed solution of HEPES buffer (pH 7.0) and ethanol (3:7 (v/v)) containing *p*-NPP and $Ln^{III}_2O_3$, $Ln^{III}$/Al-$SiO_2$ or $[Ln^{III}(H_2O)_x]_y[M^C(CN)_6]$ at 60 °C.



**Results and discussion.** The conversions of *p*-NPP to *p*-nitrophenol (*p*-NP) after 72 h for the reaction systems containing $Eu^{III}_2O_3$ (52%) and $Eu^{III}$/Al-$SiO_2$ (51%) were lower than that of corresponding $Eu^{III}$ ions acting as homogeneous catalysts in the reaction solutions (64%). On the other hand, the conversions of *p*-NPP for the reactions systems employing $Eu^{III}[Co^{III}(CN)_6]$ and $[Eu^{III}(H_2O)_x]_y[Ru^{II}(CN)_6]$ (88% for each at 72 h) were obviously higher than that of $Eu^{III}$ ions (64%) because of the enhanced surface acidity of the coordination polymers with trivalent $Co^{III}$ ions compared with that of divalent $Ru^{II}$ ions. Similar results were obtained for the reaction systems containing $Tb^{III}$ ions instead of $Eu^{III}$ ions. Thus, incorporation of Ln ions in cyano-bridged metal complexes is an effective method for heterogenization of catalytically active metal ions without losing but enhanced catalytic activity.

# A metal-free carbon catalyst for oxidative dehydrogenation of aryl cyclohexenes to produce biaryl compounds

Mingze Yang, Yongdan Li*

*Department of Chemical and Metallurgical Engineering, School of Chemical Engineering, Aalto University, Espoo, Finland*

** Corresponding author. Email: yongdan.li@aalto.fi*

**Keywords:** Biaryl synthesis, Carbocataylsis, Oxidative dehydrogenation

**Introduction.** Biaryls are a common structural unit in a wide range of fine chemicals, which find application in various fields, e.g., agrochemicals, pharmaceuticals, precursors of electronic materials, and ligands to metal ions or atoms [1]. This unit is also vastly present in natural products [1]. According to an early 2000s article, the biaryl structure exists in 4.3% of the known drugs, making it a crucial subunit for the pharmaceutical industry [2]. To avoid the toxic substrates and an unstable and precious catalyst in classic Pd-catalyzed coupling [3], the direct aromatization of functionalized aryl cyclohexenes via oxidative dehydrogenation (ODH) is a practical and potentially environmentally benign way [4]. Traditional ODH reactions are catalyzed by various transition metal and metal oxide catalysts. Over the past decade, carbon has been developed as a metal-free and green alternative catalyst for ODH reactions [5]. A wide range of carbon materials have been utilized as catalysts for ODH reactions, including both well-defined nanostructures and amorphous carbon. In addition, a broad range of substrates have been investigated However, to the best of our knowledge, the carbon-catalyzed ODH reaction of aryl cyclohexenes in the liquid phase to access biaryls is currently unreported. In this work, the carbon-catalyzed ODH of aryl cyclohexenes to biaryls is investigated and the applicability of this reaction is studied with 15 different substrates. The mechanism and active site of carbon catalysts are also discussed.

**Experimental/methodology.** Catalyst preparation: The commercial active carbon was treated with acid to remove all the impurities and treated with Air and Ar under heating respectively. The obtained sample was donated as air-oxidized active carbon($oAC_{air}$). Catalytic test: The reactions were carried at 140 $^{o}$C for 28 h under 5 bar $O_2$ pressure. The reactions were monitored with GC-FID and GC-MS (dodecane as the internal standard). Characterization: XPS, BET, FT-IR, SEM and Raman spectra were applied to characterize the catalysts. Catalyst model compound experiments, functional group blocking experiments and the effects of additives were carried out to confirm the mechanism.

**Results and discussion.** The developed $oAC_{air}$ catalyst offers improved efficiency, compared to other reported carbon allotropes like CNTs and graphite and is also comparable with metal catalysts. With the aid of kinetic study, the $oAC_{air}$ catalyst exhibited the highest activity (rate constant k= $9.1\times10^{-2}$ $h^{-1}$) and the activation energy was 54.5 kJ·mol$^{-1}$. The catalytic behaviour and robustness of the $oAC_{air}$ were confirmed by recyclability tests, which showed remarkable stability over six cycles. XPS analysis and BET analysis indicated the direct relationship between oxygenated surface area and activity. The dramatic decrease in the activity of the carbonyl group blocked catalyst and similar catalytic performance of phenanthrenequinone confirmed that the quinoidic carbonyl group is the active site of $oAC_{air}$ in the ODH reaction. The quinoidic redox cycle mechanism is proved via the active site and the acid effect, which is consistent with the carbon-catalyzed ODH of other substrates. Hammett plot suggests a positively charged intermediate and the structure of this intermediate is proposed. The substrate scope consisting of 15 differently substituted aryl cyclohexenes has proven the wide applicability of this ODH reaction.

**Keywords:** ed-shift absorption, alkali-atom modification, red-colored carbon nitride, TiO2 photoanode, photoelectrochemical water splitting

**Abstract:** Tuning the bandgap of a semiconductor to achieve strong band-to-band visible light absorption is highly desirable but challenging for photocatalysis. This work presents a facile molten-salt-assisted route to prepare red-colored polymerized carbon nitride (RPCN) nanosheets with a remarkable redshifted absorption and narrowed bandgap of 1.9 eV. Both experimental findings and theoretical calculations reveal that alkali heteroatoms are effective to tune the surface and electronic structures of carbon nitride, resulting in significantly reduced bandgap and excellent solubility. The RPCN-sensitized $TiO_2$ nanorod-based photoanode generates an impressive photocurrent density of ≈2.33 mA $cm^{-1}$ at 1.23 V versus reversible hydrogen electrode under Air Mass 1.5 G illumination without any cocatalyst, which is 2.6 folds higher than that of the bare $TiO_2$ photoanode. The new findings in this work could inspire the electronic structure engineering of semiconductor photocatalysts to greatly enhance the visible light absorption and provide a generic strategy to enhance the photoelectrochemical performance of wide-bandgap semiconductor photoelectrodes.

**Results and discussion.**

**bazzi@tamu.edu*

**Introduction.** Perylene diimide (PDI) has attracted great interest as an electron-deficient core featuring excellent optical, chemical, and thermal stabilities.[1] Polymeric systems containing PDIs have excellent flexibility, photo- and chemical-stabilities.

**Experimental.** Ring-opening metathesis polymerization[2] (ROMP)-derived mono-alkoxy poly(oxanorbornene imide) **PM1** and 1,7-di-alkoxy **PM2** bearing *bay*-functionalized perylene diimides (PDIs) were synthesized using ruthenium-alkylidene metathesis initiators (Scheme 1).

**Results and Discussion.** The monoalkoxy-derived PDI-based non-ladderphane polymer **PM1** displayed 67 to 77% of the *trans* olefin content in the polymer chain depending on the initiator used for the polymerization. In the case of the symmetrical 1,7-dialkoxy-derived PDI-based polymer **PM2** having the ladderphane type-structure, showed a significant amount of *cis* and *trans* olefin contents in the polymer chains, irrespective of the type of initiators used for the polymerization. ROMP of both monomers **M1** and **M2** proceeded in a well-controlled manner with a linear dependence of molecular weight on the monomer/initiator ratio. Optical properties of the ladderphane-based **PM2** and non-ladderphane-based **PM1** were characterized in both solution and the film state. X-ray diffraction (XRD) analysis for all the polymers showed significant π-stacking in the thin film state and the film morphology examined by AFM elucidated homogenous smooth polymer surface for both polymers in general, but with some irregularities observed for **PM1**.[3]

**Keywords:** CuO, $CeO_2$, TPR, XRD, PROX, DFT

**Introduction.**

Hydrogen production and purification are industrially important processes. Hydrogen is used for the synthesis of ammonia [1] and of numerous other chemicals [2]. $H_2$ is also used in fuel cells, but even ppm concentrations of CO poison the Pt electrodes [3]. The catalytic preferential CO oxidation (PROX) is thus a key reaction for removing traces of CO from the desired $H_2$-rich stream dedicated for fuel cells. Transition metal oxides, especially Cu-based catalysts has been shown to be efficient at low temperature for the PROX reaction.

**Experimental/methodology.**

The synthesis of $CuO/CeO_2$ nanosphere catalysts is based on the hard template method [4], with CuO nanoparticles loaded on the outer surface of hollow $CeO_2$ nanospheres by a layer-by-layer deposition technique. The presented characterization includes X-ray diffraction (XRD), high resolution transmission electron microscopy (HRTEM), CO- and $H_2$- temperature programmed reduction (TPR). For catalytic performance of PROX, the focus was on the effect of various pretreatment conditions. Additionally, density functional theory (DFT) modeling was applied to reveal the active site and low energy reaction pathways at CuO(111) .

**Results and discussion.**

The main objective of this work was to study the correlation between structure/oxidation state and the active sites/phases of Cu-based catalyst. Both, reduced and oxidized catalyst show almost the same PROX activity and selectivity. According to DFT modeling, investigating $O_2$, CO, and $H_2$ adsorption on CuO(111), two pathways for CO and $H_2$ oxidation were suggested, as displayed in Fig. 1. The results show that $Cu^+$ prefers CO adsorption, Fig. 1(a), which is energetically favored over $H_2$ adsorption, Fig. 1(b), indicating that CO oxidation is thus preferred. The spontaneous consumption of lattice O confirms that the oxidation process proceeds *via* a Mars-van-Krevelen (MvK) mechanism, in line with literature.

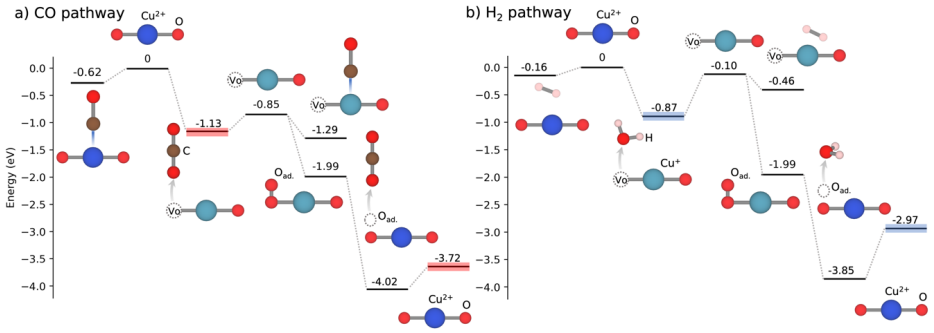

**Fig. 1.** a) CO and b) $H_2$ oxidation pathways on a CuO(111) surface.

Atomic layer deposition (ALD), a chemical vapor deposition process based on a sequential chemisorption of at least two reactants on solid surface, is an intriguing method for preparing heterogeneous catalysts with well-defined surface structures [1-2]. A recent study by Arandia et al. [3], related to this work, demonstrated the potential of zinc acetylacetonate [$Zn(acac)_2$] as an ALD reactant for tuning the surface properties of mesoporous metal oxide supports. Their study showed the beneficial effect of adding ZnO by ALD after the impregnation of copper on $ZrO_2$ for carbon dioxide hydrogenation into methanol [3]. Diethyl zinc (DEZ) is a well-known ALD zinc source. However, due to the pyrophoricity of DEZ, $Zn(acac)_2$ as a non-toxic reactant with a good thermal stability was regarded as an alternative option. This work focused on the details of ZnO ALD process used for catalyst preparation.

ZnO was added on mesoporous $ZrO_2$ (0.25-0.42 mm, BET surface area 54 $m^2/g$, median pore radius 8.3 nm) and $Al_2O_3$ particles (1.0 mm, BET surface area 158 $m^2/g$, median pore radius 4.6 nm) in a fixed bed ALD reactor. The ALD cycle was repeated up to three times for adding ZnO on $ZrO_2$. The $Zn(acac)_2$, which was vaporized at 120 ˚C, was chemisorbed on calcined supports at 200 ˚C for 3 h in the ALD reactor. The leftover acac ligands after the chemisorption were oxidatively removed in synthetic air in a tube furnace at 500 ˚C. Information on ZnO ALD on $ZrO_2$ was obtained by scanning electron microscopy (SEM) with energy-dispersive X-ray spectrometry (EDS), inductively coupled plasma-optical emission spectrometry (ICP-OES), in-situ diffuse reflectance infrared Fourier transform spectroscopy-mass spectrometry (DRIFTS-MS), density functional theory (DFT) calculations, X-ray photoelectron spectroscopy (XPS), and low energy ion scattering (LEIS). ZnO ALD on $Al_2O_3$ was analysed by ICP-OES, SEM-EDS, and in-situ DRIFTS-MS.

The zinc loading after one ALD cycle on $ZrO_2$ saturated to ca. 1.3 wt% (2.2 Zn $nm^{-2}$) while increasing amount of $Zn(acac)_2$ was pulsed through support bed. Meanwhile, the zinc loading on $Al_2O_3$ with higher specific surface area kept increasing (highest measured: ca. 2.5 wt%). XPS and XANES analyses revealed that zinc existed as $Zn^{2+}$. By EDS analysis, zinc was observed throughout a $ZrO_2$ particle with slightly lower zinc intensity near the centre of the particle. Meanwhile, an eggshell-type ZnO coating was observed on $Al_2O_3$ particles. These results indicate that the reaction of $Zn(acac)_2$ most likely reached the saturation on the $ZrO_2$ surface and not yet on the $Al_2O_3$ surface. DRIFTS results showed that acac ligands adsorbed on $ZrO_2$ were removed as $CO_2$ up to 500 ˚C, while 100 ˚C higher temperature was needed to remove them on $Al_2O_3$. LEIS analysis showed that the surface of $ZrO_2$ was efficiently covered by atomically distributed ZnO after the first ALD cycle, acting as a nucleation center for subsequent ALD cycles.

** chularat.w@vistec.ac.th*

**Keywords:** Intergrowth of zeolite, Zeolite synthesis, ETL/ERI zeolites

**Introduction.** The hierarchical zeolite with intergrowth structures exhibited many advantages over pure-phase zeolites or physical mixtures in terms of catalytic, sorptive, or molecular separation properties.[1,2] However, the development of the well-defined zeolite with intergrowth structures is still in an early stage and it often suffers from the competition of phase separation of several metastable polymorphs.[2] In addition, phase competition led to defect generation, and these defects can promote a different crystalline structure formation, referred to as intergrowths.[3,4] Herein, we demonstrate the synthesis of intergrowth zeolite of unique ETL and ERI frameworks by using a renewable silica source. In addition, the structural evolution of interfaces in ETL/ERI intergrowth zeolites has been successfully obtained. Finally, the perspectives of catalytic activity using ETL/ERI intergrowth zeolites in bioethanol dehydration to ethylene have been demonstrated.

**Experimental/methodology.** Herein, ETL/ERI intergrowth zeolites were synthesized using starting gel composition of $2.0ChCl:0.3Rb_2O:0.7Na_2O:0.25Al_2O_3:5SiO_2:100H_2O$. The characterizations, including XRD patterns, SEM, and HRTEM images, and $N_2$ adsorption/desorption isotherms, were used for obtaining the morphological, textural, and structural properties. The $NH_3$-TPD and *in-situ* FTIR using pyridine as a probe molecule were used to determine acidic properties, which are crucial for the catalytic performance of bio-ethanol dehydration.

**Results and discussion.** The different forms of ETL zeolite were obtained using various silica sources under both dynamic and static crystallization processes. For example, the pure ETL zeolite is obtained using commercial colloidal silica (CSi), whereas changing silica sources to renewable nano-silica particles (NSP) results in the formation of the ETL/ERI intergrowth zeolite. The reason of the different phase formation relates to a different rate of hydrolysis and condensation between CSi and NSP. For example, in the static mode, the amorphous was obtained after 1 day of crystallization time (CT), while the crystalline ETL/ERI intergrowth zeolites were obtained after 2 days of CT when applying with NSP as a silica source. After prolonging the CT, a maximum ERI content (21 RC%) was obtained at 6 days of CT. A combination of XRD, TEM, and ED results confirms that ETL/ERI interfaces exist, possibly derived from competitive ETL and ERI crystal formation (**Figure 1**).[3,4] The designed intergrowth ETL/ERI zeolites show the high ethylene yield (xx %) from bioethanol dehydration, whereas this situation cannot be achieved when using the pure ERI. This work opens up the perspectives of intergrowth zeolites for catalytic applications.

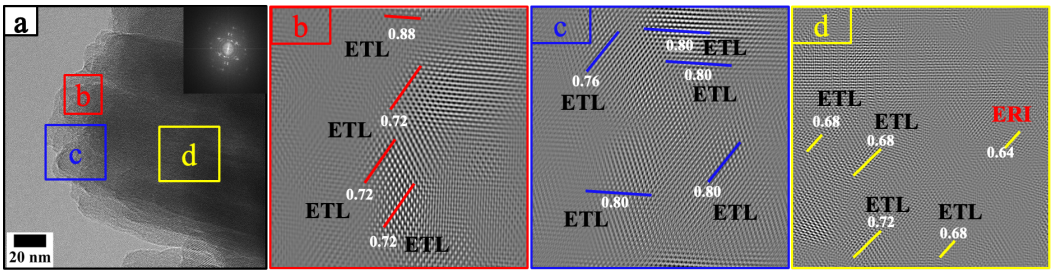

**Figure 1**. HR-TEM images of ETL/ERI intergrowth zeolite with respect to its Fast-Fourier Transform (a) and (b-d) the corresponding invert-FFT of the selected area images showing ETL and ERI phases.

**Keywords:** Ordered carbonaceous frameworks, Single-atomic metal species, Electrocatalysis

**Introduction.** Ordered carbonaceous frameworks (OCFs) are a new class of carbon materials with a three-dimensional ordered structure synthesized by simple carbonization of metalloporphyrin crystals with polymerizable moieties (Fig. 1). Carbonization *via* solid-state polymerization results in the formation of graphene-based ordered frameworks, in which regularly aligned single-atomic metals are embedded with a content as high as 9 wt%. These unique structural features afford molecular-level designability like metal organic frameworks (MOFs) together with high electrical conductivity and thermal/chemical stability.[1-5] Herein, we focus on a new type of precursor, metalloporphyrin possessing eight ethynyl moieties (**6**) to produce highly porous OCFs towards a variety of catalytic applications.

**Results and discussion.** Ni-porphyrin with eight ethynyl moieties (**6**) has been employed as the precursor. Microporosity was developed during the carbonization process, and the resulting OCF shows the largest recorded $S_{BET}$ of 673 $m^2$ $g^{-1}$ in OCFs thus far. In addition, the OCF with well-developed porosity demonstrates a unique mechanical flexibility that enables force-driven reversible transition due to the structure composed of a non-stacked graphene sheet.[6] In addition, the extension of metal species in OCFs to Co, Cu and Fe has been succeeded using the same metalloporphyrin frameworks (**6**). XAFS analysis reveals the retention of M-$N_4$ coordination units without metal aggregation in the resulting M-OCFs (M; Ni, Co, Cu, and Fe) prepared at 600˚C. Furthermore, a bimolecular crystal can be yielded by simple mixing and recrystallization process to produce Co-Cu bimetallic OCFs. SEM-EDS and HAADF-STEM-EDS clearly indicate the homogeneous dispersion of single-site Co and Cu species without segregation in the resulting OCF.[7] A series of catalysts with various types of single-atomic metal species allow the systematic screen of the catalytic performance. In the presentation, the potential catalytic applications and further development of the OCF family will be discussed.

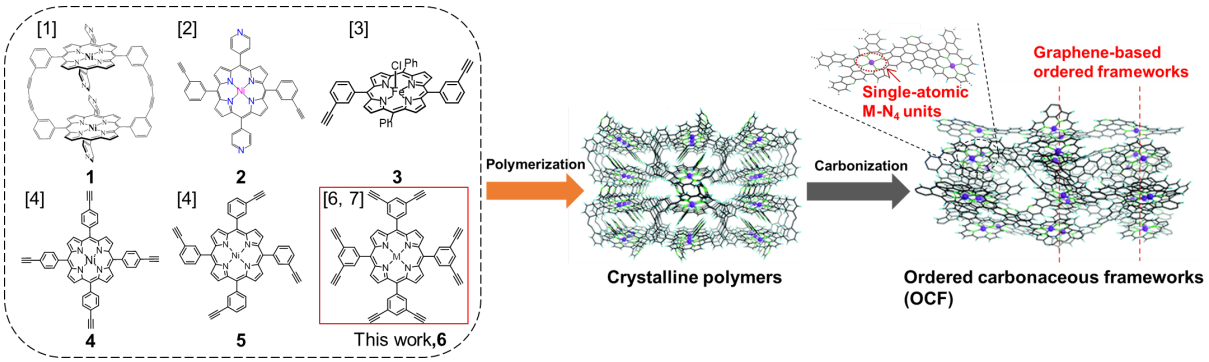

**Fig. 1** Synthetic scheme of OCFs by the carbonization of metalloporphyrins (**1**-**6**).

**Keywords:** Ethylene carbonate, $C_{60}$-$Cu/SiO_2$, methanol, ethylene glycol, electronic buffer.

**Introduction.** The conversion and usage of $CO_2$ are of increasingly significance. The synthesis of ethylene carbonate (EC) from $CO_2$ and ethylene oxide, followed by further hydrogenation to produce methanol and ethylene glycol (EG), is a relatively mild and effective technique of using $CO_2$. The first-step reaction has been industrially applied at ambient pressure. However, the hydrogenation of ethylene carbonate requires elevated hydrogen ($H_2$) pressure (typically 2–3 MPa) and temperature (200 °C) over the catalysts such as Cu, Ni, and others. Further, the poor stability of the catalysts severely blocks the industrial application, which is more challenge in low-pressure systems.[1] Recently, we have discovered that fullerene ($C_{60}$) as an electron buffer can tremendously enhance the performance of Cu catalyst ($C_{60}$-$Cu/SiO_2$) for the hydrogenation of dimethyl oxalate to EG at ambient pressure.[2] Here, we report the new progress on the structure-performance of $C_{60}$-$Cu/SiO_2$ in selective hydrogenation of ECs.

**Experimental/methodology.** The *x*$C_{60}$-20%$Cu/SiO_2$ (*X* = 0, 5%, 10%, 15%, and 20%) catalysts were prepared by a urea-assisted gelation procedure.[2] Briefly, $C_{60}$, urea, $Cu(NO_3)_2 \cdot 3H_2O$, and 28 wt% aqueous ammonia, were dissolved in 100 mL deionized water to form a suspension. Then, 40 wt% Ludox AS-40 colloidal silica was slowly dropping under mechanical stirring. The suspension was vigorously stirred at 363 K in an oil bath for 4 h. The solids were washed, dried and calcinated to obtain final catalysts.

**Results and discussion.** Compared with the $Cu/SiO_2$ catalyst, the addition of $C_{60}$ to $Cu/SiO_2$ showed different degrees of promotion effect, with the best one being 15 wt% $C_{60}$ (Figure 1). At almost ambient pressure, no deactivation of the catalyst was seen after 250 h (Figure 2). This is primarily due to that the addition of $C_{60}$ significantly promotes $H_2$ chemical adsorption and lowers the energy barrier for $H_2$ activation. Moreover, $C_{60}$ can act as an electron buffer to regulate the valence state of Cu species, which benefits the activation of C–O bonds in ECs.[2] We further find that that Cu promotes the combustion of $C_{60}$ in presence of air, and the phenomenon is observed more clearly by a thermogravimetric (TG) characterization in $N_2$ atmosphere. The available $C_{60}$ content, which is defined as the proportion of $C_{60}$ intimately contacted with the active Cu species by coordination, can be calculated by DTG curves measured in $N_2$ atmosphere (Figure 1). When this proportion is correlated with activity data, the results reveal the optimal coordination number of $C_{60}$ in $C_{60}$-20%$Cu/SiO_2$. Therefore, the finding may be set as a preliminary parameter for estimating the catalyst activity of $C_{60}$-20%$Cu/SiO_2$.

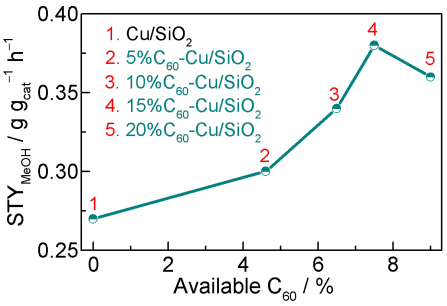

Figure 1. Catalytic performance of *x*$C_{60}$-20%$Cu/SiO_2$ samples with the different available $C_{60}$ contents.

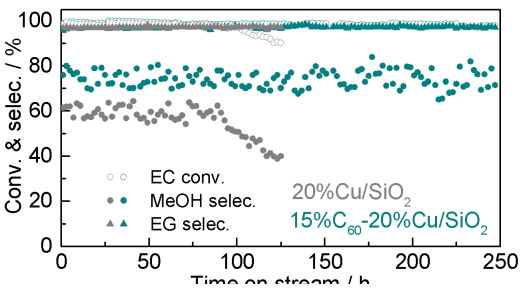

Figure 2. The stability tests in EC hydrogenation of $Cu/SiO_2$ and $C_{60}$-$Cu/SiO_2$ catalysts at 0.5 MPa and 453 K.

**Introduction.** The selective hydrogenation of the $NO_2$ group in nitrostyrene over heterogeneous catalysts is challenging due to strong dependency of selectivity to several factors, for example to the metal nanoparticles (NPs) size and geometry, and the nature of the support. Herein, we propose an in-situ synthesis approach to confine and control the size of Pt NPs within a non-polar Silicalite-1 (S-1, MFI type zeolite) to obtain active and highly selective catalysts for the selective hydrogenation of the $NO_2$ group in 3-nitrostyrene.

**Experimental.** Pt was confined in S-1 through an in-situ encapsulation procedure where the Pt precursor is introduced in the synthesis gel, yielding Pt@S-1 with ~1.2 nm Pt NPs dispersed in the zeolite micropores. The selectivity is evaluated in the hydrogenation of 3-nitrostyrene (NS), nitrobenzene (NB), styrene (ST), NB and ST binary mixture, and ST hydrogenation in presence of aniline (AN). The role of confinement on selectivity is studied by comparing the performance of Pt@S-1 with the supported homologue Pt/S-1 with similar Pt particle size (1.9 nm Pt NPs). The role of host polarity is studied by comparing the non-polar Pt/S-1 with the polar $Pt/SiO_2$-2.2 bearing Pt NPs of similar size (2.2 nm) to Pt/S-1. Finally, the particle size effect is evaluated by comparing the catalyst $Pt/SiO_2$-2.2 with the commercial $Pt/SiO_2$-3.7 (3.7 nm Pt NPs).

**Results and discussion.** The Pt@S-1 confined catalyst demonstrates excellent selectivity to $NO_2$ hydrogenation in 3-nitrostyrene (70-80%), threefold higher than the commercial $Pt/SiO_2$-3.7, and this selectivity is more stable at high conversions than the supported Pt/S-1 (Fig. 1a). ST and NB competitive hydrogenation reveals the critical role of the host polarity in determining selectivity. The polar $SiO_2$ support enables the hydrogenation of both NB and ST, with higher activity in the C=C hydrogenation (Fig. 1d,e). The non-polar S-1 support on the other hand strongly suppresses ST hydrogenation and favors NB hydrogenation. This observation is further confirmed by DRIFTS adsorption experiments showing that ST could displace adsorbed NB and vice versa over the polar catalysts, meanwhile only NB could replace ST adsorbed on S-1 based catalysts. For catalysts with the same host, those with smaller Pt NPs are less active in C=C hydrogenation. Finally, very high ST conversion rates are obtained over $SiO_2$-based catalysts in presence of AN (Fig. 1f), similar to those obtained for ST hydrogenation in the absence of NB (Fig. 1c); meanwhile it was much lower over the confined Pt@S-1 and affected to a lesser extent over Pt/S-1 suggesting the preferential adsorption of AN versus ST on the S-1 based catalysts.

In summary, the high $NO_2$ selectivity over Pt@S-1 in the hydrogenation of NS and NB + ST binary mixtures is explained by the lower C=C hydrogenation activity due to the decreased polarity of S-1 compared to $SiO_2$ on the one hand, and the smaller Pt NPs than the external Pt/S-1 due to size constraints imposed by confinement, on the other hand. The selectivity is further enhanced by AN adsorption on Pt@S-1 that decreases the efficiency to ST adsorption and hydrogenation compared to individual ST hydrogenation (Fig. 1c), thus explaining the stable selectivity at high conversions.

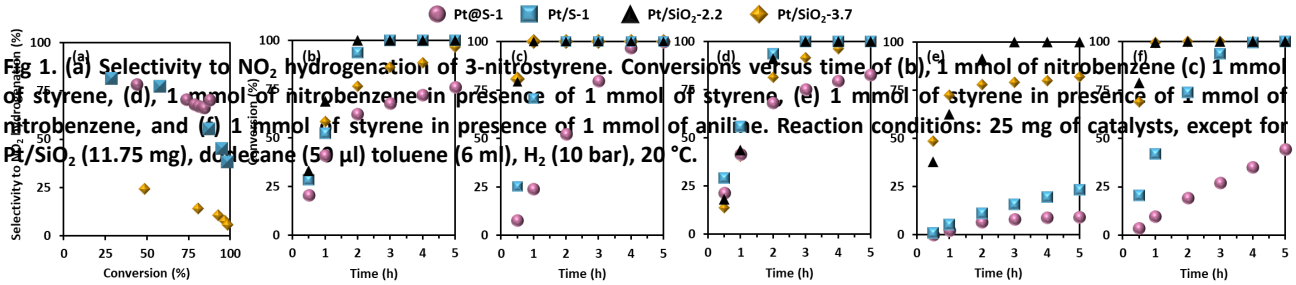

**Fig 1. (a) Selectivity to $NO_2$ hydrogenation of 3-nitrostyrene. Conversions versus time of (b), 1 mmol of nitrobenzene (c) 1 mmol of styrene, (d), 1 mmol of nitrobenzene in presence of 1 mmol of styrene, (e) 1 mmol of styrene in presence of 1 mmol of nitrobenzene, and (f) 1 mmol of styrene in presence of 1 mmol of aniline. Reaction conditions: 25 mg of catalysts, except for $Pt/SiO_2$ (11.75 mg), dodecane (50 µl) toluene (6 ml), $H_2$ (10 bar), 20 °C.**

# Determination of the mechanism of poisoning the catalytic surface with chlorine originating from the support precursor

**Keywords:** residual chlorine; methane reforming; mechanism; poisoning

**Introduction.** There are many reasons for the deactivation of catalytic systems. This can be caused by carbon deposits, sintering, or poisoning of the active surface. Many catalyst poisons e.g. phosphine, arsenic compounds, sulfur compounds, and chlorine block active surfaces. The aim of the work was to investigate and determine the mechanism of poisoning of catalytic systems with chlorine originating from the decomposition of the support precursor.

**Experimental/methodology.** The 20%Ni/5%$La_2O_3$-95%$Al_2O_3$ catalyst used in the study of the catalytic mechanism of surface poisoning was prepared in three stages. Initially, the $Al_2O_3$ support was obtained by precipitation using ammonia as a precipitating agent to obtain a pH of the solution in the range of 9-10. Then, the $Al_2O_3$ compound was used to obtain the $La_2O_3$-$Al_2O_3$ system using the wet impregnation preparation method. The nominal loading of $La_2O_3$ was 5%. Finally, the prepared oxide system was impregnated with nickel. The nominal metal content in the obtained catalyst was 20%.

The obtained catalytic system was subjected to physicochemical tests: X-ray diffraction (XRD), Time-of-Flight Secondary Ion Mass Spectrometry (TOF-SIMS), Temperature-Programmed surface reaction, and tests of catalytic activity in the mixed methane reforming (MRM) process. The volume ratio of the reaction reagents in each test was as follows: $CH_4$:$CO_2$:$H_2$:$H_2O$:Ar = 2:2:1:0.9:1.25 [1].

**Results and discussion.** In this work, the influence of the catalytic support precursor on the activity of the nickel catalyst in the mixed methane reforming process was investigated. TPSR tests carried out in a helium atmosphere showed that in the temperature range of 25 – 900 °C chlorine is removed from the system in the form of hydrogen chloride. However, this process is not 100% efficient. The use of TOF-SIMS analysis showed that the catalyst prepared with lanthanum (III) chloride after the reduction process showed significant chlorine poisoning of the system (Figure 1). Finally, the catalytic activity tests showed that the activity of this system is lower than the catalyst prepared with the use of lanthanum (III) nitrate (V) precursor (Table 1). The result of this work is the proposed mechanism of surface chlorine poisoning from the catalytic precursor.

**Table 1. $CH_4$ and $CO_2$ conversions for monometallic catalyst system prepared from nitrate and chloride support precursor.**

| Catalytic system /Support precursor | Conversion of $CH_4$ after 3h reaction | Conv of aft reaction |
|---|---|---|
| 20%Ni/5%$La_2O_3$-95%$Al_2O_3$ / Lanthanum (III) nitrate (V) | 71% | 68% |
| 20%Ni/5%$La_2O_3$-95%$Al_2O_3$ / Lanthanum (III) chloride (V) | 49% | 56% |

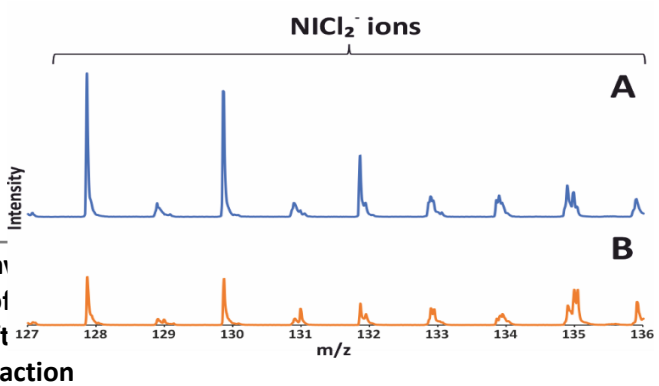

**Figure 1. TOF–SIMS spectra of the 20%Ni/5%$La_2O_3$–95%$Al_2O_3$ catalyst (after**

**Keywords:** Hydrogen, crude oil, crude−to−hydrogen , reforming.

## Introduction

Hydrogen demand has increased by around a 50 % since the beginning of the century due to the global growth of essential chemicals production and rising environmental requirements. The petrochemical industry is the leading consumer of hydrogen because it is necessary for a wide range of products. In this industry, ammonia (66 %) and methanol (22 %) are the main targeted products [1]. The one−step crude−to−hydrogen process is a promising route to obtain hydrogen directly from converting crude oil. This process can be carried out by steam (SR) or autothermal (ATR) reforming [2]. The crude−to−hydrogen process is interesting because it allows for obtaining hydrogen directly and it can take advantage of the existing infrastructure and know−how of refineries.

This work proved that crude−to−hydrogen is a promising alternative for hydrogen production directly from crude oil. We tested this process on a laboratory scale for several feeds of crude oil and catalytic technologies and with a preliminary cost analysis study with the current market values.

## Experimental/methodology

Several catalysts were prepared following various methods and charecterized by different techniques. The feed of mixed water and crude oil was a liquid (emulsion) or a gas−liquid (liquid crude oil pushed by steam). A HPLC pump controlled the feed of this mixture (water−to−oil w/o mass ratio= 6), to a packed bed reactor at $W/F_{Crude}$= 40 $g_{cat} \cdot g_{crude}^{-1}$ $min^{-1}$, 800 $^0$C, and 1 bar, using a 15 wt. % of $N_2$ as carrier and internal pattern. The collection of condensable products (*e.g.* water and heavy hydrocarbons) was a condensator operating at 10 $^0$C. These products were mainly water (>95 wt. %) and no further analyisis was performed over them. Non−condensable products were analyzed by an online GC. Coke formed in the catalyst was obtained from difference between initial and final mass of catalyst. The average mass balance was greater than 86 % for all catalytic tests.

## Results and discussion

Handling crude oil and water mixtures is a complex matter that we addressed by two ways. The first one was preparing emulsions with different w/o ratios that behave as non−Newtonian fluids but are stable. However, reaction results showed that their evaporation was uneven, causing pressure increase and making it unfeasible to operate. The second way was by pushing crude oil with steam. This way provided uniform evaporation and stable pressure for longer. Reaction results showed different performances for the tested catalyst. These resuslts can be correlated with catalysts properties, such as structure or metal content, and reaction conditions. In the best case, we achieved a maximum of 80 mol. % of hydrogen in the gas product stream and 14 h of uninterrupted operation. Our simulations showed that SR produces more hydrogen, but its energy costs are more significant, while ATR has a lower hydrogen production but has lower (and even close to zero) external energy demand. Because the needed equipment and infrastructure is the same as in any current refinery, the economic viability of the process depends mainly on the prices of the raw materials. Hydrogen production cost ($\$ \cdot kg^{-1}$) by crude−to−hydrogen is lower than that of natural gas SR when crude is below 40 $\$ \cdot bbl^{-1}$ and natural gas is above 8 $\$ \cdot MMbtu^{-1}$.

# Enhanced oxygen reduction reaction activity of $BaCe_{0.2}Fe_{0.8}O_{3-\delta}$ cathode for proton-conducting solid oxide fuel cells via Pr-doping

Xin Zhou, Jian Zhang, Yicheng Zhao* ,Yongdan Li[2]

[1]*Department of Chemical Engineering and Technology, Tianjin University, Tianjin, 300072, China*

**E-mail for Yicheng Zhao: zhaoyicheng@tju.edu.cn*

**Keywords:** Proton-conducting solid oxide fuel cell, Praseodymium doping Barium ferrite, Oxygen surface exchange.

**Introduction.** Under the global energy shortage and environmental pollution, solid oxide fuel cells (SOFCs), as efficient and clean power generation devices with wide fuel flexibility, have received extensive attention in recent years [1]. At a lower temperature, the cathode polarization dominates the cell loss of PCFCs [2]. Therefore, developing highly active cathode materials for PCFCs has become a research focus. Among the existing cobalt-free PCFC cathodes, mixed ionic-electronic conducting $BaFeO_{3-\delta}$-based materials have been widely studied considering the low price, and good chemical stability. In recent years, Pr has been used as a dopant in electrode materials of SOFCs. In this work, Pr is partially substituted for Fe in $BaCe_{0.2}Fe_{0.8}O_{3-\delta}$ as a cathode material for PCFCs. The effects of the Pr-doping on the surface property and oxygen surface exchange kinetics are studied.

**Experimental/methodology.** Cathode powders of $BaCe_{0.2}Fe_{0.8}O_{3-\delta}$, $BaCe_{0.2}Fe_{0.7}Pr_{0.1}O_{3-\delta}$, $BaCe_{0.2}Fe_{0.6}Pr_{0.2}O_{3-\delta}$ and $BaCe_{0.2}Fe_{0.5}Pr_{0.3}O_{3-\delta}$were synthesized through an EDTA-citrate sol-gel method [3]. Stoichiometric $Ba(NO_3)_2$, $Fe(NO3)_3 \bullet 9H_2O$, $Ce(NO_3)_3 \bullet 6H_2O$and $Pr(NO_3)_3 \bullet 6H_2O$ were dissolved in deionized water at 60 °C. Then citric acid and EDTA were added to the aqueous solution at a molar ratio of 1:1:1.5 for total metal ions: EDTA: citric acid. The solution was stirred at 90 °C until a yellow gel was formed, which was subsequently heated to 350 °C for 2 h, and then calcined at 1000 °C for 5 h. $BaZr_{0.1}Ce_{0.7}Y_{0.2}O_{3-\delta}$ electrolyte was prepared through a solid-state reaction method [4]. The anode substrate and the BZCY electrolyte powders were co-pressed at 300 MPa and then calcined at 1350 °C for 5 h. The cathode slurry was screen-printed on the electrolyte layer, followed by calcination at 950 °C in air for 3 h.

**Results and discussion.** The cathode is composed of a cubic $BaFeO_{3-\delta}$ phase and an orthorhombic $BaCeO_{3-\delta}$ phase, and Pr is doped in both phases. The partial substitution of Pr for Fe decreases the content of the $BaFeO_{3-\delta}$ phase, leading to lower electrical conductivity. $BaCe_{0.2}Fe_{0.6}Pr_{0.2}O_{3-\delta}$ has the most adsorbed oxygen and $Fe^{3+}$ on the surface, resulting in the fastest oxygen surface exchange kinetics and the highest activity. The partial pressure of $H_2O$ shows a negligible effect on the polarization resistance of the cathode. In contrast, the polarization resistance increases remarkably with the decrease of oxygen partial pressure, indicating that the rate of the cathode process is controlled by the surface exchange of oxygen. At 700 °C, $BaCe_{0.2}Fe_{0.6}Pr_{0.2}O_{3-\delta}$ shows the lowest polarization resistance of 0.057 Ω $cm^2$, and a single cell with that cathode exhibits the highest maximum power density of 562 mW $cm^{-2}$.

# Boosting of metal-support interactions between Ru with sodium titanate nanowire on the hydrogenolysis of polyolefins under mild conditions

Xueping Zhang[1], Guo-Ping Lu[1]

[1]*School of Chemistry and Chemical Engineering, Nanjing University of Science & Technology, Xiaolingwei 200, Nanjing 210094, China*

**Keywords:** hydrogenolysis of polyolefins, metal-support interaction, Ru nanoparticles, sodium titanate nanowires, liquid alkanes

**Introduction.** Polyolefin is the most widely used plastic, accounting for about 57% of the total plastic in the world [1], and its non-degradable properties make the recycling of plastic waste the most important link in "plastic control" [2]. The catalytic hydrogenolysis of polyolefins has attracted wide attention because of its relatively mild reaction conditions, good reaction activity and good product selectivity. Therefore, it is of great practical significance to explore the catalysts for hydrogenolysis of polyolefins. Ru, as one of the most active metals in the hydrogenolysis of polyolefins with C-C bond, provides an excellent choice for the hydrogenolysis of polyolefins [3]. It has been found that the support type has a great influence on the performance of Ru catalysts for hydrogenolysis of polyolefins. Herein, we explore a Ru catalyst supported on sodium titanate nanowires for hydrogenolysis of polyolefins.

**Experimental/methodology.** In the synthesis process of Ru/NTO-NH, sodium titanate nanowires (NTO) were first prepared by hydrothermal stirring approach, Ru was loaded on NTO by impregnation reduction approach, and the metal-support interaction (MSI) was adjusted by changing the calcination process parameters. In addition, the Ru/NTO-NH catalyst has better catalytic performance than general Ru/$TiO_2$ catalyst. Under the reaction conditions of 180 °C, 1 MPa $H_2$, and 8 h, it can effectively convert low-density polyethylene (LDPE) to high selective hydrogenolysis to high value liquid alkanes.

**Results and discussion.** In this work, a series of novel NTO supported Ru catalysts have been developed, in which significant MSI between Ru and NTO are observed. Ru/NTO-NH has stronger MSI than other Ru catalysts, which is attributed to sequential N2 calcination and H2 reduction. The improved MSI of Ru/NTO-NH is conducive to the formation of smaller, more positively charged and NTO coated Ru NPs, which results in higher H coverage rate and weaker alkane adsorption capacity. Therefore, this catalyst is beneficial to the hydrogenolysis of LDPE internal C-C bonds under mild conditions (180 oC, 1 MPa), leading to full conversion and high selectivity to liquid alkanes (88%). The hydrogenolysis of other polyolefin plastics including HDPE, PP, LDPE plastic bags can be also achieved by Ru/NTO-NH with good conversion and selectivity. It also exhibits excellent stability and recyclability, and no significant activity degradation is observed after 10 runs.

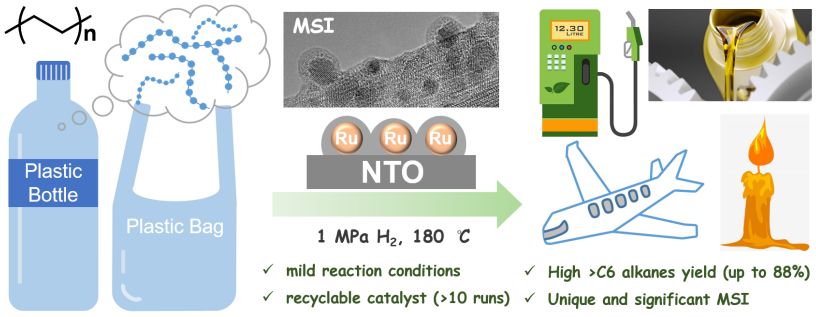

**Figure 1.** Catalytic application of Ru/NTO-NH catalyst in hydrogenolysis of plastics.

**Keywords:** Catalytic hydrogenation, Nitrobenzene, Furfural, Halloysite.

**Introduction:** Noble metal (NM) mediated catalytic hydrogenation is an important topic in the chemical industry, which provides a clean and environmentally friendly strategy to produce highly valued commodities. However, the high cost and scarcity of NMs has limited their use or scalability. The use of NM nanoparticles (NPs) confined to the inner surface of nanotubes has emerged as an attractive methodology to achieve this goal [1]. One interesting material for this purpose are halloysite nanotubes (HNT), which have an alumina inner wall and a silica outer wall [2]. Selective functionalization of the inner surface of HNT could provide metal NP-based catalysts with significant efficiency and operational stability. On this way, this contribution is aimed in the synthesis and catalytic evaluation of Pd nanoparticles supported onto the inner surface of organo-modified halloysite to provide highly efficient and operational stable catalysts for the hydrogenation of two kind of molecules: (1) nitrobenzene (NB) to produce aniline (AN) as model reaction for the production of amines of pharmaceutical interest and (2) furfural (FUR) to produce 2-methyl furane (2MF) or tetrahydrofurfuryl alcohol (THFOL) as model reaction for biomass valorization [3].

**Experimental/methodology.** The halloysite nanotubes were pre-treated by pyrolysis at 400°C. Then, the inner surface was organo-functionalized by contacting the halloysite with dopamine hydrochloride (DOPA) in ethanol (DOPA/HNT = 0.01 mass ratio) in an Ar atmosphere. The deposition of the Pd NPs was carried out using a methanolic solution of palladium (II) chloride precursor, which was contacted with the organo-functionalized nanotubes and dried in vacuum to obtain the final solid. Different palladium metal loadings 0.25, 0.50, 1.0 and 2.0% (w/w%) were evaluated. The solids were pyrolyzed and reduced with $H_2$. The obtained catalysts were characterized by the following techniques: TGA, NMR, ICP-MS, $H_2$-Chemisorption, XRD, Nitrogen adsorption isotherm, SEM-EDAX, TEM and XPS. The catalytic activity of the catalyst was evaluated in NB as well as FUR hydrogenation using ethanol or dodecane as solvents, respectively, at 30°C and 10 bar of $H_2$ pressure for NB and 120°C and 20 bar of $H_2$ for FUR, with constant magnetic stirring. The reactions were quantified using GC-FID.

**Results and discussion.** The physicochemical characterization of the Pd supported catalyst displayed that the HNT-DOPA surface area decrease after the DOPA immobilization. In addition, TGA show that the organic content on the support was similar to the nominal loading value. In addition, the $H_2$-chemosorption indicate a decrease of the metal dispersion with the increase of metal content. The XPS analysis showed $Pd^{\delta+}$ surface species, which increased with the increase of the metal loading. All the catalyst showed good catalytic performance, for NB and FUR hydrogenation, that fitted to a pseudo-first kinetic model and a high selectivity to the desired AN or THFOL products, respectively. Among them, the 0.5Pd/HNT-DOPA catalyst show the higher catalytic efficiency. Furthermore, this catalyst displayed the optimal operational stability reaching 5 recycles remaining a high conversion and selectivity to the AN and THFOL products, respectively.

# Ru Nanoparticles Immobilized on Guanidinium-Based Supported Ionic Liquids Phases as Adaptive Hydrogenation Catalysts

Yuyan Zhang,[1] Liqun Kang,[1] Serena DeBeer,[1] Alexis Bordet,[1*] Walter Leitner [1,2*]

[1] *Max Planck Institute for Chemical Energy Conversion, Mülheim an der Ruhr, Germany*

[2] *Institut für Technische und Makromolekulare Chemie, RWTH Aachen University, Germany.*

**Corresponding Author's E-mail address: alexis.bordet@cec.mpg.de / walter.leitner@cec.mpg.de*

**Introduction.** Adaptive catalytic systems are capable of adjusting their performance in response to changes in their environment, and are thus attracting increasing attention to cope with the dynamics associated with the use of renewable resources (intermittent energy supply, variations in feedstock quality, etc.).[1-2] Recently, our group reported the immobilization of Ru nanoparticles (NPs) on a $CO_2$-responsive tertiary amine-functionalized polymer-grafted silica support (PGS).[1] The resulting multifunctional catalytic system was applied to the hydrogenation of ketone-containing furan derivatives, and responded adaptively to the feed gas composition (full hydrogenation under $H_2$, no ketone hydrogenation under $H_2/CO_2$). In this case, the Ru-catalyzed reversible formation of ammonium formate species by reaction of $CO_2$ and $H_2$ at the amine-functionalized support was identified as trigger for the selectivity switch. While this catalyst was demonstrated to be fully adaptive, the complex polymeric structure and the heat treatment required to decompose the ammonium formate and regenerate the original activity of Ru NPs were identified as limitations.

**Experimental/methodology.** In this context, we propose here an alternative catalyst design in which Ru NPs are immobilized on a simple guanidinium-based supported ionic liquids phase (SILP) (Figure 1a).[3] The prepared Ru@SILP material was characterized by a combination of techniques including electron microscopy, solid state NMR, and X-ray absorption spectroscopy. While ammonium formate species cannot form through $CO_2$ hydrogenation with such catalyst structure, we hypothesize that the guanidinium IL-like environment may stabilize formic acid sufficiently for it to act directly as a trigger to switch selectivity.

**Results and discussion.** The Ru@SILP catalyst was applied to the hydrogenation of biomass-derived furfuralacetone (**1**) as a model reaction. Full hydrogenation to the saturated alcohol **2** was observed under pure $H_2$, as expected for Ru NPs. In contrast, the C=O hydrogenation activity was shut down under $H_2/CO_2$, and the saturated ketone **3** was obtained. Satisfyingly, the selectivity switch was found fully reversible and products **2** and **3** were produced alternatively in high yield and selectivity simply by changing the composition of the feed gas between $H_2$ and $H_2/CO_2$ (Figure 1b). Detailed investigations and characterizations showed that the Ru-catalyzed reversible formation of formic acid by $CO_2$ hydrogenation act as trigger for the selectivity switch. Such selectivity switch was not observed using Ru@$SiO_2$ or imidazolium-based Ru@SILP catalysts, and the guanidinium IL environment was found essential to reach a concentration of formic acid high enough to enable adaptivity.

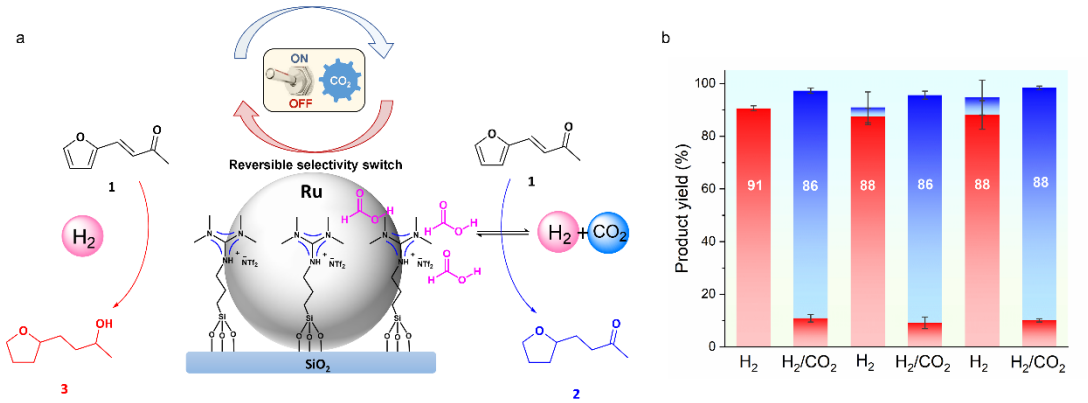

**Figure 1.** (a) Hydrogenation of furfuralacetone under $H_2$ or $H_2/CO_2$ as feed gas. (b) Reversibility study, reaction conditions: Ru@SILP (0.005 mmol), furfuralacetone (50 eq., 0.25 mmol), 1,4-dioxane (0.65 mL), $H_2$ (15 bar) or $H_2/CO_2$ (45 bar, 1:2), 80°C, 16 h, red-yield of **3**, blue-yield of **2**.

**Keywords:** Zeolite, Confinement, Extra-framework alumina, Extra-framework silica, alkane cracking

**Introduction.** Catalytic active sites in zeolites are constituted by both the bridging SiOHAl groups that act as Brønsted acid sites (BAS) and by surrounding microporous cavities that solvate confined species involved in catalytic cycles[1]. Both the cavity framework and extra-framework species afford such constraint and solvation and influence catalytic reactions[2, 3]. The presence of extra-framework alumina (EFAl) in proximity of a BAS enhances its catalytic activity in n-pentane cracking by 50 folds. Extra-framework silica (EFSi) is another type of extra-lattice species, however its role in catalytic reactions is hitherto unidentified. Here we controllably create EFSi in the vicinity of BAS ion MFI zeolite, and show the different mechanisms for the enhancement of catalytic activity in protolytic cracking of n-pentane in comparison to that of EFAl.

**Experimental/methodology.** Parent H-MFI zeolite was obtained by dealuminating on a commercial H-MFI (CBV 2314 from Zeolist) with ammonia hexafluorosilicate and further calcination at 773K. EFAl was created by controllable steaming of the parent H-MFI. EFSi was grafted into H-MFI by adsorbing n,n-dimethyltrimethylsilylamine and calcined at 773K for 5h.

**Results and discussion.** The presence of EFAl or EFSi in H-MFI makes a portion of BAS with nearby EFAl or EFSi. In order to differ from normal BAS, they are denoted as EFAl-BAS or EFSi-BAS. The turnover frequencies (TOFs, rate normalized to total BAS) for overall cracking, dehydrogenation and different cracking pathways of n-pentane reaction on MFI zeolites all show linear increase with the portion of EFAl-BAS or EFSi-BAS in the total BAS (Figure 1). By extraploting TOFs to 100%, the TOF of all reaction pathways were obtained for EFAl-BAS and EFSi-BAS. As shown in Figure 2, the TOF on EFAl-BAS is 50-fold higher than normal BAS. This significant of enhancement was attributed to the higher transition entropy, overcompensating the increase of the activation energy. However, on EFSi-BAS, the increment of TOF was only 2-fold higher. This enhancement was attributed to the lower activation energy.

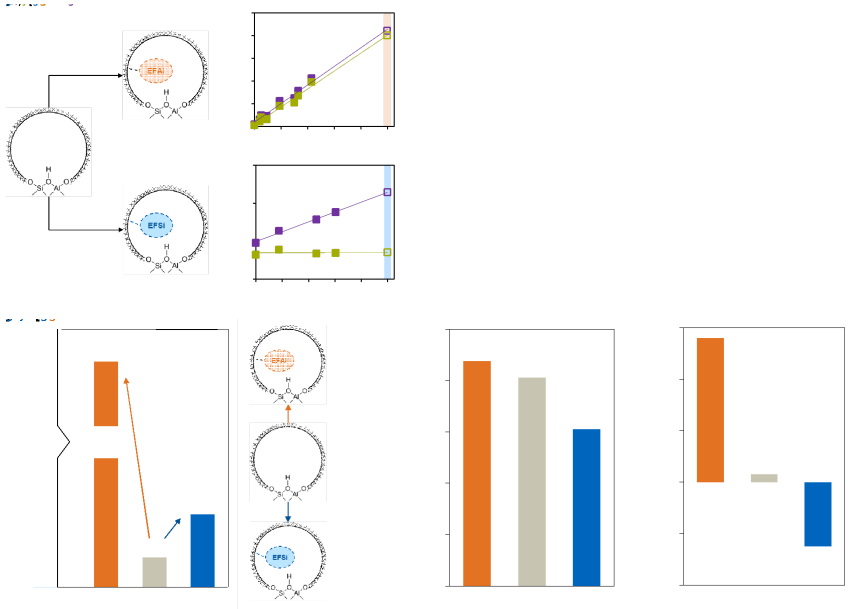

**Figure 2.** The influence of EFAl and EFSi on the TOF (753 K), intrinsic activation enthalpy and entropy for n-pentane cracking on H-MFI zeolites.

**Keywords:** MOFs, Ag clusters, oxidative cross-coupling, styrenes, sulfones, phenylacetylenes, one pot.

**Introduction.** The direct catalyst conversion of alkenes to alkynes is an unmet synthetic pathway with high potential impact in organic synthesis.[1] Alkynes are pluripotential building blocks for organic synthesis, which engage in a multitude of reactions such as hydrogenation, hydroaddition, cross–coupling, metathesis and pericyclic reactions. However, alkynes are generally expensive and difficult to implement in kilogram studies since their synthesis often relies on highly energetic intermediates. In this contribution we will show how the synthesis of different metal species in well-defined solid catalyst has allowed to carry out the challenging direct conversion of styrenes to phenylacetylenes in one pot.[2]

**Experimental/methodology.** First of all, the reaction was carried out using different homogeneous catalysts. Then, a metal–organic framework (MOF), in particular $Fe^{3+}Ag^0_2$@MOF, was synthesized in order to perform the reaction with a heterogeneous catalyst. Once the reaction parameters were optimized, the reaction mechanism was studied using different techniques. Finally, the reaction scope was done with many compounds.

**Results and discussion.** The solid $Fe^{3+}Ag^0_2$@MOF is capable of catalyzing the oxidative cross-coupling of styrenes with phenyl sulfone, to give vinyl sulfones in yields up to >99%. Vinyl sulfones can be transformed, in situ, to the corresponding phenylacetylene products in high yields, after filtration of the catalyst, which can be reused.

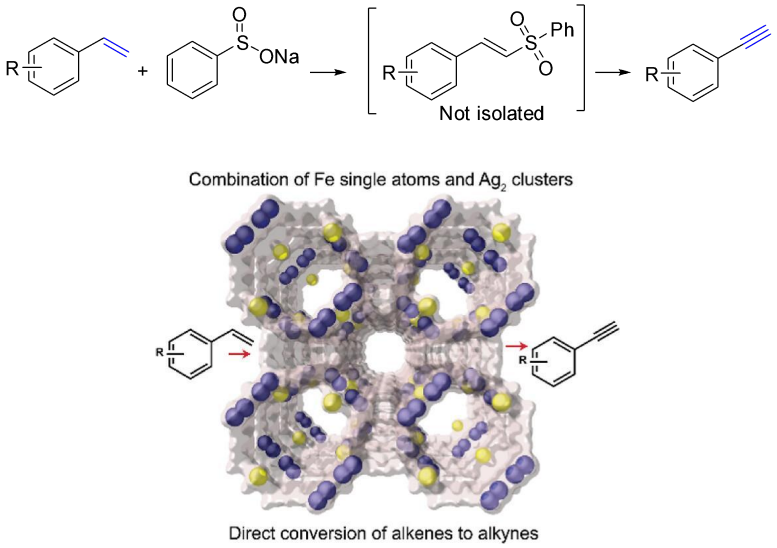

**Figure 1**: Reaction scheme for the formation of alkynes from alkenes.

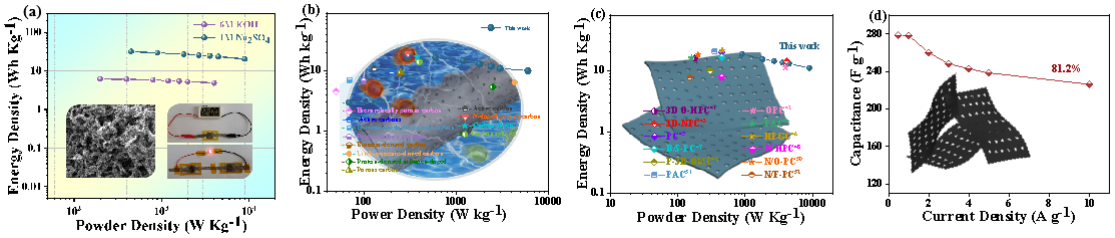
**Keywords:** Carbon nanospheres, carbon nanotubes, carbon nanosheets, supercapacitor



**Introduction**

As a type of energy storage device that falls somewhere between traditional capacitors and batteries, the supercapacitor has the advantages of energy saving and environmental protection, high power density, fast charging speed, long cycle life, etc.[1, 2] One of the key factors affecting the performance of the supercapacitor is the electrode material, and carbon nanomaterials are the most widely studied and applied electrode materials for supercapacitor[3]. Carbon nanotubes/nanofibers with a one-dimensional (1D) structure have a relatively regular pore structure, a large specific surface area (SSA), high conductivity and chemical stability [4]. Carbon nanosheets with a 2D structure have a large SSA, high electrical conductivity, and stable thermal and chemical properties [5]. Herein, we synthesized carbon materials with different dimensions as electrodes for supercapacitor. We were systematically investigated the electrocatalytic performance of these carbon materials and the relationship between their structure and performance.

**Experimental/methodology**

The following methodology was adopted: silica assisted strategy, template co-assembly method for carbon nanofibers and carbon nanotubes; Interfacial self-assembly guide strategy for carbon nanosheets.

**Results and discussion**

**(a) Hierarchically porous carbon nanofibers with tunable morphology and outstanding capacitive performance. (b) Ragone plots for the carbon nanotube symmetric supercapacitors. (c) Ragone plots for the carbon nanosheets symmetric supercapacitor. (d) Rate performance of the porous carbon nanosheets.**

# Recovery of gold from melted boraxes with simultaneous production of pure BF3 Catalyst, also suitable for doping Silicon for semiconductors and Graphene

Author's Name : T. Zucca[1*]

[1]*Industrial and Civil Engineering Professional Office Ing. Tullia Zucca, Comazzo, Italy*

[*]*Corresponding Author's E-mail address : info@gandzsas.com*

**Keywords:** keyword 1 : Gold Recovery in mining and industrial electronic wastes, keyword 2 : BF3 pure Catalist , keyword 3 : Doping Silicon for semiconductors and Graphene

**Introduction.** The invention belongs to a continuously expanding field, given that precious metals are no longer used only in the production of jewels and luxury items, but are increasingly used in electronic devices which are increasingly used throughout the world. More, this invention produces pure BF3, an important Catalist , fitted for a lot of process: Friedel - Crafts acylation and alkylation reactions . These reactions are not exactly catalytic, since $BF_3$ is consumed. For example:

$$PhH + RX + BF_3 \rightarrow Ph\text{-}R + H^+ + BF_3X^-$$

More :polymerization reactions of unsaturated compounds such as alkenes .isomerization reactions of saturated and unsaturated hydrocarbons, cracking of hydrocarbons in the oil industry, esterification and condensation reactions, synthesis of other boron compounds such as boranes and borates, synthesis of lubricant additives, P-type doping in the manufacture of semiconductors , doping of both silicon and graphene.

Untill now BF3 has been produced in different way, but never so pure as our new process is able to obtain.

**Experimental/methodology:** The granulated borax lavas , derived from precious metal castings in mines or from disused electronic devices, containing Gold , is dispersed in the whole mass of the reagent, aqueous solution of hydrofluoric acid with a titre of 40% of HF in H2O .

The solid/liquid slurry immediately enters the chemical reactor, which can also be a common reactor which is slightly stirred and with a fixed vent for the gaseous reaction product, but which in our plants will preferably be represented by the controlled cavitation machine, a special construction for this Process, given that hydrofluoric acid has the ability to attack very strongly the normal construction materials of chemical plants.

To respect the reaction times, the slurry is recycled in a loop on the machine, but it is also possible to recycle it in a large loop on the static mixer, in case it is necessary to add another reagent, up to the optimal stationary reaction regime.

The adoption of our controlled cavitation machine will certainly make the process more efficient by reducing reaction times and minimizing energy consumption, which however in the process in question is in itself very low, making this new process very convenient also from this point of view.

The end of the reaction and therefore the release of all the gold that was occluded in the solidified borax matrix after melting, is easy to prove, as it occurs that the gaseous flow of boron trifluoride , the reaction product, gas already at 12°C under the atmospheric reaction conditions, which is continuously vented and bubbled in a container partially filled with diethyl ether , which is brought to the titre up to 46% of boron trifluoride etherate . Boron trifluoride can be absorbed in other chemical compounds, such as Toluene, Methanol or other Chemicals. In any case it is advisable to store the boron trifluoride absorbed in diethyl ether or other chemical , at a very widespread catalyst, in various fields, its marketability is therefore high. We specify that this by-product synthesized by us is purer than those already on the market, obtained by other methods.

**Results and discussion** . BF3 , direct product of the chemical reaction, should not be considered a by-product of the process, even if the main product is considered to be recovered gold, because it has very important uses. Gold recovery and simultaneous production of BF3, is a really milestone in updated technologies.

# $H_2$ and carbon production through Fe-catalyzed methane decomposition

**Keywords:** $H_2$, methane decomposition, Carbon Nanotube.

**Introduction.** $H_2$ will play a key role in the decarbonisation to reach a reduction of GHG of 55% by 2030 and the net zero emissions by 2050 and in the REPowerEU Plan [1]. Green $H_2$ obatined by water electrolysis uisng renewable energy will be the main contributor in the $H_2$ economy; nevertheless, other solutions are searched to bridge the gap between the conventional steam methane reforming (grey $H_2$) and water electrolysis. Catalytic decomposition (or cracking) of methane (CDM) is a valuable COx-free hydrogen production technology [2]. The added-value is the production of carbon materials for special applications. However, the key advantage of the methane cracking, the production of solid carbon, also provokes the catalyst deactivaiton and clogging of the reactor, hence hampering the process implementation. Herein we present the work in progress within the framework of the Horizon Europe STORMING project to obtain low cost catalysts for the production of $H_2$ and carbon nanotubes (CNTs) [3]. Fe-based catalysts are developed by a combination of theoretical (Density Functional Theory, DFT) and experimental methodologies with the aim of increasing the catalyst lifetime and controlling the properties of the CNTs.

**Experimental/methodology.** Catalysts are synthetized by co-precipitation and calcination. The Fe loading, composition of the oxide matrix (e.g. $Al_2O_3$ or spinel) and presence of promoters are modified, also following the inputs given by DFT. A screening of the catalysts and reaction conditions (temperature, composition of the feedstock, and GHSV) is performed in a fixed-bed quartz reactor. The characterization of the fresh and spent catalysts, including the carbonaceous deposits, is performed by XRD, $H_2$-TPR, micro-Raman, SEM and TEM.

**Results and discussion.** The selective production of $H_2$ through the methane decomposition at tempeartures below 800 °C is feasible over the Fe-based catalysts investigated. The $H_2$ productivity and the properties of the carbonaceous materials, e.g. degree of crystallinity and morphology, are largely dependent on both the type of catalyst (Fe loading and support) and reaction conditions. For instance, carbon fibers are produced with high loaded $Fe/Al_2O_3$ catalysts. Besides the composition of the catalyst, its activation procedure and the GHSV are key parameters to be tailored to increase the catalyst lifetime and to obtain CNTs with controlled properties.

# Effect of the internal wettability of catalyst supports on gas-production reactions: study of $H_2O_2$ decomposition

F.D. Bernal Juan[1*], A. Banerjee[1], L. Lefferts[1]

[1] *Catalytic Processes and Materials Group, Faculty of Science and Technology, MESA+ Institute for Nanotechnology, University of Twente, PO Box 217, 7500 AE Enschede, The Netherlands*

**Keywords:** wettability, catalyst support, bubble evolution, mass transfer, effective kinetics

Despite the relevance of the formation of gas bubbles in multiphase catalytic reactions, the number of studies that address this issue is limited. It has been shown that bubbles influence mass and heat transport [1,2]. For example, bubbles detaching from a catalyst particle surface, or moving inside the pore network, can enhance mass transfer [2,3]. But it's also true that bubbles covering the catalytic surface can also hamper the diffusion of reactants, thus limiting the reaction. Within our research group we have shown that it is possible to manipulate the external and internal wettability of a catalyst support [4,5]. These studies show that it is possible to enhance the transport of chemical species present in the gas phase in a three-phase reactor. However, the understanding of how the internal wettability of this new type of support influences bubble formation or movement in gas-evolving reactions is lacking. In this study, we use as a model system to shed some light on these matters the catalytic decomposition of $H_2O_2$ (eq. 1) in aqueous solution on hydrophilic and partially hydrophobic catalysts supports ($Pt/Al_2O_3$). This catalytic reaction is simple but we have observed that it is possible to readily fall under internal mass transfer limitations.

$$2H_2O_2 \xrightarrow{cat} 2H_2O + O_2 \qquad (1)$$

A series of supported catalysts with increasing hydrophobicity have been synthesized as reported earlier by physically mixing powders of hydrophilic and hydrophobic alumina [4]. The prepared catalysts were tested in a batch reactor under stirring, and the reaction rate is calculated by measuring the oxygen evolution rate. The described experimental setup allowed the determination of mass transfer effectiveness factors varying the stirring speed and $H_2O_2$ concentration. This is significant as this allows the comparison of the Thiele's pore effectiveness factor with experimental data, and determine the effect of bubbles forming due to the catalytic reaction.

# Tuning the catalytic activity of supported non-noble metal nanoparticles in oxidation reactions of aliphatic alcohols

Chiara Bersani,[1] Alvise Perosa,[1] Daily Rodríguez-Padrón, [1] and Maurizio Selva*[1]
[1]*Dipartimento di Scienze Molecolari e Nanosistemi, Università Ca' Foscari di Venezia, 30123 Venezia, Italy*

*selva@unive.it

**Keywords:** green chemistry, catalysts design, supported nanoparticles, non-noble metal catalysts, selective oxidation reactions

**Introduction.** The fundamental role of hetergeneous catalysis in the chemical industry has raised in recent years, looking forward the design of more environmentally-friendly processes which be compatible with the sustainable development goals.[1] In this context, the synthesis of efficient, selective, stable and low-cost catalytic materials is a highly pursued objetive.[2] Considering the aforementioned premises, through this contribution, the preparation of a series of carbon-supported non-noble metal nanoparticles was accomplished via a sustaineble strategy and their catalytic activity was investigated in the oxidation of aliphatic alcohols, being able to tune the products distributions by controlling the reaction conditions.

**Experimental/methodology.** The catalytic materials were prepared following a two-step protocol based on an impregnation step of the biomass-derived carbon source with the selected non-noble metal precursors and a subsequent thermal treatment. The materials were fully characterized following a multitechnique approach and their catalytic activity was tested in the oxidation of 1-hexanol (as model aliphatic alcohol). Furthermore, a substrate scope investigation was carried out considering primary and secondary alcohols.

**Results and discussion.** This contribution aimed at the design of a sustainable methodology for the preparation of selective catalytic materials. It is worth to highlight that a biomass-derived feedstock was employed as carbon source and that the synthetic strategy allowed the formation of homogeneous and well-dispersed non-noble metal nanoparticles, as confirmed from TEM-analysis. The catalytic oxidation of 1-hexanol was studied employing the prepared catalytic samples, leading to a remarkable outcome in particular for molybdenum-based systems. Moreover, the most efficient catalytic material was used to perform a full parametric analysis and subsequently a substrate scope investigation was accomplished under the optimized conditions. As well, it was possible to stablish a relationship between the catalytic performance and the textural, morphological and chemical features of the samples. Finally, the materials displayed an outstanding reusability for, with negligible loss of the catalytic activity along 5 reaction cycles.

[*]*aksoylu@boun.edu.tr*

**Keywords:** CO Methanation, Synthetic Natural Gas, $CH_4$ Production

**Introduction.** Owing to uneven and limited distribution of the natural gas reserves and the concerns about the rising greenhouse gas emissions, industrial and academic studies have focused on the production of synthetic natural gas (SNG)[1]. The current work is a part of the ongoing project conducted in our SNG&HydTec Lab that ultimately aims the design and development of industrial catalysts for a novel, economically feasible, coal to SNG production technology. The main purpose of this particular work is to design and develop novel methanation catalyst(s) having high methane production activity and selectivity with performance stability allowing efficient methane production even for feeds having $H_2$:CO<3 through combining CO methanation with WGS reaction.

**Experimental/methodology.** A series of Ni based methanation catalysts were designed and prepared. In preparation, types of metals, promoters, supports, metal loadings, pretreatment conditions were used as experimental parameters. The performance of the catalysts was determined experimentally in ranges of 200-400 °C, under both ideal flow (ie. feeds having $H_2$:CO=3) and realistic flow conditions (feeds having $H_2$:CO<3, including $CO_2$, steam, etc).

**Results and discussion.** Figure 1 shows the CO conversion values at three different feed compositons and at two different temperatures for 16 different catalyts. At 400 °C, for $H_2$:CO=3, all catalysts, except 5%Ce 10%Ni/$ZrO_2$, showed similar CO conversion performances (93 to 98%). When $H_2$/CO ratio was decreased to 2, CO conversion values were not obviously changed for most of the catalysts. However, when the $H_2$:CO ratio was lowered to 1, both CO conversion and $CH_4$ yield values decreased. Comparison of CO conversion results obtained at low temperatures indicates more significant differences between catalyst performance. For example, at 250 °C, only 6 of the 16 catalysts show CO conversion performances even with ideal $H_2$:CO feed ratio of 3. Moreover, 5%Ce-10%Ni/γ-$Al_2O_3$ is the only catalyst that works at 250 °C for $H_2$:CO=2 with good catalytical activity and stability.

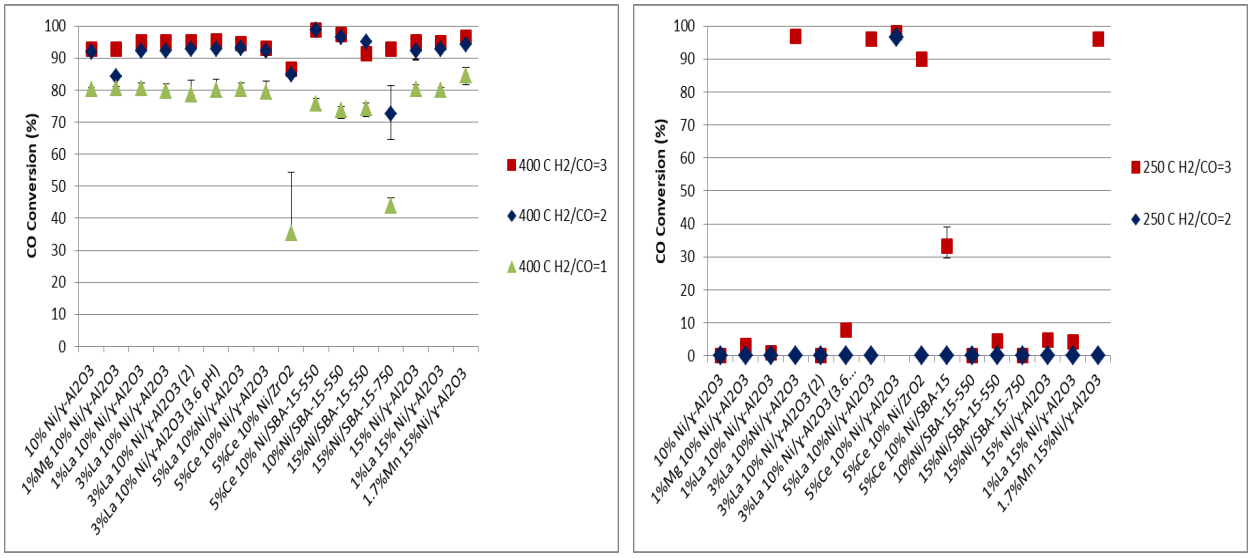

**Figure 1.** CO Conversions for different $H_2$/CO ratios at 400 °C (a), at 250 °C (b)

# Novel versatile covalent phenyl-BTBT-based triazine extended as metal-free heterogeneous photocatalyst

M.Carmen Borrallo-Aniceto[1*], Mercedes Pintado-Sierra[2], Félix Sánchez[2], Marta Iglesias[1]
[1]*Instituto de Ciencia de Materiales de Madrid, CSIC, Madrid 28049, Spain*
[2] *Instituto de Química Orgánica General, CSIC, Madrid 28006, Spain*
[*]*mcarmen.b@csic.es*

**Introduction.** Polymers based on covalent triazine networks (CTFs) are a class of porous organic polymers (POPs) characterized by excellent chemical and thermal stability, large specific surface areas, well-defined microporosity, and high nitrogen content [1].
The combination of triazine units (acceptor groups) with donor groups (aromatic groups) in a conjugated structure makes CTFs excellent candidates for use in photocatalytic reactions [2,3].
Thus, in this work, we have prepared a CTF-based polymer using a novel dinitrile monomer based on the semiconducting benzo[b]benzo[4,5]thieno[2,3-d]thiophene (BTBT) core with extended conjugation through phenyl units for its applications in oxidation reactions, Diels-Alder and halogenations.

**Experimental/methodology.** In this work, a triazine with BTBT skeleton has been successfully prepared. The synthesis of the monomer has been carried out in three steps: First, 2-chlorobenzaldehyde is reacted with NaHS, followed by bromination at positions 2 and 7. This is followed by Suzuki-Miyaura cross-coupling using 4-cyanophenylboronic acid to extend the BTBT moiety with additional phenyl rings.
The synthesis of the catalyst is performed by microwave activation using trifluoromethanesulfonic acid obtaining CTF in quantitative yield, which is insoluble in water and in all common organic solvents.

**Results and discussion.** To confirm that the monomer is part of the polymeric network we have performed 13C CP/MAS NMR in solid state, and the thermogravimetric analysis (TGA) curves showed that the polymer has a good thermal stability (Td= 560ºC) (figure 1). The photocatalyst was evaluated in different reactions such as selective oxidation reactions (sulfides to sulfoxides, hidroxilation), Diels-Alder reactions and halogenations with excellent conversions (100%) and yields (>98%) using 5 mol% catalyst (figure 2).

**Keywords:** CCU; surface plasmon resonance; photocatalysis; *in operando* monitoring; Sabatier reaction

**Introduction.** Two major challenges that we as society currently face are securing our future energy supply by switching from fossil fuels to sustainable energy sources, and reducing $CO_2$ emissions. CCU techniques are aimed at capturing $CO_2$ and putting it to good use. A promising CCU technique is the chemical conversion of $CO_2$ to $CH_4$, which is a safe and easy-to-handle energy carrier with a high gravimetric storage density. Conventionally, the Sabatier process ($CO_2 + 4H_2 \rightarrow CH_4 + 2H_2O$) catalyzed by supported metal nanoparticles such as Ni, Rh and Ru requires activation at temperatures between 300°C and 500°C. Here, we present $SiO_2$ and $Al_2O_3$-supported Ru nanocatalysts tailored for use of sunlight as energy source instead of conventional heating. Using mildly concentrated sunlight as sole energy source (up to 6.66 $kW \cdot m^{-2}$) and supported Ru nanocatalysts of a size between 0.8 nm and 3.4 nm, we achieved a methane production rate up to 0.63 $mol \cdot g_{Ru}^{-1} \cdot h^{-1}$ at ≥ 99% selectivity and a catalyst bed temperature of 220°C.[1] To distinguish between photothermal and non-thermal contributions, which is of interest both from a fundamental and application perspective, we monitored the temperature at the surface and inside the catalyst bed *in operando* using a tailored optical sensor, which to date has only been demonstrated offline.[2]

**Experimental/methodology.** Two different methods were used for decoration of the supports, viz. γ-$Al_2O_3$ and Stöber $SiO_2$, with Ru nanoparticles: (1) deposition-precipitation followed by chemical reduction (CR) using $RuCl_3$ as a precursor, and (2) impregnation with $Ru_3(CO)_{12}$ and subsequent high-temperature decomposition (TD).[1] The chemical composition of the prepared catalysts, their nanostructure and optical characteristics - UV-vis-NIR reflectance, skin depth and emissivity – were studied in detail. To distinguish between photothermal heating and potential non-thermal contributors, e.g. transfer of hot electrons to an electron-accepting orbital of an adsorbate in close proximity, a single thermocouple measurement of the catalyst bed temperature does not suffice. Instead, accurate *in operando* temperature monitoring of the catalyst bed is required. For that purpose, we applied fiber Bragg grating based fiber optic temperature sensors.[2] By positioning multiple sensors at various depths, we were able to accurately monitor not only the top surface temperature during the reaction, but also quantify temperature gradients.

**Results and discussion.** The Ru nanoparticles in Ru/γ-$Al_2O_3$-CR were slightly larger than in Ru/γ-$Al_2O_3$-TD (1.2 vs. 0.8 nm). In addition, Ru nanoparticles were deposited on Stöber $SiO_2$ using both deposition techniques. Ru/$SiO_2$ particles were larger than the ones deposited on γ-$Al_2O_3$ (2.5 and 3.4 nm for CR and TD, respectively). Taking into account the size differences between the Ru nanoparticles, all catalysts displayed similar activity (0.14–0.63 $mol \cdot g_{Ru}^{-1} \cdot h^{-1}$) and selectivity (≥99%) in the sunlight-powered Sabatier reaction. We monitored the temperature of the catalyst bed during the reaction as function of the sunlight intensity, the flow rate and the feedstock composition to differentiate between photothermal and non-thermal contributors to the sunlight-powered $CO_2$ methanation

**Introduction.**

Ziegler-Natta catalysts for the production of isotactic polypropylene are formulations in which $TiCl_4$ and an organic Lewis base ('Internal Donor', ID) are co-adsorbed on a nanostructured $MgCl_2$ support; this solid precatalytic phase is subsequently contacted with an $AlR_3$ activator, usually complexed with another organic Lewis base ('External Donor', ED) [1,2]. Under polymerization conditions, some IDs react with the $AlR_3$ and desorb from $MgCl_2$ surface [3]; in this case the action of active site modification is dominated by the ED [2,4]. No attempts to purposely modulate ID/$AlR_3$ reaction kinetics and, therefore, to control the distributions of catalytic species and of relevant polymer properties thereof have been reported so far. In the proposed research approach, we have integrated a state-of-the-art high-throughput experimentation (HTE) workflow and fast computational tools to investigate the question systematically.

**Experimental/methodology.**

Studies of the ID/$AlR_3$ reactivity in solution and on the surface ($MgCl_2$/ID model adducts) were performed using a Freeslate Extended Core Module (XCM™) robotic platform [5]. $MgCl_2$/ID/$TiCl_4$ precatalysts were tested in propene homopolymerization with a Freeslate Parallel Pressure Reactor (PPR48) platform [6], and the produced polymers were characterized by means of Rapid-Gel Permeation Chromatography (GPC), Analytical Crystallization Elution Fractionation (ACEF) and $^{13}C$ NMR all used in HTE mode. All molecules were manipulated on GaussView[7] and all the calculations run on Gaussian 16.[8]

**Results and discussion.**

A robust dataset of ID/$AlEt_3$ reactivities in solution was built-up using a training library of 22 molecules. For the investigated IDs, all featuring carbonyl moieties, carbonyl reduction in solution turned out to follow a single well-defined kinetic law; in addition, the apparent specific rate ($k_{app}$) values nicely populated the desired modulation range (i.e., $k_{app}$ values between those of reference dibutylphthalate and diisobutylsuccinate). Unexpectedly, ID/$AlEt_3$ reactivities following ID chemisorption onto $MgCl_2$ turned out to be rather insensitive to individual ID structures, which likely indicates strong surface-specific effects. In addition, catalyst modification by a known competent ED resulted into substantial enhancements of stereoselectivity and molecular weight capability (which in most systems closely approached the levels of a reference dibutylphthalate-containing system), but not into a broadening of the molecular weight distributions. A multiple regression Quantitative Structure-Property Relationship (QSPR) model was implemented to rationalize ID surface reactivity with $AlEt_3$. Using a Machine Learning approach for features selection, a satisfactory QSPR equation was obtained with 2 steric and 3 electronic descriptors (using suitably selected catalyst features).

** Corresponding author: javier.ruizmartinez@kaust.edu.sa*

**Introduction.** The chemoselective hydrogenation of the C=C bond in cinnamaldehyde (CAL) to obtain hydrocinnamaldehyde (HCAL) remains challenging over Pt-based heterogeneous catalysts. Reported catalysts are often complex and selectivity remains below 90%. Herein, we report selectivities of 99% by utilizing Pt NPs encapsulated in Silicalite-1 zeolite for improved support effects and smaller Pt NPs.

**Experimental/methodology.** Pt was encapsulated in S-1 through an in-situ encapsulation procedure where the Pt precursor is introduced to the synthesis gel, yielding Pt@S-1 with 0.8 nm Pt NPs dispersed in the zeolite micropores. The selectivity in the hydrogenation of cinnamaldehyde was evaluated at 100°C and 10 bar $H_2$ in toluene. The support effect was investigated by comparing Pt/S-1-ex and Pt/$SiO_2$-ex, which were prepared by impregnating colloidal Pt NPs possessing Pt NPs size exclusively on the surface of Silicalite-1 and $SiO_2$, respectively. Particle size effect was investigated by comparing Pt@S-1 with Pt/S-1-ex and encapsulated catalysts with different particle sizes prepared through in-situ encapsulation or incipient-wetness impregnation. The catalyst properties were further characterized by CO chemisorption followed by DRIFTS, and the spent catalysts were analyzed by STEM.

**Results and discussion.** The confined catalyst, Pt@S-1-in, achieved 99% HCAL selectivity at 78% CAL conversion (fig. 1a), significantly higher than a commercial Pt/$SiO_2$ (85%) at similar conversion level (74%). The reasons for such high selectivity were thoroughly investigated. Catalysts with the same Pt particle size but different supports (fumed $SiO_2$ versus silicalite-1) revealed that the support polarity plays a significant role in enhancing selectivity (fig 1a,b). Catalysts with lower silanol density and thus decreased polarity show significantly improved HCAL selectivity. However, the selectivity of Pt/S-1-ex shows a rapid decrease in selectivity at higher conversions, not observed in encapsulated catalysts. The subsequent analysis of spent catalysts revealed that catalysts suffer from some sintering under reaction conditions, however, the encapsulated catalysts maintain the smallest particle size. The onset of hydrocinnamyl alcohol formation appears to be correlated with the particle size. The catalyst with the largest particle size (Pt/S-1-ex, fig. 1c), and thus the most detrimental Pt(111) facets, forms HCOL early in the reaction whereas the catalyst with the smallest Pt particles (Pt@S-1-in, fig. 1d) presumably only forms HCOL after some sintering has occurred.

In summary we have demonstrated that Pt@S-1 enhances the HCAL selectivity, achieving the highest reported selectivity for Pt-based catalysts. The selectivity is due to the reduced polarity of the S-1 support, but there is a noticeable enhancement due to the confinement which restricts the size of the Pt NPs.

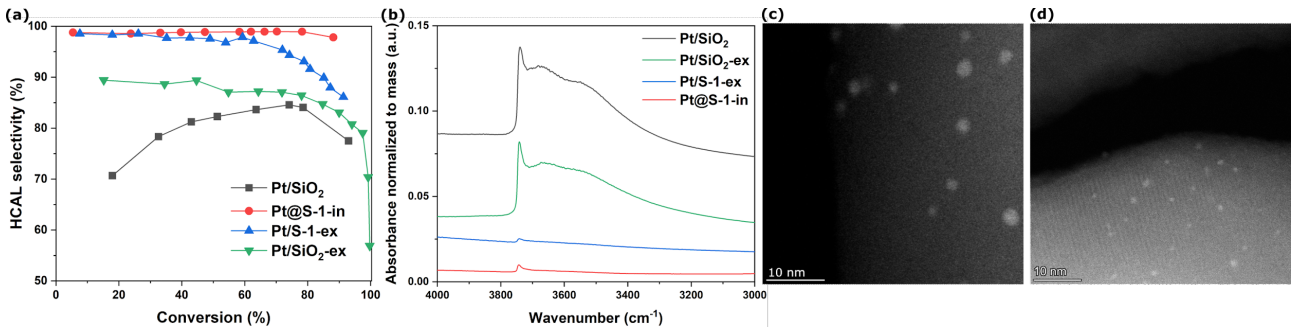

**Figure 1. (a) CAL conversion vs HCAL selectivity. Reaction conditions: CAL (300 mg), Pt (1 mg), $H_2$ (10 bar), toluene (6 ml), 100°C. (b) Silanol region of the FTIR spectrum for catalysts. Representative HAADF-STEM image of (c) Pt/S-1-ex and (d) Pt@S-1-in.**

# $ZrO_2/NH_2$-$SiO_2$ bifunctional flow microreactor for deacetalization-Knoevenagel domino process

A. Ciemięga[1*], K. Maresz[1], J. Mrowiec-Białoń[1]

[1] *Institute of Chemical Engineering Polish Academy of Sciences, Gliwice, Poland*
*([*]ciemiega@iich.gliwice.pl)*

**Keywords:** domino process, microreactors, silica monolith

**Introduction.** Domino reactions involve two or more consecutive reactions leading to the final product without addition of any new substrates, with no intermediates` isolation and employing one fixed workup procedure. This methodology, used for the formation of complex molecules, was evolved for biologically important natural substances, agrochemicals and pharmaceuticals production. One of the challenges in this area is to elaborate catalysts with functionalities which are able to cohabitate and act cooperatively or independently [1].

In this work, the benefits of micro-flow technology and bifunctional heterogeneous catalysis were combined. Silica monolithic cores of microreactors were functionalized with both acid (zirconia) and base (amine) active groups. Microeactors were tested in the deacetalization – Knoevenagel condensation domino process.

**Experimental/methodology.** Silica monoliths of hierarchical pore structure were modified with zirconium isopropoxide and propylamine or polyamine precursors. Chemical and structural characteristics were obtained using FTIR, thermogravimetry and nitrogen sorption analysis. Catalytic experiments were performed in the flow regime. The synthesis of ethyl α-cyanocinnamate was carried out using benzaldehyde dimethyl acetal and ethyl cyanoacetate as substrates. Catalytic experiments were conducted in: i) microreactor doped with $ZrO_2$, ii) microreactor with amine group and iii) bifunctionalized microreactor. The performance of microreactors modified with different amine centers was compared.

**Results and discussion.** Monolithic silica was successfully functionalized with both acid and base sites which was confirmed by TG and FTIR analysis. The catalytic studies of hydrolysis and condensation carried out in $NH_2/ZrO_2$-doped microreactor and monofunctionalized microreactors indicated that the application of one-stage process translates to better overall performance. Polyamines as a base catalyst of the Knoevenagel reaction improve the efficiency and selectivity of the tandem process.

# Simultaneous mesoporization and metal incorporation offers synthetic and catalytic benefits

Danny Verboekend*[1] and Martin d'Halluin[1]

[1]*Zeopore Technologies, Interleuvenlaan 23, 3001 Leuven, Belgium*
**danny.verboekend@zeopore.com*

**Keywords:** Mesoporous zeolite, metal deposition, bifunctional catalysis

**Introduction.** In many zeolite-based catalytic applications, a metal function is included to yield optimal performance. For example, in hydro-processing reactions, such as cracking and isomerization dewaxing, nickel is deposited on the catalyst to provide the required hydrogenation function.

Zeopore has achieved to combine high-quality mesopore formation with a controlled and highly tunable metal deposition (Figure 1). The method can be applied to any zeolite and most non-noble metals. Resulting metal-containing zeolites can then be shaped into catalysts, such as extrudates afterwards. Hence, the method of metal deposition is fundamentally different compared to standard metal-containing catalysts [1], in which first an extrudate is made, to be subsequently complemented with a metal using in an impregnation step.

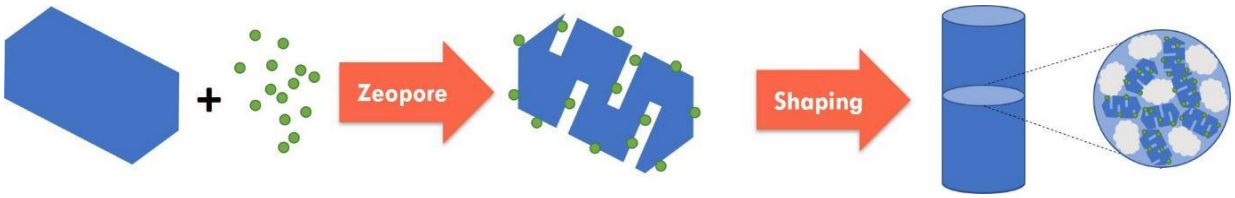

**Figure 1:** Zeopore's technology entails incorporation of metals (green) on the zeolite (blue) during mesoporization.

**Experimental/methodology.** The unique properties of Zeopore's metal-containing zeolites become obvious from almost any method of characterization. In the contribution, we will use various case studies, on for example Mg-ZSM-5, Mg-ZSM-23, and Ni-USY on both the powder and the extrudate level, to demonstrate how this class of materials contains superior porous properties, improved metal dispersions (near 100% dispersion), unique acidity profiles, and increased (hydro)thermal stability, using a variety of analytical techniques, such as $N_2$ sorption, FTIR spectroscopy with adsorbed pyridine, elemental analysis, chemisorption, and electron microscopy.

**Results and discussion.** Obviously, the proof of the pudding is in the catalytic performance. Zeopore is currently actively exploring the potential of this type of metal-containing zeolites in a number of applications, such as hydrocracking, dewaxing, methanol conversions, and aromatics conversion. We will demonstrate outstanding results in diesel dewaxing by hydro-isomerization using unidirectional zeolites, attaining -over standard mesoporous zeolites [2]- an order-of-magnitude lower diesel losses as a function of cloud point improvement and a simultaneous unique hydrogenation performance of aromatics present in the diesel feed. Also, a case on Mg-containing ZSM-5 in methanol to propylene will be demonstrated, evidencing, besides the expected 3-to-5-fold lifetime enhancement, an over 20% increased selectivity to propylene.

**Introduction**

Methane and carbon dioxide, the two most powerful greenhouse gases, can be exploit through Methane Dry Reforming reaction (MDR) to produce syngas in a more sustainable way. However, MDR is still not used at industrial level because of its high endothermicity, and easy deactivation of catalysts that are commonly supported ones. Deactivation occurs for two main reasons: carbon coke deposition and sinterization of active phase. To minimize these problems other classes of catalysts can be investigated. Perovskites should provide chemical and mechanical resistance, less coking, but also strong interactions of active phase with the bulk of material, and poisoning resistance [1]. This also thanks to a reducing treatment called "exsolution" [2], that is responsible of active phase formation. Exsolution should shape well anchored and dispersed nanoparticles on surface, formed by transition elements extracted from lattice. In this work, a base material was synthesized using lanthanum, iron and cerium, because of their coke resistance properties, and nickel, that is the active metal for MDR.

**Materials and methods**

The synthesis was carried out with the sol-gel method using nitrates salts as metal precursors, ethylen glycol and citric acid. The solid obtained was grounded and calcinated in air at 700°C for 4 h, divided into three parts and reduced under three different reducing conditions, at 800°C in $H_2$/He gasesous mixture. This to understand the effect of this treatment on activity and stability properties of the catalysts.

**Results and discussion**

The sample reduced with the lower heating rate (5°C/min) had the best MDR performance, with $CH_4$ and $CO_2$ conversions of 42% and 59% respectively in the first hours. TPR analyses showed different profiles for this catalyst, if compared with the other two that gave the same reduction peaks. This indicate the formation of different species on the surface of the best catalyst. SEM analyses further explained the different activity behaviours registered. On the surfaces of the reduced materials, particles were visible if compared with starting material that had a bare surface. The difference is on the best catalyst's surface, because better shaped and dispersed nanoparticles were formed, while on the other ones the surface seems to be damaged or bigger agglomerates were generated. By an XRD analyses it was possible to confirm the extraction of small cations from the lattice, so this could prove that exsolution happened. On spent catalysts was detected only amorphous carbon by TPO, an advantage for a future possible regeneration of this type of catalysts.

**Conclusions**

The three different exsolution conditions demonstrated how this treatment directly influences the catalysts activity and stability. This was confirmed from the analyses carried out on the catalysts, highliting the morphological and structural differences occurred thanks to exsolution. Further tests must be done to understand wich are the best conditions, but the results here reported show that this type of catalysts could be suitable for MDR purposes.

# Activity Enhancement in Au-Pd Bimetallic Systems as a Result of Co-Operation Between Individual Redox Reactions

Isaac T. Daniel[1*], Xiaoyang Huang[1], Ouardia Akdim[1], Mark Douthwaite[1], Kai Wang[1], Liang Zhao[1], Richard J. Lewis[1], Samuel Pattisson[1], Donald Bethell[1], Steven McIntosh[2] & Graham J. Hutchings[1]

## Introduction

Bimetallic Au-Pd catalysts are commonly seen to give significant rate enhancements over their monometallic analogues [1]. Herein, it is demonstrated that in catalytic alcohol oxidation over bimetallic Au and Pd catalysts, dehydrogenation (DH) and oxygen reduction (OR) can be coupled; a process termed Co-operative Redox Enhancement (CORE) [2]. Importantly, this mechanism enables significant DH rate enhancements to be achieved and is distinctively different to traditional synergy.

## Experimental

Supported Au and Pd catalysts were synthesized by sol immobilization and the conversion of 5-hydroxymethylfurfural (HMF) was used as the model reaction. Both thermo- and electrocatalytic investigation were used to assess five catalytic systems. Amongst others, catalyst characterization was performed *via* scanning transmission electron microscopy (STEM) and x-ray photoelectron spectroscopy (XPS).

## Results and Discussion

In the oxidative dehydrogenation (ODH) of HMF, a physical mixture of monometallic catalysts crucially shows a greater activity than a traditional alloy, with maximum activity observed for a supported Janus-type particle (Au@Pd/C) (**Figure 1a**). This highlights the importance of phase separation of active sites within the bimetallic system. Further thermochemical investigation shows that OR is intrinsically linked to the overall rate of ODH, and that the conductivity of the catalyst support is vital to facilitate electron transport. Therefore, a system is proposed whereby electrons produced during DH are consumed during OR, occurring over Au and Pd sites, respectively (**Figure 1b**). Electrochemical analysis, including linear sweep voltammetry, confirms the scheme and the specific roles of each metal. Finally, a kinetic model based on the CORE system accurately predicts the shape and maxima of activity across a range Au/Pd molar ratios (**Figure 1c**) [3]. This CORE effect is a wholly new observation which could change how researchers approach catalyst and process design.

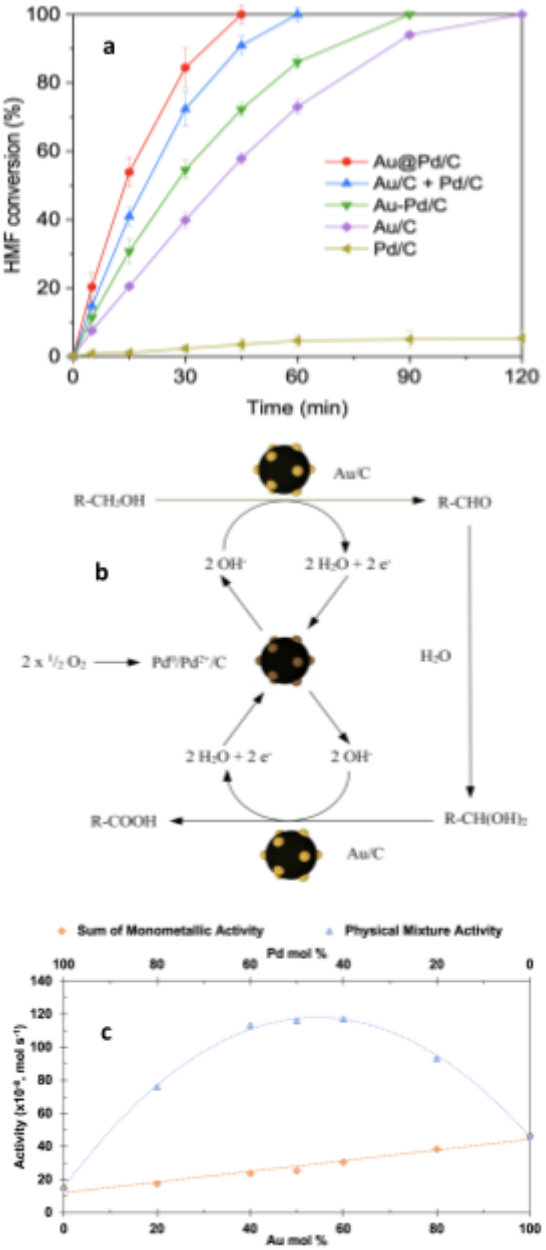

**Figure 1.** (**a**) HMF ODH over two hours for five different catalytic systems. (**b**) The proposed CORE system for supported Au and Pd catalysts. (**c**) The activity enhancement due to CORE effects over a range of molar ratios for a physical mixture catalytic system.

# Metal-Organic Framework-derived Catalysts for Upgrading of an Acetone-Butanol-Ethanol (ABE) mixture

K. Deekamwong[1,2*], C. Phawa[1], J. Wittayakun[1], S. Prayoonpokarach[1]

[1]*School of Chemistry, Institute of Science, Suranaree University of Technology, Nakhon Ratchasima, Thailand*
[2]*Institute of Research and Development, Suranaree University of Technology, Nakhon Ratchasima, Thailand*
[*]*Krittanun.d.aa@g.sut.ac.th*

**Keywords:** MOFs, Acetone-Butanol-Ethanol

**Introduction :** An intermediate mixure of acetone, butanol, and ethanol (ABE) produed by fermentation from biomass have been currently gaining significant attention for making high-value chemicals and fuels [1]. This ABE udgrading required a metal/metal oxide catalysts with a high reaction temperature (160-300 °C) under autogeneous pressure to create the coupling alcohol/ketone products. There are some reports revealed that the use of magnesium or aluminium oxide-based catalysts can transform the ABE mixture. Those catalytic performance exhibited good activities. However, a modification of such catalyst type is difficult to enhance selectivity and productivity [2]. Therefore, the development of catalyst capable of efficient and selective transformation of ABE is still a formidable challenge. Herein, we aimed to explore the heterogeneous catalytic ABE updgrading reaction by using metal-organic framework-derived catalyst which is easier to design and functionallization. Moreover, the correlation between the upgrading products and physicochemical properties and reaction parameters will be investigated.

**Experimental/methodology :** In a typical reaction condition, 10 mg of Ni-ZIF-8 and 0.5 mL ABE mixture with/without $K_2CO_3$ were added into a 0.6-mL micro-reactor maded by stainless steel tube reactor, capped, and then heated to a desired temperature for 24 h. After cooling down, the product mixtures were analyzed by GC-FID and GC-MS. The spent catalysts were further charaterized by several X-Ray techniques, spectroscopic techniques.

**Results and discussion :** The ABE conversions demonstrated a modest catalytic activity in the absence of a catalyst, as indicated in Table 1. While employing Ni-ZIF-8, the conversions were increased by more than double. Similar compounds produced under both conditions include aliphatic ketones like 1-butanal and 3-heptene-2-one. In contrast, the reduction in overall ABE conversions was seen when Ni-ZIF-8 and $K_2CO_3$ were used as catalyst and co-catalyst, respectively. However, alicyclic ketone such as isophorone and 3, 5-dimethyl-2-cyclohexene-1-one were mainly produced. The product selectivity may result from acid-base properties of the catalysts. These results suggested the use of ZIF-derived catalyst are promising heterogeneous catalyst for ABE upgrading.

**Table 1.** Catalytic performance of ABE upgrading reaction

| | **Catalyst** | | |
|---|---|---|---|
| | **none** | **Ni-ZIF-8** | **Ni-ZIF-8 with $K_2CO_3$** |
| **Acetone conversion** | 38.7 | 63.8 | 75.1 |

# The transesterification process of vegetable oils based on heterogeneous catalysts of rare and alkaline earth metals

D. Dendek[1*], M. Zakrzewski[1], T. Maniecki[1]

[1]*Department of Chemistry, Institute of General and Ecological Chemistry, Lodz University of Technology, Zeromskiego 116, 90-924 Lodz, Poland*

[*]*daria.dendek@dokt.p.lodz.pl*

**Keywords:** biodiesel; transestrification; vegetable oils, heterogeneous catalyst

**Introduction.** One economically produced method of biodiesel is the transesterification of vegetable oils. Currently, different types of catalysts such as homogeneous and heterogeneous are used. However, the latter shows greater efficiency, multiple use, and environmental friendliness. Alkaline and rare earth metals in particular are recoverable and can give high-quality products. For example, calcium oxide (CaO) is a commonly used component of catalytic systems in the production of biodiesel in the transesterification process due to its wide availability, low cost, and non-corrosive. Another example is $La_2O_3$, which provides stability and prevents the washing out of the active ingredient during the transesterification reaction. Yan et al. in their work found that the system containing $La_2O_3$ and CaO is resistant to oil feedstocks containing a high content of free fatty acids in the transesterification process [1]. The addition of lanthanum may affect the stability of the system and the possibility of obtaining higher activities. The aim of the work is to optimize the transesterification process based on systems based on $La_2O_3$ and CaO and to find a correlation between the alkalinity/acidity of the surface and the activity of the catalyst.

**Experimental/methodology.** The CaO-$Al_2O_3$, $La_2O_3$-$Al_2O_3$, and $La_2O_3$-CaO catalysts were prepared in two stages. First of all, $Al_2O_3$ and CaO supports were obtained by the precipitation method using ammonia water or sodium hydroxide as precipitation agents. Then, the $Al_2O_3$ compound was covered with CaO in the ratio of 70:30 and 50:50, and $La_2O_3$ in the ratio of 70:30 using wet impregnation. The $La_2O_3$-CaO system (ratio 30:70) was synthesized also by impregnating CaO using lanthanum (III) nitrate (V) salts. Finally, the catalysts were calcined at 800 ℃ for 4 hours. The obtained catalytic systems were subjected to physicochemical tests: X-ray diffraction (XRD), Atomic Absorption Spectrometry (AAS), and Temperature programmed desorption (TPD-$CO_2$). The catalytic systems were subjected to the transesterification process in various conditions (p = 1atm, temperature range 50 – 150 °C, time = 0.5 – 1.5h) using an autoclave and then the resulting solution was tested using high-performance liquid chromatography (HPLC).

**Results and discussion.** The prepared catalytic systems were subjected to the transesterification process, in which 30 ml of rapeseed oil, 10 ml of methanol, and 250 mg of catalyst were used each time. After the process, the product was separated from the catalyst and subjected to HPLC tests, which allowed us to calculate the conversion of triglycerides. The obtained conversions of the 5 main components of rapeseed oil were very similar, therefore they were averaged and presented in

Table 1. XRD studies of the above catalytic systems showed the presence of CaO, $La_2O_3$, and $Al_2O_3$ structures depending on the used sample. The AAS study allowed us to confirm that the content of calcium and lanthanum in the catalytic systems agrees with the amount initially introduced into the systems. TPD-$CO_2$ studies showed that the CaO-based system has more basic sites than the $La_2O_3$ system, which is in good agreement with the conversion results.

**Table 1. Triglyceride conversion for the used catalytic systems.**

| Catalyst | Conversion [%] |
|---|---|
| $La_2O_3/Al_2O_3$ 70:30 | 28 |
| $CaO/Al_2O_3$ 50:50 | 28 |
| $CaO/Al_2O_3$ 70:30 | 36 |
| $La_2O_3$/CaO 30:70 | 96 |

**Introduction.** Fly ashes are generated worldwide on a massive scale because of industrial energy production from fossil fuels based on coal and heavy oil combustion. Through the last few decades, there was a lot of studies focused on various methods of valorization of fly ashes (FAs). However, one of the most ambitious applications is the use of FAs as precursors to obtain functional materials such as catalysts, catalytic supports, or sorbents. In this work we discuss several representative examples of efficient use of FAs as valuable precursors to synthesize i) advanced materials of catalytic importance, including oxide phases active in such reactions as DMR, de$NO_x$, deSoot or ammonia oxidation, ii) supports for transition metals or metal ions tailored for catalytic systems applied e.g., in $CO_2$ hydrogenation or iii) in synthesis of zeolites. Our goal was to select and to indicate the decisive parameters of fly ashes, determining their possible catalytic applications [1]. Such sustainable pro-ecological approach remains in agreement with principles of circular economy and permits to exploit high potential of fly ashes as synthetic raw materials.

**Experimental/methodology.** Six types of FAs obtained from industrial coal-fired power plants have been investigated to be used as starting components for synthesis of catalytic materials mentioned above. All ashes were generated by coal combustion in pulverized-fuel boilers. Additionally, one type of ash generated during heavy oil combustion has also been studied. Bare oxides, supported oxide systems containing both support and active phase prepared from fly ashes as well as NaX and MCM-22 zeolites were synthesized by optimized wet chemistry procedures. All FAs used for syntheses and the obtained new materials have been
in-depth characterized by XRF, XRD, RS, BET, SEM and DRIFT.

**Results and discussion.** The results of structural, textural and functional characterization of FAs as starting components for synthesis of both oxide systems and zeolites have been obtained [2]. Optimized parameters and dedicated synthetic pathways ensuring high efficiency towards target products and giving a possibility to control surface architecture of the final systems, have been proposed. The role of such critical parameters as the presence of residual carbonaceous impurities, the content ratios of the glass to crystalline phases or Si to Al have been elucidated. Moreover,
the importance of such textural properties as specific surface areas, particle types and their size distributions have been analyzed in detail. The obtained results clearly confirmed the complex nature of the fly ashes and their evident potential to be used for synthesis of such functional materials as e.g., oxide catalytic systems or zeolites.

**Keywords:** zeolites; synthesis; crystallization, ozone, acid site distribution

**Introduction.** Despite extensive tuning of zeolite catalyst, little is known on the synthetic origin of acid sites and their distribution at the sub-nanoscale. Even more, the effect of calcination is often unconsidered. This work demonstrates bottom-up rational selection criteria for synthesis of SSZ-13 (CHA) and ZSM-5 (MFI) with tuned Al and acid site distributions. It is demonstrated that Al and acid siting change during prolonged synthesis and during thermal activation. Many recent findings suggest that zeolite catalysis is influenced by synergistic effects (BAS-BAS; BAS-LAS) derived from acid site proximity or Al distribution.[1] Next to adequate post-synthetic treatments,[2] delicate engineering of zeolite crystallization (synthesis) is possible with control over crystal dimensions, morphology and charge deficit. Hence, synthesis is an important consideration when making application oriented materials with tuned Al and acid site proximity.
**Experimental/methodology.** Five crystallization systems are studied yielding ZSM-5 (MFI) and SSZ-13 (CHA), made either via interzeolite conversion or conventionally.[3,4] Synthesis evolution is tracked in time for stoichiometrically identical synthesis systems, obliviate the used SDA ($1Si:0.025Al:0.35SDA^{+}:0.35OH:{\sim}15H_2O$). The synthesis output is analysed via elemental analysis, P-XRD, N2-physisorption, (D)TGA, TEM-EDX and (Pyridine) FT-IR and aqueous $Co^{II}$-exchange (DCC).
**Results and discussion.** Overall, Al was identified as key component during all stages: (FAU) dissolution, nucleation, assembly and maturation. The latter is generalized through an in-depth comparison with literature.[5] Single-parameter variations applied during synthesis of siliceous SSZ-13 showed that both kinetic and thermodynamic components influenced Al distribution.[3] Most significantly, it was found that internal arrangement of Al in SSZ-13 still evolves with synthesis time. The extent of synthesis evolution varies dependent on the synthesis system (OSDA-zeolite combo), which was previously unreported in literature. TPA/Na containing ZSM-5 has a strongly evolving DCC, whilst no DCC evolution is detected over (oven) time for TMAda/Na containing SSZ-13.[4] Our work adds novel insights on the synthesis processes that regulate the final acid site distributions within zeolites by taking into account the mobility of ionic charge. It is proposed that internal rearrangement of Al occurs at the level of cages towards more thermodynamically favored Al (charge) separation.[4;6] Furthermore, Al distributions are also found to change with calcination. We engineered a low-temperature ozone activation process for zeolites.[7] In parallel to Al mobility upon prolonged synthesis, elevated calcination temperature also affects the internal Al distributions, as well as Al speciation. A picture is drawn how Al speciation evolves with activation temperature, also taking into account the synthesis-specific reality (crystal size, stability, etc.).[8] Understanding the mostly unconsidered effect of 'synthesis + activation temperature' may not only help to explain conflicting literature reports, but it may also significantly enlarge the toolbox for bottom-up rational engineering of future catalysts.

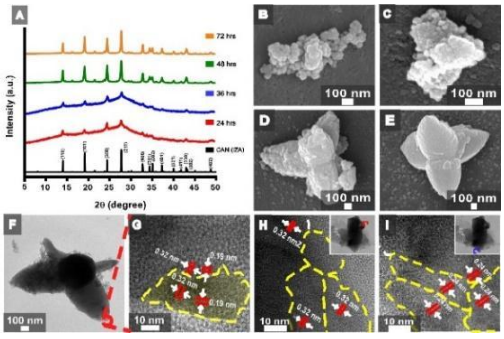
**Introduction.** Zeolite with its unique pore architecture and tunable acid site distribution has emerged as a prominent candidate in the multi-dimensional application field[1]. Conventional synthesis of zeolite in the solvothermal process includes several disadvantages including high solvent consumption, low yield, high operational pressure, and environmental concerns making these processes economically challenging. To mitigate these challenges, researchers have developed various new strategies. Recently, a new pathway, the solid-state transformation has been reported which has the potential to become the greener approach to synthesizing zeolite for the industry with commercial profitability. Although studies have successfully postulated the formation mechanism of several zeolite frameworks, the control over morphological growth and hence the intrinsic properties is still elusive[2]. Our work has established mechanistic insights into the crystallization of zeolite in solid-state synthesis.

**Experimental/methodology.** The pure cancrinite phase was synthesized by taking the solid raw materials in appropriate quantities into a mortar pestle, grinding the solid mixture for at least 20 minutes, and then transferring it to the Teflon-lined acid bomb digestor. After that, it was heat treated various times at 120˚C. The solid product was washed thrice with DI water while centrifugation, after which dried at 60˚C overnight and collected.

**Results and discussion.** In this study, we have investigated the mechanistic insights of a zeolite framework, CAN synthesize via solid-state transformation. Systematic powder X-ray diffraction studies of the samples synthesized after 24, 36, 48 and 72 hrs. have revealed the presence of an initial slow crystallization process up to 36 hrs. followed by an accelerated growth phase producing a complete crystal phase after 48hrs. suggesting the presence of typical complex reactions at the initial stage that occurs in the hydrothermal synthesis of zeolite[3]. Morphological evolution study using scanning electron microscopic (SEM) images revealed to form a unique 'dendrimeric' shaped morphology whose surfaces were seemed to highly roughen as they comprised domains of spheroidal particles. These rough surface starts to smoothen with further heating up to 72 hrs (figure 1E). The investigation of the nanoparticle agglomeration phenomenon using HRTEM imaging revealed the attachment of nanoparticles among themselves and with the bulk through typical crystallographic planes of the CAN phase. Domains having nanoparticles with oriented attachment can be seen in images H and I. Although, the common crystal plane varies with the different positions of the particle. This suggests the formation of individual domains having the single-crystal-like feature. These domains finally agglomerate to form the final bulk particle which is a meso crystal rather than a single crystal as complete grain boundary migration is still elusive. Based on these observations it can be suggested that in solid-state transformation, nanoparticles tend to follow a hybrid non-classical mechanism for morphological growth.



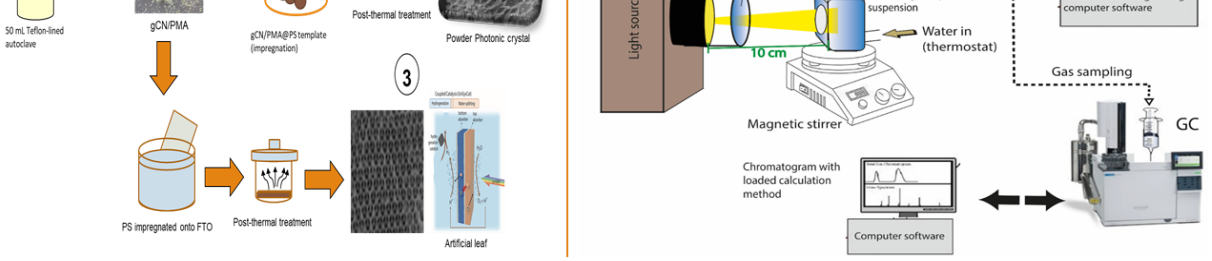


**Figure 1. The figure illustrates powder XRD pattern of the synthesized solids depicted in the image (A), the (B-E) (SEM) images of the as-synthesized particles. (F-I) HRTEM image was taken for the particles synthesized after 72 hrs. of heating.**

**Introduction.**
When used as a photocatalyst for light-driven catalyzed reactions, graphitic carbon nitride[1] (gCN) exhibited very low catalytic performances due to the slow charges separation and their fast recombination but, at least it provides one of the best chemical frameworks for the synthesis of highly efficient photocatalysts useful to better achieve the light-harvesting process[2,3]. In this study, we fabricated for the first time a photonic crystal material like inverse opal structure made up P-doped gCN backbone with metal ions confined in the lattice structure then, the PC has been applied as photocatalyst for efficient light harvesting and charge separation in photocatalytic $H_2O_2$ synthesis, hydrogen evolution and photo-electrochemical water splitting.

**Experimental/methodology.**

Figure 1: Synthesis method of PCs (a), Experiemntal photocatalytic setup for catalyzed reactions (b).

As displayed in figure 1.a, the synthesis method consisted first of the preparation of a bulk composite made up gCN and polyoxometalate (POM). By a chemical wet impregnation, a colloidal solution is then formed by immersion of the bulk solution into a dispersion of Polystyrene spheres. After post-thermal annealing, the final P-doped PC was obtained and characterized. By the use of the experimental setup, as displayed in figure 1.b, the PCs samples were applied for light-driven $H_2O_2$ synthesis and hydrogen evolution. PEC was also used for overall water-splitting reactions.

contact e-mail: fabien.drault@uclouvain.be

**Introduction.** Tuning silica ($SiO_2$) nanostructures from one-dimensional (1D) to three-dimensional (3D) nanotubes (NTs) networks is of great interest. Indeed, free-standing 3D $SiO_2$ NTs membranes could be useful for several applications, and in particular for heterogeneous catalytic systems involving flow chemistry and continuous processes[1]. Indeed, $SiO_2$ is a well-known catalysis support with a high versatility for tailoring. The advantage of the proposed nanotubes synthesis method resides in the possible multi-functionalization of their inner and/or outer surfaces by different active sites, which could be incompatible when in direct contact. To this aim, polycarbonate track-etched (PCTE) membranes (provided by it4ip) with an interconnected cylindrical nanopores system have been used as template[2].

**Experimental/methodology.** The synthesis of 3D $SiO_2$ NTs (Figure 1) consists in the two following steps: sol-gel deposition[3] within the pores of the PCTE membranes and extraction of this template. In addition, selective gold nanoparticles (Au NPs) functionalization of the $SiO_2$ nanotube's inner surface has been performed by electroless deposition[4].

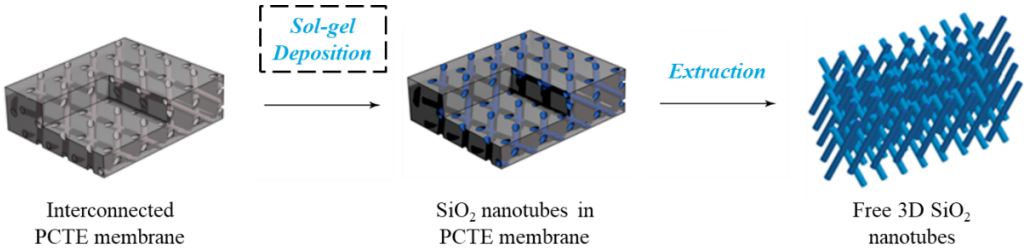

**Figure 1 – Two step synthesis for the production of free 3D $SiO_2$ NTs using interconnected PTCE membrane.**

**Results and discussion.** The obtained nanostructures were characterized by multiple techniques (i.e. electron microscopy (Figure 2), XRD, $N_2$ physisorption, XPS) at each step of their elaboration, allowing the identification of key parameters to control silica sol-gel and gold electroless deposition. Interestingly, 1D and 3D $SiO_2$ NTs with different structural porosities were succesfully prepared and, the NTs porosity was shown to strongly impact the subsequent Au deposition process. Indeed, different Au amounts were deposited, ranging from 11 to 4 wt.% at the surface of mesoporous and non-porous $SiO_2$ NTs, respectively, indicating that Au NPs are mainly localized inside the $SiO_2$ tubes when their pore walls are non-porous.

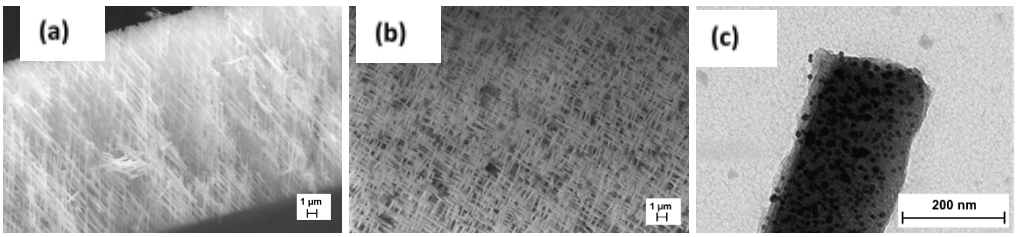

**Figure 2 – SEM images (a) of the side, (b) top view of the obtained free-standing 3D $SiO_2$ NTs functionalized by Au NPs and (c) TEM image of a single $SiO_2$ NTs functionalized by Au NPs.**

# The reduction/oxidation potential of nickel, cobalt, and copper oxides derived from various precursors

P. Gwóźdź, A. Łącz, S. Komarek, K. Kornaus, E. Drożdż*

*AGH University of Science and Technology in Krakow, Faculty of Materials Science and Ceramics, Poland*
**edrozdz@agh.edu.pl*

**Keywords:** nickel oxide, cobalt oxides, copper oxides, nitrate precursor, acetate precursor, catalyst

**Introduction.** Ni, Co, and Cu oxides are one of the most commonly used materials in environmental catalysis and/or for energy conversion technologies. However, the catalytic abilities of these oxides are strongly related to their physiochemical properties such as particle size and particle size distribution, specific surface area (SSA), and the oxidation state of metal in the oxides' structure. The motivation to start the presented research was the diverse and often inconsistent results of temperature-programmed reduction studies conducted on the above-mentioned oxides presented in the literature.

**Experimental/methodology.** Ni, Co, and Cu oxides were obtained by the thermal decomposition of proper acetates and nitrates. The various heating rates were applied – 1 deg/min and 10 deg/min to achieve a different morphology. The obtained powders were characterized in terms of phase and chemical composition (XRD, EDS), microstructure (SEM, BET, DLS – *Dynamic Light Scattering*), and reduction properties (TPR/TPOx). Additionally, commercially available Ni, Co, and Cu oxides were characterized and used as reference materials.

**Results and discussion.** The results of phase composition analysis showed that regardless of the precursor used (nitrates or acetates) the final products of the decomposition are the proper oxides - NiO, $Co_3O_4$, and CuO. TG/DTA curves for the thermal decomposition of nickel, cobalt, and copper nitrates are shown in Figure 1. The obtained oxides, derived from various precursors, do not differ significantly in the specific surface area and particle size distribution within the applied heating rate. However, these parameters are different when comparing the oxides obtained with different heating rates. To determine the influence of the microstructure of the powders on their reducing properties mainly, the temperature of reduction beginning, and the character of the TPR profiles (the number of reduction peaks and maximum temperature of the reduction peaks) TPR measurements were carried out for materials obtained by the thermal decomposition of both precursors. In addition, TPR measurements of reference materials were carried out. These oxides were also characterized in terms of their structure and microstructure.

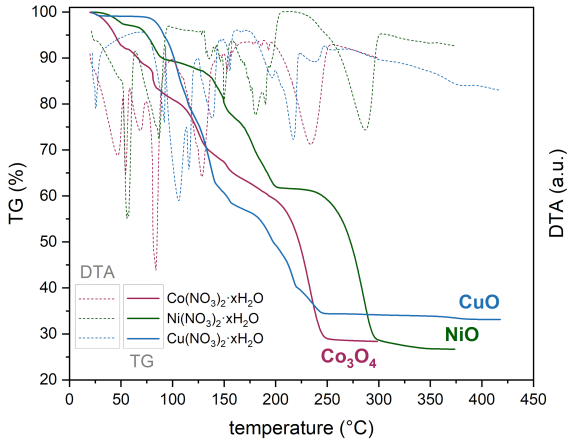

Figure 1. The TG/DTA curves of thermal decomposition of Co, Ni, and Cu hydrate nitrates.

# P, O-co-doped carbons as a catalysts in 1-cloro-4-nitrobenzene hydrogenation

E. S. Duran-Uribe[1*], E. V. Ramos-Fernadez, A. Sepulveda-Escribano

*Laboratorio de Materiales Avanzados, Departamento de Química Inorgánica – Instituto Universitario de Materiales de Alicante, Universidad de Alicante, Alicante, Spain*

**Keywords:** Doped carbon, nitroarenes reduction, metal-free catalyst

**Introduction.** The catalytic hydrogenation of nitroarenes to obtain anilines has received great industrial interest, due to the simplicity of the process and the low by-products formation [1]. Doped carbon-based materials are promising candidates for their use as metal-free catalysts in chemical reduction of nitro compounds [2]. Some studies have shown that surface modification of carbon with heteroatoms such as N improves the catalytic activity [3]. However, a study on the effect of oxygenated groups on activated carbons, as well as the effect of different types of phosphorus, has not been carried out. Therefore, in this study the use of O- and P-doped carbons for the hydrogenation of 1-chloro-4-nitrobenzene was proposed. In addition, the effect of the different functional groups and synthesis methods on the catalytic activity was studied.

**Experimental** For the preparation of O-doped carbons, RGC30 (commercial mesoporous carbon) was stirred for 48 h in a 6 M $H_2O_2$ solution and then washed with water several times. Finally, the generated oxygen surface groups were partially removed by heat treatment in an inert atmosphere. For the preparation of P, O-codoped carbon the RGC30 and PA (phytic acid) were mixed and subsequently pyrolyzed in a furnace under inert atmosphere at different temperatures. The catalysts were finally tested in the hydrogenation of 1-chloro-4-nitrobenzene (CNB) using hydrazine as reducing agent.

**Results and discussion** After pyrolysis of PA and RGC30, the presence of phosphorus in the carbon was observed by XPS, which is characterized by peaks from 132 to 134 eV in the P 2p region in all catalysts. Furthermore, it was observed that different phosphorus functional groups were obtained depending on the pyrolysis temperature, the amount of PA and the pretreatment of the precursors. The synthesis route in which PA is polymerized on RGC30 was found to be the most suitable one, resulting in surface phosphorus with a binding energy close to that of $C_3PO$, where phosphorous is inside the carbon structure (132 eV). On the other hand, the synthesis route in which there was no pretreatment prior to pyrolysis is the most suitable one for obtaining phosphorus outside the carbonaceous structure, as $CPO_3$ (133,5 eV). Finally, an increase in the oxygenated groups was observed after treatment with $H_2O_2$. An increase in quinone, ester, anhydride and carboxyl groups was observed. However, when the catalyst was treated at 900 °C in an inert atmosphere, a decrease in quinone and carboxyl groups was observed. When testing the catalytic activity for the hydrogenation of CNB (**Fig. 1**), it was observed that, regardless of the treatment of the catalyst, a selectivity of more than 99% is obtained for chloroaniline. The treatment significantly affects the activity. The oxidised catalyst (RGC30_OX) shows better catalytic activity than RGC30. In addition, an increase in catalytic activity was observed when the catalysts was doped with P (RPA1.0P9PP, RPA1.0P9PP_OX).

**Introduction.** By tuning the concentration and location of catalyst dopants, such as sulfur or phosphorus, the properties of catalysts can be changed. A known example is the doping of Pt-catalysts with sulfur in the dehydrogenation of hydrocarbons. The sulfur-dopant blocks strong adsorbing Pt-sites, which leads to a simultaneous increase in activity and selectivity.[1] Phosphorus can also influence the properties of the catalytically active metal by changing the electronic and geometric properties of the metal particles in the catalyst.[2,3] In this study, we show a promising effect of P-doping for Pt-catalysts, distinctly increasing their catalytic activity in cycloalkane dehydrogenation.

**Experimental/methodology.** Two different P-modification methods are developed and compared. The first method involves wet impregnation of a $Pt/Al_2O_3$ catalyst with phosphorous acid, followed by a reduction with hydrogen. The second method involves the decomposition of sodium hypophosphite at temperatures above 250 °C in a furnace upstream of a $Pt/Al_2O_3$-catalyst, by which a P-doped Pt-catalyst is obtained.

**Results and discussion.** It is observed, that reduction temperatures of 600 °C are required to fully activate a P-doped Pt-catalyst for the dehydrogenation of perhydrobenzyltoluene (H12-BT), to obtain a higher activity than the corresponding P-free material. At the same time, the pure $Pt/Al_2O_3$ suffers from sintering at high reduction temperatures, an effect that is efficiently suppressed by P-doping (Figure 1).

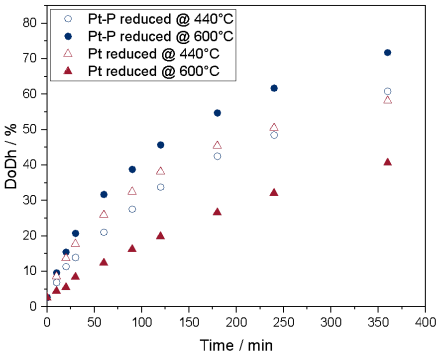

**Figure 1 Degree of dehydrogenation (DoDh) over time for 3 wt.% Pt-catalysts with and without 0.9 wt.% P, supported on $Al_2O_3$, reduced at 440 or 600 °C. Catalysts tested at H12-BT:Pt = 2000:1. 15 g H12-BT, initial inertization with Ar, reaction at 250 °C, 1 atm. Degree of dehydrogenation measured *via* refractive index.**

In addition, setting an optimal P:Pt-ratio is essential to achieve high activities, since both, too low and too high levels of phosphorus lead to an activity loss. Investigations using TEM revealed that the Pt-P-catalysts have average particle sizes below 1 nm despite the high-temperature reduction step. To understand the effect of P-addition *via* the two synthesis methods, XPS, STEM-EDX, CO pulse chemisorption and $NH_3$-TPD measurements are conducted. With these studies material properties, such as particle sizes and distribution, electron density, as well as surface acidity are elucidated. In summary, the here presented study gives insights into the function and role of phosphorus in P-modified transition metal catalysts and demonstrates the high potential of these materials for dehydrogenation reactions and their high-temperature stability.

[*] *krossing@uni-freiburg.de*

**Keywords:** Methanol Synthesis, $CO_2$ hydrogenation, heterogenous catalysis, fluorination

**Introduction.** The largest part of todays produced methanol is synthesized based on fossil resources *via* a catalytical process. Regarding the current climate problem, a more sustainable synthesis route such as the hydrogenation of $CO_2$ would be desirable. In almost all industrial MeOH catalyst systems, the actual catalysis is mainly based on the catalytically active Cu/ZnO pair, with one or more supporting oxides (such as $Al_2O_3$, called support or promotor[1]) being added. For a MeOH synthesis from $CO_2$ and $H_2$ instead of CO and $H_2$, $Al_2O_3$ is unsuitable as a promotor, here $ZrO_2$ was discovered as a promising alternative (CZZ system).[2] Investigations on binary Cu/ZnO systems have shown that treatment with fluorine increases MeOH productivity and selectivity.[3,4] When trying to transfer the positive effect of fluorination to the ternary CZZ system, it was found that Zr acts as a "fluorine magnet" and no positive effect on productivity or selectivity is observed.[5] This work deals with Mg as an alternative to Zr that is compatible with the fluorination process.

**Experimental/methodology.** Catalyst materials were prepared *via* a conventional co-precipitation method: nitrate salts of the metals (Cu, Zn, Mg) were dissolved in $H_2O$ and precipitated by adding $Na_2CO_3$ solution (1 M) while temperature and pH were kept constant. The precipitated products were then washed and dried in a spray drying process. Afterwards, these precursors were calcinated (300 °C) and a further treatment was done by reaction of the precatalysts with $F_2$. Catalysis testing was done at 250 °C and 40 bar, $CO_2 : H_2 = 1 : 3$. The outlet gas stream was analyzed by an in-line gas chromatograph. Further characterization techniques for the catalyst materials were ICP-OES, SEM, EDX, pXRD, IR-spectroscopy, fluoride ion chromatography, XPS, $N_2$-physisorption (BET) and TGA.

**Results and discussion.** Several different catalysts with different compositions (Cu : Zn : Mg = 3.75 : 1.73 : *X*; *X* = 0.5, 1.0, 2.0) and under different synthesis conditions (variation of synthesis temperature, pH and aging time) were produced. A total of 5 different CZMg systems were produced, all of which were treated with about 1.4 wt% $F_2$, thus 10 different systems were obtained. The catalyst systems show good tunability in their physical and chemical properties as well as in their catalytic properties. The treatment with fluorine (1.4 wt%) leads in all cases to an increase in the methanol productivity (see figure 1, up to 150 %) and selectivity. In the case of MeOH productivity, this is most likely due to an increase in the number of $ZnO_{1-x}$ defect sites.[3,4] The increase in the MeOH selectivity is most likely due to an increase in the activation energy for the competing RWGS reaction.[4] Interestingly, an increase in fluorine content leads to a significantly increased long-term stability, which is the subject of our current research.

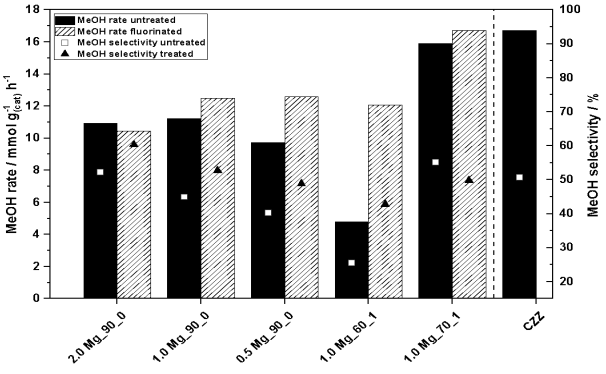

**Figure SEQ Figure * ARABIC 1.** MeOH rates and selectivities of all synthesized catalyst systems (in pairs untreated and fluorinated). The data set of the CZZ benchmark system has been added for comparison.

# Biodegradable polymer synthesis via acyclic diene metathesis (ADMET) polymerization

Vajk Farkas[*1,2], Paul T. Anastas[3], Robert Tuba[1,3]

**Keywords:** biodegradable polymers, ADMET, olefin metathesis

**Introduction.**

Recently, polybutylene adipate terephthalate (PBAT), polybutylenesuccinate (PBS) and polybutylene carbonate (PBC) gain more and more attention as alternative biodegradable polymers for polypropylene (PP) and low-density polyethylene (LDPE).[1,2] The synthesis of these polymers via acyclic diene metathesis polymerization of diallyl esters and diallyl carbonate offer a less energy-intensive process compared to the traditional polycondensation method.

Commercially available, first-generation Grubbs catalyst (G1) had already been investigated in the past years. Ben-Haida and his co-workers reported that in the case of diallylterephtalate G1 was not able to reach high polymerization degree (PD) of 4 with molecular weight ($M_w$) of 1.0 *kDa* and polydispersity (PDI) of 1.25. In the case of diallyladipate, G1 showed slightly higher activity with PD of 7, $M_w$ of 8.3, and PDI of 6.38.[3].

**Results and discussion.**

Newly synthesized cyclic (alkyl)(amino)carbene (CAAC) catalyst has been proven to be most efficient catalyst, when the polymerization was carried out in bulk with mechanical stirring at 75°C with 0.5 mol% catalyst load. Advanced polymer chromatography (APC) analysis showed acceptable molecular weight of the synthesized polymer. The unsaturated polymer can be hydrogenated at high pressure (20 bar) and high temperature (100°C) using 10% palladium on carbon.

# Investigations into modulation of ZSM-5 acidity via modifier-assisted synthesis

M.H.Z. Faruqi[1], M. Kumar[1*]

[1]*Department of Chemical Engineering, Indian Institute of Technology Delhi, New Delhi, India*
**manjeshkumar@chemical.iitd.ac.in*

**Keywords:** *Zeolite crystallization, ZSM-5, zeolite growth modifier (ZGM), zeolite acidity*

**Introduction.** ZSM-5 is a medium-pore silica-rich zeolite requiring high crystallization temperatures (423-473 K) and alkaline pH (>11) for synthesis. Acid sites in zeolite ZSM-5 are responsible for a variety of reactions such as conversion of methanol to gasoline/olefins, paraffin isomerization, etc [1]. Also, shape-selective catalysis in zeolites is achievable via modulation of crystal size and morphology to enhance exposure of certain crystal facets using zeolite growth modifiers [2]. Thus, tuning zeolite acidity along with modulation of crystal morphology is an interesting proposition for enhanced catalytic activity. Here, we present a novel approach to synthesize ZSM-5 with controllable acidity.

**Experimental/methodology.** The zeolite ZSM-5 was synthesized using hydrothermal method [3]. TEOS was added to a solution containing $NaAlO_2$ and TPAOH solution resulting in a dense gel formation. In the next step, a solution containing NaOH, TPABr, and deionized (DI) water was added. ZGM was added to the resulting mixture and stirred at room temperature for 20 hr, transferred to a Teflon-lined stainless-steel autoclave, and hydrothermally treated at 180°C for 48 hr.

**Results and discussion.** In this study, ZSM-5 crystal was synthesized by varying physicochemical growth conditions of mother liquor for zeolite synthesis before high-temperature hydrothermal treatment. The effect of monovalent and divalent salts on the morphological and acidity characteristics of the zeolite was investigated.

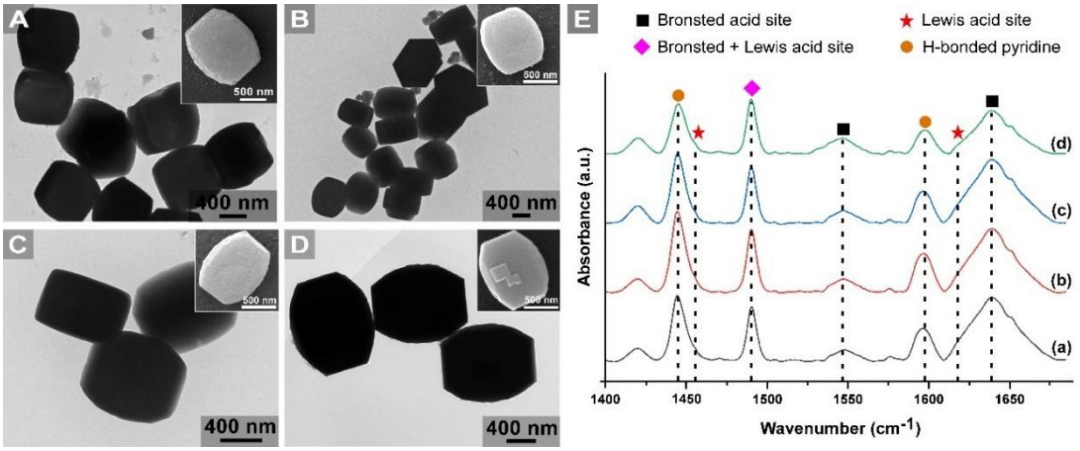

**Figure-1: TEM and SEM (inset) images of synthesized ZSM-5 crystals showing twinned boat morphology in (A-D). (A) ZSM-5 control sample showed crystal size ~1.5 µm. (B) ZSM-5 synthesized in presence of $Li^+$ ions resulted in elongated (along c-axis) and faceted crystals with crystal size ~1.5-2 µm. (C) Presence of divalent $Ca^{2+}$ ions during ZSM-5 synthesis resulted in crystal size ~1 µm. (D) Synthesis in presence of divalent $Mg^{2+}$ resulted in uniform crystal size of ~1-1.5 µm. (E) represents IR spectra of pyridine adsorbed ZSM-5 samples in above order (A-D) for comparison of acidity characteristics.**

The results indicated that, apart from affecting the particle size and morphology, growth modifiers can also be used to tune the acidity characteristics of zeolite ZSM-5. Significant changes in Bronsted and Lewis acidity were observed on switching between monovalent and divalent modifiers, which can be attributed to variable interaction of ions with framework and/or extra-framework constituents.

# Controlling the Crystallite Size and Polydispersity using Colloidal Silica Stabilizing Agent

Aditya[1], Manjesh Kumar[1*]

[1]*Department of Chemical Engineering, Indian Institute of Technology Delhi, New Delhi, India*
[*]*manjeshkumar@chemical.iitd.ac.in*

**Keywords:** Catalysis, Stablizing agent, Growth modifiers, Polydispersity

**Introduction.** Tailoring the physical properties of advanced functional materials is crucial to ensure their superior performance for various applications. It requires a comprehensive understanding of their mechanistic pathways of formation [1],[2]. Here, we are investigating the industrially relevant zeolite, specifically SSZ-13, that has been used extensively in a myriad of applications such as selective catalytic reduction, Methanol to Olefin reaction, among others. Tuning the polydispersity, size, and morphology of the zeolite crystals has been a major challenge for efficient catalyst design. Owing to these challenges, we have designed a novel synthetic protocol to develop SSZ-13 crystals that can control the size, dispersity, and morphology of the particles. The approach uses economically viable modifiers that make the process commercially relevant. The SSZ-13 crystals were synthesized by modulating the physicochemical growth conditions of the mother liquor to produce crystals with varying size ranges and improved dispersity. We tracked the growth of crystallite under static and dynamic conditions using modifiers to develop the optimized particle size and distribution. To establish better control over the dispersity of particles, we investigated the effect of various salts (monovalent, divalent, trivalent) acting as counter ions or stabilizing agents on the growth dynamics of the mother liquor.

**Experimental/methodology.** The synthesis of SSZ-13 zeolite was carried out using the hydrothermal method[3]. NaOH was mixed with Deionized water followed by the addition of Structure Directing Agent (SDA), $Al(OH)_3$, LUDOX AS-40/HS-40, and the mixture were stirred for 2h at room temperature. This solution was then subjected to high-temperature hydrothermal treatment for 4-7 days in dynamic conditions.

**Results and discussion.** The conventional SSZ-13 crystals synthesized using the two silica sources produces a bimodal distribution of particles with size varying from nanometer to microns. It is desirable to synthesize the crystals with reduced polydispersity and smaller sizes for better catalysis. We explored the use of colloidal stabilizers here that are extensively used for obtaining stable LUDOX solutions namely $Na^+$ and $NH_4^+$ ions. Here, we show in figure 1 (A, B) control sample of SSZ-13 having bimodal particle distribution. In figure 1(C, D, E, F) shows that the additional rational design principle helped us to obtain a smaller (~260 nm) and larger crystal of 2 µm .The new synthesis protocol was able to achieve the monodisperse population. It is interesting to observe that particle morphology evolved from cubic shape to polyhedron (figure 1 E & F). We carried out detailed particle distribution analysis by volume and numbers to track the crystallization evolution which helped us to understand the growth phenomena. A comprehensive mechanism and complete library of particles were generated that will be presented during the conference. Our study presents a comprehensive picture of controlling particle attributes using mechanistic know-how.

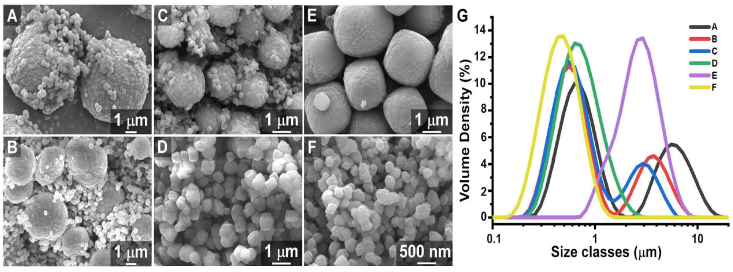

**Figure 1:** SEM images of the sample A)SSZ-13 control synthesized using LUDOX AS-40 B)control synthesized with LUDOX HS-40. C) Modifier 1 shows bimodal distribution like control samples. D) Modifier 2 shows mono-disperse particle with average size of ~520 nm E) Modifier 3 resulted in corrugated cubical particle with an average size of ~2 µm. F) Modifier 4 shows octahedral shaped particle with an average dimension of ~260 nm. G) Particle size distribution curve depicting the unimodal and bimodal distributions obtained by modifiers.

# Mechanochemical synthesis of $Ru/CeO_2$ catalysts for $CO_x$-free $H_2$ production from ammonia decomposition

A. Felli[1,*], M. Danielis[1], M. Zampol[1], A. Trovarelli[1], S. Colussi[1]

**Keywords:** Cerium oxide, mechanochemical synthesis, Metal-Support Interaction.

**Introduction.** $Ru/CeO_2$ is one of the most promising catalysts for the $H_2$ production from ammonia decomposition thanks to the chemical properties of cerium oxide and its interaction with Ru [1]. In this work, we studied $Ru/CeO_2$ catalysts prepared with a mild ball milling approach, which is a green, easy-to-do and fast method to prepare a solid catalyst [2]. For the first time, we evaluated the catalytic activity of milled catalysts towards $NH_3$ decomposition and we studied the parameters which could affect their performances, underlining the importance of the metal-support interaction (MSI) between Ru particles and $CeO_2$ support.

**Experimental/methodology.** Commercial $CeO_2$ (Rhodia) was calcined at different temperatures (550°C, 800°C, 900°C and 1200°C) for 4h (10°C/min) to evaluate the morphological properties of the supports. Ruthenium acetyl acetonate in powder form was milled with the different $CeO_2$ supports in a Pulverisette 23 Minimill for 20 minutes at 15 Hz (details reported elsewhere [2]) and calcined in air at 550°C for 2h. A conventional catalyst was also prepared via wet impregnation using $CeO_2$(550) as support. X-ray diffraction (XRD), $N_2$ adsorption, Temperature programmed reduction (TPR) and Raman spectroscopy were used for characterization. $NH_3$ decomposition was studied by loading 50 mg of sample in a tubular quartz reactor from RT to 550 °C exposed to 30 mL/min of 5% $NH_3$ in He monitoring gases by a micro gas chromatograph.

**Results and discussion.**

| | BET S. A. ($m^2g^{-1}$) | $I_{Ru\text{-}O\text{-}Ce}/I_{F2g(Ce)}$ (a. u.) | $NH_3$ conv. at 360 °C (%) |
|---|---|---|---|
| $RuCeO_2$(550) | 115 | 0.14 | 83.5 |
| $RuCeO_2$(800) | 71 | 0.06 | 65.0 |
| $RuCeO_2$(900) | 35 | 0.05 | 56.9 |
| $RuCeO_2$(1200) | 4 | <0.01 | 23.9 |

**Left: $NH_3$ conversion for $RuCeO_2$(550), $RuCeO_2$(800), $RuCeO_2$(900) and $RuCeO_2$(1200). Right: surface area (SA), Metal-Support Interaction ($I_{Ru\text{-}O\text{-}Ce}/I_{F2g(Ce)}$) evaluation from Raman spectroscopy and $NH_3$ conversion at 360 °C for all the samples.**

Light-off curves show an increase in catalytic activity for $NH_3$ conversion as SA increases; however, $RuCeO_2$(800) and $RuCeO_2$(900) show similar activity, despite having significantly different SA. In order to identify which parameter mainly affects the catalytic activity, we employed several characterization techniques to study the $Ru/CeO_2$ system. While XRD and TPR analyses show a qualitative difference in Ru dispersion among all the samples, Raman spectroscopy reveals that $RuCeO_2$(800) and $RuCeO_2$(900) possess an analogue Metal-Support Interaction, which could explain their similar performances despite a different SA. A more in-depth study to confirm the role of MSI between Ru and $CeO_2$ in ammonia decomposition is under way employing other characterization techniques.

Several industrial catalytic processes are currently being investigated as pathways to store renewable energy in chemical molecules in smaller decentralized plants. The whole family of processes is termed Power to X (PtX) with X representing the target molecule/product. While most of the processes within the PtX envelope are industrially established, the new boundary conditions of small-scale renewable energy-based plants can require a significant redesign of the catalytic materials to withstand the expected harsher reaction conditions. We have been focusing especially on the stability of promoters under reaction conditions and have developed a new design concept combining the physical structure of an oxidic support material with the provision of promotional functionality – empowered supports – and demonstrated this concept in the iron-based Fischer-Tropsch synthesis (FTS).

The exact speciation of promoter elements in classic catalysts under reaction conditions is still not fully resolved. Low concentrations and promoter mobility [1] present the most significant challenges in this regard. Without a clear understanding of the interaction between the promoter and the active phase, catalyst optimization through design is not possible. Innovative preparation techniques have shown that when an intimate contact between the active phase and the promoter is achieved, the promoting effects observed surpass effects reported for catalysts prepared with conventional impregnation approaches [2].

Based on a rhombohedral $LaAlO_3$ perovskite, a series of supports was synthesized, partially replacing La with K and Al with Mn. Extensive laboratory and synchrotron-based characterization was conducted to ensure that the promoter elements are indeed incorporated in the perovskite structure. Iron oxide nanoparticles were subsequently deposited on these materials. Following a reductive treatment in hydrogen at elevated temperatures, the activity of the catalysts under FTS reaction conditions was investigated.

A combination of XRD, TEM and XAS confirmed the success of the perovskite synthesis. When Mn is present, the average oxidation state of Mn is elevated, countering the charge imbalance induced by the replacement of $La^{3+}$ with $K^{+}$. Reductive treatment reduces the average oxygen coordination of the La site from 12 to 11 stabilizing $K^{+}$, especially in $La_{0.9}K_{0.1}AlO_3$.
While iron supported on $LaAlO_3$ showed no enhanced activity or selectivity compared to conventional supports, the presence of K in the perovskite structure significantly enhances CO conversion. To achieve a comparable conversion, the space velocity had to be increased by a factor of 3.75. Under these conditions, the promoted catalyst displays a lower methane selectivity and enhanced chain growth as well as a much higher olefin to paraffin ratio in the hydrocarbon product. The $CO_2$ selectivity, the product of the water-gas shift reaction (WGS), is only slightly increased. The addition of small amounts of Mn further reduces methane and $CO_2$ selectivity while maintaining the high olefin to paraffin ratio. Higher Mn contents are detrimental to the CO conversion and increase the yield of short chained hydrocarbons. Compared to iron supported on $LaAlO_3$ promoted conventionally via potassium impregnation, the here developed materials have a much lower C1 product fraction, predominantly due to the decoupled enhancement of the FTS and the WGS reaction by the potassium incorporated in the perovskite structure compared to potassium species obtained through impregnation.

We have no reason to believe that the here described effects represent a singularity for the chosen promoters and the FTS but expect that this new catalyst design concept can also be applied to and improve various industrially relevant promoter dependent catalytic processes such as the Haber-Bosch synthesis.

**Keywords:** Alloys, mesopores, macropores, Sol-gel, supported catalysts, template-free

Supported catalytically active liquid metal solution (SCALMS) catalysts have shown promising results in improving activity and longevity for dehydrogenation and oligomerization reactions.[1, 2] In SCALMS catalysts, small amounts of an active metal (e.g. Pt, Rh, Ni, Pd) are dissolved in a low melting metal (in this case Ga) matrix, resulting in liquid alloys at reaction conditions. The unique reactivity and catalytic performance of SCALMS is attributed to the presence of its highly active and dynamic single active sites at the metal-gas interface. In literature, it has been shown that this interface, determined by the Ga droplet size, is an important component that is affected by surface morphology and roughness.[1, 3]

Often an overlooked component of catalyst design, this contribution explores novel synthesis routes for $\gamma$-$Al_2O_3$. $\gamma$-$Al_2O_3$ is a structural polymorph of alumina which has a wide range of applications in catalysis as either an active phase or support. By designing supports with ideal uniform, rough surfaces of defined morphology, the next generation of tailored SCALMS can be achieved. Our approach to $\gamma$-$Al_2O_3$, using novel template-free glycothermal and sol-gel methods, creates supports of varying porosity profiles. This contribution will discuss the location (**Fig. 1)** of the decorated Ga droplet relative to the various $\gamma$-$Al_2O_3$ pore networks and explore which pore size range is best suited to the next generation of SCALMS catalyst.

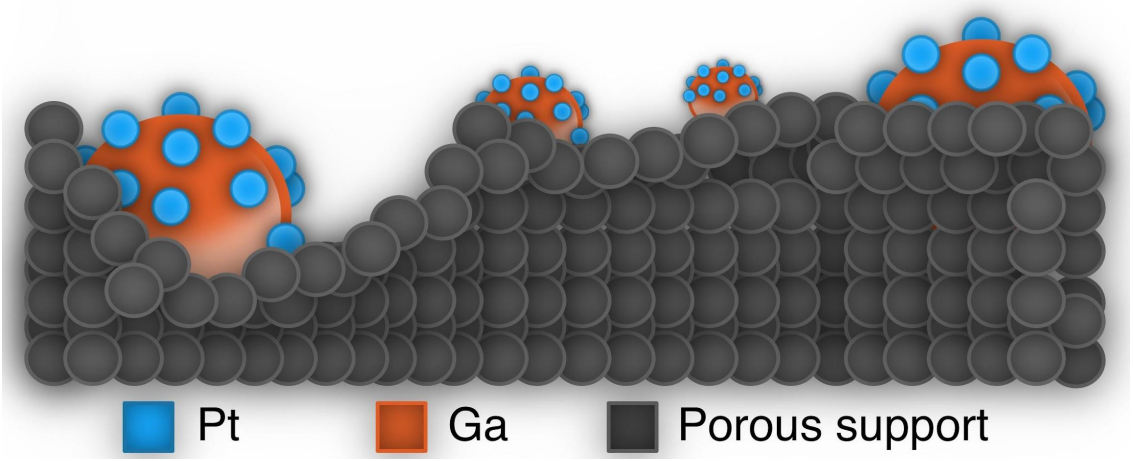

**Figure 1: A visualization of Pt decorated Ga droplets on the surface of a porous support.**

**Introduction.** The mechano-chemical activation of powder materials represents an interesting opportunity for the sustainable functionalization of heterogeneous catalysts [1,2], by inducing meta-stable phase transformations on metal oxides [3,4] or promoting unique metal-support interactions on supported metal catalysts [1,5]. Here, the simple mechanical action on pure $CeO_2$ supports was investigated in terms of textural, morphological and redox properties, as a function of starting material and milling intensity, allowing for the prediction and design of $CeO_2$ powders properties for catalytic applications by dry milling.

**Experimental/methodology.** Different $CeO_2$ powders were obtained from commercial ceria (Rhodia) by calcination in static air at 550°C, 900°C, 950°C and 1200°C. Then, the powders were milled at mild (ME) and high (HE) energy milling conditions, for times ranging between 0.5 and 8 hours, and their morphological, textural and redox properties were followed by means of $N_2$ adsorption isotherms, X-ray diffraction (XRD), dynamic laser scattering (DLS), Raman spectroscopy and and $H_2$ reduction (TPR). The redox activity was evaluated in CO oxidation tests under 2%CO, 5%$O_2$ in $N_2$, at a GHSV≈80000 $h^{-1}$.

**Results and discussion.** Under mild energy milling, variations of the initial properties of the $CeO_2$ powders are observed only at long (> 2h) milling times (not shown) while the most significant changes in $CeO_2$ redox and morphological properties are achieved by high energy milling. Most noticeably, the surface area of ceria powders tends to an equilibrium value (Fig.1a), due to crystallite breakage being induced on larger particles and agglomeration promoted on smaller particles [1]. Simulaneously, the mechanical action generates defects on the ceria surface [4,5], highlighted by the appearance of a Raman band at 600 $cm^{-1}$ (Fig.1b). Despite reduction in surface area (Fig.1a) and porosity (not shown), the increased amount of surface disorder leads to enhanced redubility at low temperatures (>500°C, Fig.1c), which leads to improved catalytic performance in reaction where oxygen exchange is required and could potentially act as anchoring points for metals when used as a support oxide.

**Figure 1. BET surface area (a), Raman spectra (b) and $H_2$ consumption below 500°C (c) as a function of milling time at high energy for selected samples.**

# A chemo-enzymatic oxidation cascade to activate C–H bonds with in situ generated $H_2O_2$

D. R. Ford, R. J. Lewis and G. J. Hutchings
***Max Planck-Cardiff Centre on the Fundamentals of Heterogeneous Catalysis FUNCAT, Cardiff Catalysis Institute, Translational research hub, Cardiff University, 4 Blackweir Terrace, CF10 3EY, Cardiff, UK*** FordDR@cardiff.ac.uk

**Key words:** AuPd, hydrogen peroxide, non-specific peroxygenase, cascade, oxidation.

**Introduction.** The evolved non-specific peroxygenase enzyme from *agrocybe aegerita* (PaDa-I variant) is demonstrated to be highly selective for hydroxylation reactions of C-H groups, only requiring a continuous low-level quantity of $H_2O_2$ to function. Supported AuPd nanoparticles shows great promise in fulfilling this requirement, utilising $H_2$ and $O_2$ gas to produce a continuous stream low concentration $H_2O_2$ in a one-pot oxidation cascade.
**Experimental/methodology**. 1%wtAuPd /$TiO_2$ catalysts were prepared by an excess-chloride co-impregnation procedure.[1] Chemo-enzymatic cascade reactions were performed in a one-pot system under conditions that maintain enzyme stability.
**Results and discussion.** Chemo-catalysed $H_2O_2$ synthesis (Figure 1a (black squares)) in absence of enzyme was determined, showing sufficient production for enzymatic reactions to occur. Assessment of the enzyme-mediated activation of C-H bonds was carried out via hydroxylation of cyclohexane (Figure 1a), ethylbenzene (Figure 1b) and isophorone (Figure 1c) in the tandem enzymatic/catalytic reaction. Through optimisation of the process, total turnover numbers may be reached which rival current state-of-the-art co-enzymatic systems. We consider that this chemo-enzymatic approach has potential for a wide range of applications in tandem reactions due to the ease of adaptation into current reactor technology and infrastructure, lower energy input as there is not requirement for illumination compared to recent photocatalytic approaches and inherent efficiency of the process in only producing water as a byproduct without the requirement for organic molecules such as MeOH as a supply of electrons. The nature of the catalyst materials as both effective hydrogenation and oxidation catalysts significantly extends the scope of the reaction cascades that can be considered and can open the pathways to efficient tandem heterogeneous/biocatalytic processes.

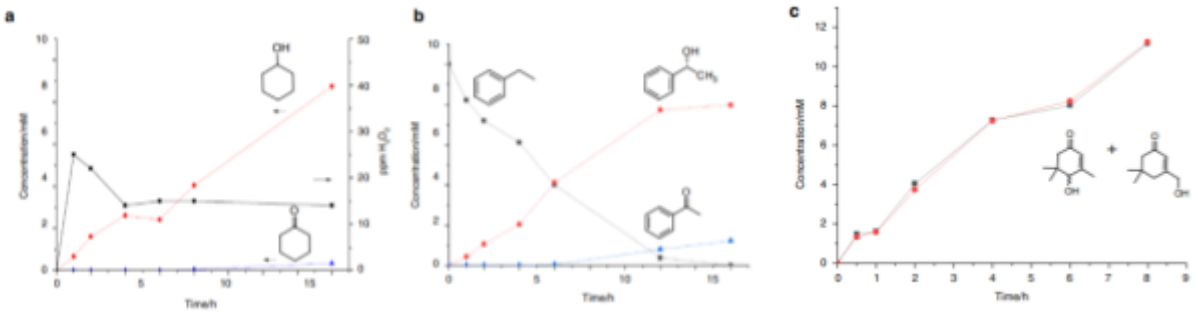

**Fig. 1** Time-on-line hydroxylation reactions of a $H_2O_2$ production (black squares) (in the absence of enzyme) and cyclohexane oxidation to cyclohexanol and cyclohexanone b Ethylbenzene oxidation to 1-phenylethanol c Isophorone oxidation to 4 and 7-hydroxyisophorone.

**Keywords:** Water treatment, microporous ceramic membranes, click chemistry.

**Introduction.** Water is a valuable resource, crucial to all living organisms and multiple human activities, such as domestic uses, agriculture and industry. However, several emerging organic pollutants end up in vital aquatic compartments, such as surface water, groundwater and even drinking water. The appearance of these pollutants has been discovered at all stages of resource management systems and their negative impact on human and environmental health has become increasingly evident, even when found in trace concentrations [1]. However, both traditional treatments and the most advanced technologies available are ineffective in the removal of these micropollutants.

The aim of the SmartOxidation project is the use of catalytic ozonation in the presence of catalysts immobilised on microporous ceramic membranes for the creation of a unique solution leading to the removal of emerging organic pollutants and allowing the reuse of the wastewaters. Carbon materials, especially in powder form, have already been proven suitable for advanced oxidation treatment processes [2] due to their unique textural and superficial properties that can easily be modified. Microporous ceramic membranes are an interesting support for carbons materials owing to their high thermal, mechanical and chemical stability, high hydrophilicity, porosity and resistance to ozone. Additionally, the combination of these two materials leads to an increase in effluent flow and prevents biofouling. Our goal is the development of new ultra-thin film composite membranes and the study of their behaviour for catalytic ozonation.

**Experimental/methodology.** The strategic designing and synthesis are performed via click chemistry to achieve high interfacial adhesion between the support and the catalytic material by adding an azide moiety-containing material with an alkyne-functionalised phase. The design is done with activated carbons with high surface area and $\alpha Al_2O_3$ membranes with conical and parallel pores, both materials modified prior to the functionalisation with azide and alkyne groups to activate their surface and to enhance their catalytic behaviour. This approach allows fast-rate reactions with high chemical yields using non-toxic solvents, simple reagents and straightforward reaction conditions.

Various characterisation techniques including Fourier transform infrared spectroscopic (FTIR), Raman spectroscopy, X-ray photoelectron spectroscopy (XPS), scanning electron microscopy (SEM), energy dispersive X-ray spectrum (EDX) and $N_2$ physisorption were used to ascertain the successful functionalisation of the materials.

**Results and discussion.** The results demonstrated the incorporation of high amounts of azide and alkyne groups in both $\alpha Al_2O_3$ membranes and activated carbons. In addition, the XPS results suggested the incorporation of a homogeneous population of the azide groups on the surface with a better vertical orientation, which is more accessible and reactive for click reaction.

# Imidazolium-based hypercrosslinked ionic polymer as metal-free catalyst for *N*-formylation of amines with $CO_2$ and Phenylsilane

Beatriz Fuerte-Díez, Elizabeth Rangel-Rangel, Marta Iglesias, Eva M. Maya

*Instituto de Ciencia de Materiales de Madrid. CSIC, C/ Sor Juana Inés de la Cruz, 3, 28049, Spain*

**b.fuerte.diez@csic.es*

**Introduction.**The utilization of $CO_2$ as a raw material for the synthesis of chemicals is an opportunity to convert a harmful gas for the environment into an added-value compound. Formamides can be prepared from $CO_2$ and are an example of versatile chemicals [1]. The use of an ionic liquid as metal-free catalyst for this reaction has gained great interest since it allows the reaction to be carried out in mild conditions: room temperature and moderated $CO_2$ pressure [2]. We present a supported ionic-based catalyst prepared by Friedel-Crafts type reaction, by reacting biphenyl and 1-benzyl-3-methylimidazolium chloride (BzmimCl) and its performance as heterogeneous catalyst in the formylation of amines to obtain formamides.

**Experimental.** The catalyst HCP-BzmimCl was obtained by reaction of biphenyl (0.37 mmol) and BzmimCl (1.5 mmol) in DCM under inert atmosphere in the presence of $AlCl_3$ (16.04 mmol) as catalyst at 50°C for 48 hours. The solid was isolated by filtration, washed with HCl 0.005 M, water and then purified by Soxhlet extraction with methanol.

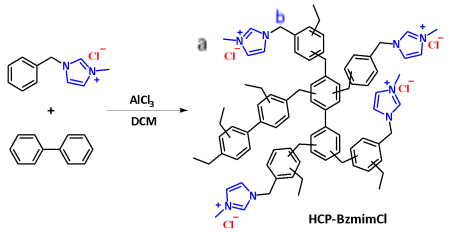

**Figure 1. Synthesis of HCP-BZmimCl**

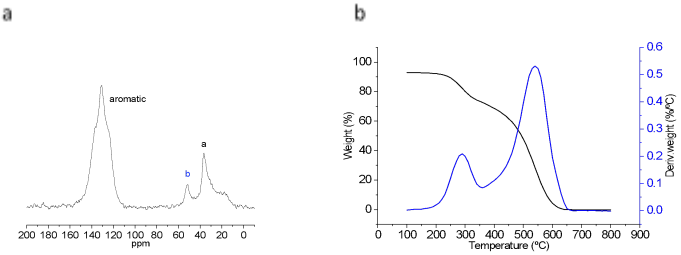

**Figure 2. $^{13}$C-NMR (a) and TGA (b)**

**Results and discussion.** The $^{13}$C-NMR HCP-BzmimCl shows the characteristic signal attributed to the methyl groups of the imidazolium and to the methylene groups (Figure 2a). The thermogravimetrical analysis (TGA) (Figure 2b) indicated thermal stability with an initial degradation temperature close to 300°C. The elemental analysis showed the incorporation of two units of BzmimCl per biphenyl group.

HCP-BzmimCl results an effective catalysts for N-formylation of amines with $CO_2$/$PhSiH_3$ (table 1). Whith a 10mol% catalyst a conversion of 75% (50% selectivity) was obtained (entry 1), if a 20mol% catalyst was employed we obtained selectivily the formamide (entry 2). The addition of 2 mmol of DMF to the reaction mixture reduces considerably the reaction time (entry 3) because it activates Si-H and N-H bonds. A control experiment in the absence of catalyst confirms that it is essential to obtain acceptable yields and selectivities (entries 4 and 6). With N-methylaniline as susbtrate, the product is selectively obtained but in lower yield (entry 5). The catalyst can be reused at least for 5 cycles maintained their structure.

**Table 1. Synthesis of formamides from amines and $CO_2$ using HCP-BzmimCl as catalyst. [a]**

| Entry | amine | Time (h) | Additive (mmol) | Conv. (%) | Select. (%) |

**Keywords:** Supported metal nanoparticles, Polyoxometalate, Bifunctional catalyst

**Introduction.** The designs of the metal nanoparticle surfaces and metal-metal oxide interfaces are important for developing efficient hydrogenation catalysts. Recently, composites of Au nanoparticles (NPs) with metal oxide clusters (polyoxometalate, POM) as a protective ligand have been reported[1)]. We have reported that Lindqvist-type POMs composed of group V elements, $[Nb_6O_{19}]^{8-}$(Nb6) and $[Ta_6O_{19}]^{8-}$(Ta6), exhibit strong base catalytic activity due to the high local negative charge of the surface O site[2)]. In this study, the basic POMs were modified on the surface of $Al_2O_3$-supported AuNPs by a simple adsorption method (Fig. 1), and the Au NPs catalysts with Au-POM interfaces were applied to the hydrogenation of aromatic nitro compounds.

**Fig. 1. POM-modified $Al_2O_3$-supported Au NPs.**

**Experimental.** $Al_2O_3$-supported Au nanoparticles were prepared by the impregnation method. NaOH aq. Was added to 10 mM $HAuCl_4$aq. up to pH=9 and then $Al_2O_3$ was suspended in the solution ($Au/Al_2O_3$). $Au/Al_2O_3$ was dispersed in aqueous solutions of POM ($K_8Nb_6O_{19}$, $K_8Ta_6O_{19}$, and $K_8SiW_{11}O_{39}$)in excess of Au content. After vacuum-drying at 333 K for 2 h, POM-modified $Au/Al_2O_3$ (Nb6-$Au/Al_2O_3$, Ta6-$Au/Al_2O_3$, and SiW11-$Au/Al_2O_3$) was obtained. Catalytic hydrogenation of *p*-nitrophenol (*p*-NP), nitrobenzene (NB), or p-nitrostyrene (*p*-NS) was performed in an autoclave (catalyst: 5 mg, substrate: 62.1 μmol, methanol: 1 mL, $H_2$: 1 MPa, reaction temperature: 353 K, reaction time: 2 h).

**Results and discussion.** STEM-EDX analysis and ICP measurement indicated that the surface of the Au NPs (2.7 nm ± 2.0 nm, 0.68 wt%) were decorated with $[Nb_6O_{19}]^{8-}$ or $[Ta_6O_{19}]^{8-}$ (8.0 or 18 mmol/$g_{cat}$ as the polyoxometalates). Nb K- and Ta $L_3$-edge XAFS spectra showed that the Lindqvist structure of $[Nb_6O_{19}]^{8-}$ and $[Ta_6O_{19}]^{8-}$ maintained their structures after modification.

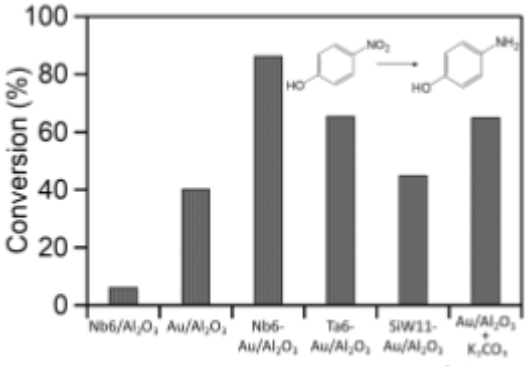

**Fig. 2 Conversion p-NP over POM-$Au/Al_2O_3$.**

Fig. 2 shows the conversions of p-NP over the POM-modified $Au/Al_2O_3$. The catalytic activity of $Au/Al_2O_3$ was significantly enhanced by modification with $[Nb_6O_{19}]^{8-}$ and $[Ta_6O_{19}]^{8-}$, whereas $[SiW_{11}O_{39}]^{8-}$ modification did not enhance the activity. $[Nb_6O_{19}]^{8-}$-adsorbed $Al_2O_3$ (Nb6/$Al_2O_3$) hardly showed activity. The reaction proceeded with $Au/Al_2O_3$ when $K_2CO_3$ was added as a base, suggesting that the base plays a crucial role in the reaction. In addition, the modification with $[Nb_6O_{19}]^{8-}$ increased the conversion of NB and p-NS in their hydrogenation reactions. In summary, we have developed a composite catalyst with AuNPs and POM that drove the efficient $H_2$ activation at the AuNPs-POM interface, and the cooperation of the reduction activity of AuNPs and base catalytic activity of $[Nb_6O_{19}]^{8-}$ and $[Ta_6O_{19}]^{8-}$ resulted in the efficient hydrogenation activity of p-NP[3)].

# Synthesis of heterogeneous catalysts by gliding arc plasma

F. Hanon*, E. M. Gaigneaux**

*UCLouvain, Institute of Condensed Matter and Nanosciences (IMCN), Louvain-la-Neuve, Belgium*
** fanny.hanon@uclouvain.be; ** eric.gaigneaux@uclouvain.be*

**Introduction:** Glidarc plasma (GP) is an ecologic and economic promising technique for the synthesis of catalysts with interesting properties ($TiO_2$, $SnO_2$, $MnO_2$, $FeO_x$) [1,2]. The addition of a post-discharge (PD) step in the synthesis of some of them ($MnO_x$, $FeO_x$) has also improved their characteristics (higher specific surface area and catalytic activity) (Fig.1) [2,3]. In the literature, it is suggested that the reason why metallic precursors form precipitates during the discharge and why the formed solid is transformed during the PD is mainly due to the principal species generated (OH°, NO°, $H_2O_2$, $HNO_3$, $HNO_2$). However, these hypotheses were never proven before. The aim of our research is therefore to understand how the synthesis of catalysts by GP works and how the method could be improved.

**Methodology:** The radicals generated in the GP can induce the precipitation of the corresponding (hydr)oxides of metal precursors solutions exposed to the discharge. The formed suspension is either subjected to a PD step at a certain temperature for a certain time or is direclty centrifugated. The recovered solid is then dried and calcined to obtain the final catalyst (Fig.1).

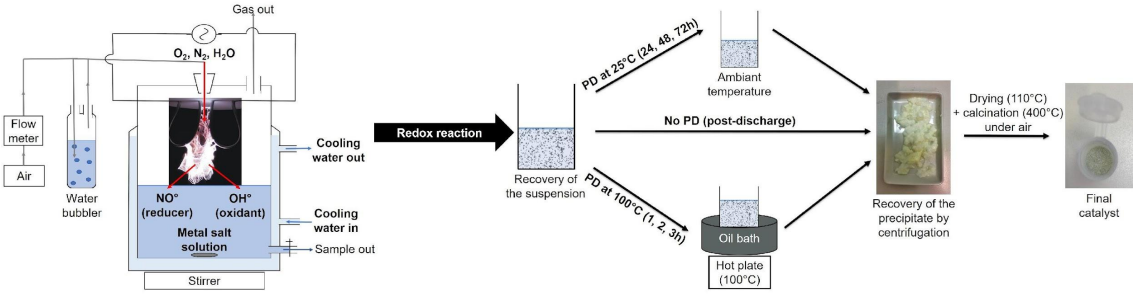

*Fig.1: Scheme of the GP reactor and methodology for catalysts synthesis by GP*

**Results and discussion:** The factors that impact the ability of a precursor to react by GP were first identified. These parameters are, among others, the acidification of the medium during the discharge due to the formation of $HNO_3$ and $HNO_2$, the oxidation state of the precursor and its capacity to react spontaneously with water, and the types of species formed thanks to the carrier gas. Indeed, contrary to the majority of the precursors that do not form solids by GP (Ni, Bi, ...), all precipitating metal salts are able to form a metal or (hydr)oxide at low pH. Moreover, among the precursors reacting by GP, some are spontaneously but slowly oxidized/reduced to (hydr)oxides in water ($KMnO_4$, $TiCl_3$, $Fe(SO_4)_2$, $(NH_4)_2Fe(SO_4)_2$) and others are hydrolyzed before reacting with the plasma species ($HAuCl_4$, $SnCl_2$, $SnSO_4$). Finally, depending on the type of carrier gas used ($N_2$, Ar, $O_2$), the precipitation of precursors reacting by humid air GP does not always take place, demonstrating the importance of some species on the reaction.

It will also be shown that the PD is a thermal and temporal maturation stage where the species formed during this step have no effect on the way the solid changes. Hence, the thermal effect of the PD could be reproduced directly during discharge by removing the cooling system during the exposure. Under these conditions, solids with similar characteristics to those obtained in PD (higher specific surface area and catalytic activity) were developed but much faster. For example, $SnO_2$ synthesized from $SnCl_2$ by GP is catalytically more active when a PD step is performed but is even more active if the exposure is done without the cooling system (Fig.2).

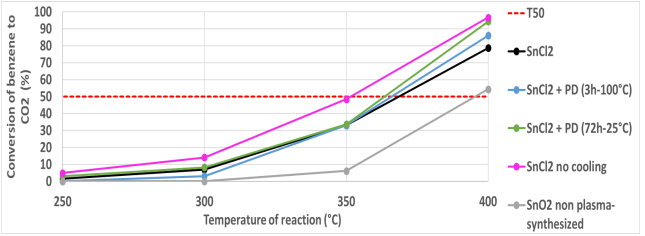

*Fig.2: Conversion of benzene to $CO_2$ as a function of the temperature of reaction of $SnO_2$ synthesized from $SnCl_2$*

# A highly activating electron-rich phosphasilinane ligand for Pd catalyzed C-X coupling reactions

*Dr. Detlef Gaiser*[1], *Dr. Michael Gock*[1], *Sabrina Kräh*[2], *Prof. Dr. Oliver Trapp*[2]

[1]*Heraeus Precious Metals, 63450 Hanau, Germany*

[2]*Ludwig-Maximilians University, Munich/Germany*

Coupling reactions play an important part in the syntheses of sophisticated active ingredients for pharmaceutical, agro- and fine-chemistry. These reactions have become an essential tool in drug synthesis and design. Many of these coupling reactions run with the help of homogeneous palladium phosphine catalysts. Highly influential for the conversion of a specific substrate is the use of the right ligand. Years of research have proven that effective biaryl phosphane (Phos) ligands are very effective choice in many cases. However, heteroatom-containing substrates strongly influence these reactions, as they complicate the coupling due to their competitive coordination to the palladium catalyst and different electronic structure.[1] As a consequence, previous Phos ligands only achieve good yields at high temperatures and long reaction times. We present here a highly active Phos ligand (SabPhos) that supplies excellent yields for C-N coupling reactions at ambient temperature. A silicon containing phosphane provides a pyramidal structure of the phosphorus while reducing steric hindrance. In palladium catalyzed reactions, this ligand rapidly couples a broad range of heteroaryl chlorides via C-C bonds with boronic acids and C-N bonds with secondary amines in high yields under mild conditions.[2]

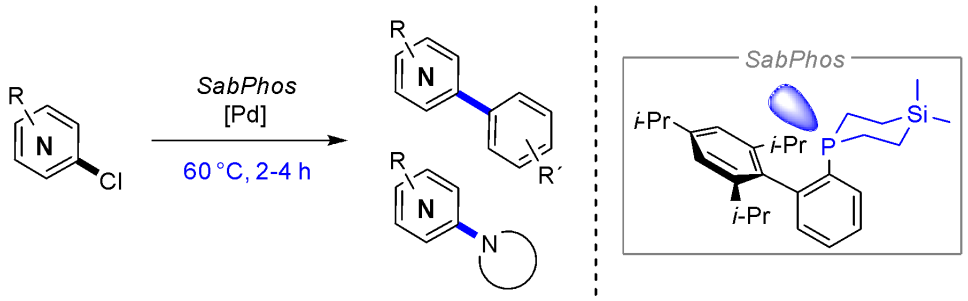

Figure: SabPhos Ligand enables effective palladium catalyzed C-X bond formation of heterocycles under mild conditions.

# Surface nickel complexes as models for heterogeneous oligomerization catalysts

S. Aïssiou[1*], N. Merle[1], M. Sauthier[1]
[1]*Unité de Catalyse et Chimie du Solide—UMR CNRS 8181, Univ. de Lille, 59652 Villeneuve d'Ascq, France*
[*]*samy.aissiou@univ-lille.fr*

**Keywords:** Sustainable fuels, oligomerization of olefins, nickel, surface organometallic chemistry

## Introduction.

Since the development of sustainable processes for light olefin production (ethanol dehydration, $CO_2$-to-light-olefins), oligomerization has become relevant for the production of sustainable fuel. But while nickel has already proven to be efficient in homogeneous oligomerization (SHOP, Dimersol), industrial processes using heterogeneous nickel-based catalysts are still rare [1]. Also, on a mechanistic point of view, the nature and formation of the active sites remain elusive. In order to answer to these questions, nickel-based model catalysts have been synthesized using surface organometallic chemistry (*SOMC*). This methodology gives access to well-defined supported species and has been successfully used for various applications including the synthesis of well-defined, efficient metathesis catalysts [2].

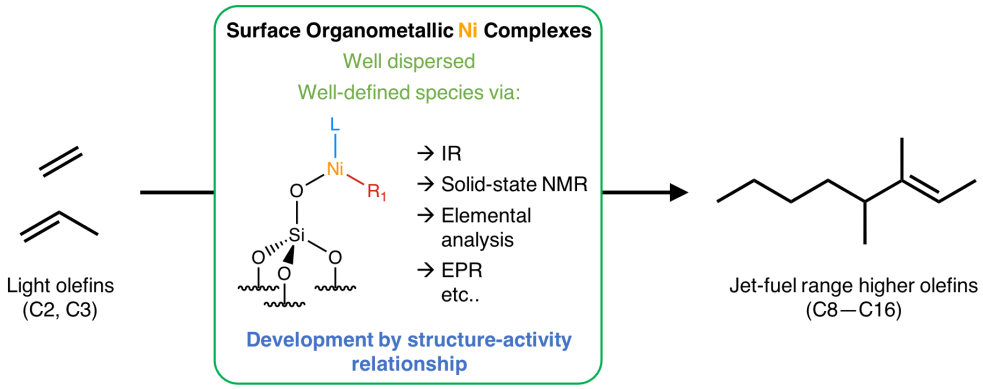

**Fig 1. Well-defined supported catalysts as models for the oligomerization of light olefins into sustainable jet-fuel**

## Experimental/methodology.

Model catalysts have been synthesized by reacting organometallic nickel complexes with surface silanol groups on a variety of supports ($SiO_2$ or $SiO_2$-$Al_2O_3$ of various Si/Al ratios). Thermal treatment of the supports allows to obtain well-dispersed nickel complexes. Catalysts are characterized via IR (DRIFT), solid-state NMR, EPR, and elemental analysis. A tubular fixed bed reactor is used to investigate how pressure, temperature and olefin flow rate affect the selectivity/activity of each different compound.

## Results and discussion.

Infrared analysis as well as elementary analysis both indicate successful chemical grafting (creation of a nickel-oxygen bond between metal support) of a variety of complexes. Solid-state $^{1}H$ and $^{13}C$ NMR experiments show that on highly dehydroxylated silica (pure amorphous silica treated at 700 °C) at least two, closely related surface species are formed. EPR experiments suggest that one the species at least is paramagnetic. Preliminary catalytic experiments have confirmed the activities of such catalysts in ethylene oligomerization, and their performances are compared to those of a classical heterogenous catalyst.

**Keywords:** Exsolution, Heterointerface, Perovskite oxides, Oxidation reaction, Surface reconstruction

**Introduction.** Heterointerfaces (Nanoparticles/support) obtained through exsolution have shown extraordinary performance compared to conventional impregnation. During the exsolution, one or various elements of a mixed oxide are brought to the surface due to applied stress creating partial socketed nanoparticles. These exsolved platforms have shown extraordinary performance for catalytic reactions such as water splitting, oxygen reduction, and thermal oxidation, among others. In this work, we rationally investigated the evolution of an exsolved Ru-surface, which will allow us to design and control these catalytic systems, also containing other different elements.

**Experimental/methodology.** We prepared $La_1Fe_{0.9}Ru_{0.1}O_3$ oxide through a sol-gel method with a final calcination temperature of 750 °C. Ru was exsolved under $H_2$ at 800 °C to obtain the heterointerface $Ru_{Exsolved,\ NPs}/La_1Fe_{0.9}Ru_{0.1-x}O_3$. Propane thermal oxidation was used as a catalytic test to understand the surface reactivity during the different steps. TEM, EDX, XPS, and XRD were the main characterization techniques used to trace the material transformations.

**Results and discussion.** Conventionally, ruthenium present 4+ as an oxidation state when forming oxides, $RuO_2$. However, Ru exhibits other oxidation states in different compounds. Through XPS, we found that Ru is mainly present as 3+ after calcination. The presence of $Ru^{3+}$ proves that Ru substituted Fe into the perovskite-like structure in which, in its stoichiometric form, B-site presents mainly 3+ as oxidation state. After exsolution, $Ru^0$ appeared, indicating the formation of NPs on the surface. We also detected $Ru^{4+}$ and assigned it to oxidative passivation of the metal under air when the sample was prepared and transferred for the XPS analysis. XRD showed that the perovskite-like was obtained and preserved after exsolution. Combining these characterization results and the catalytic tests, we were able to track the surface evolution during the different treatment steps and after the catalytic test. These changes are summarized in **Figure 1**.

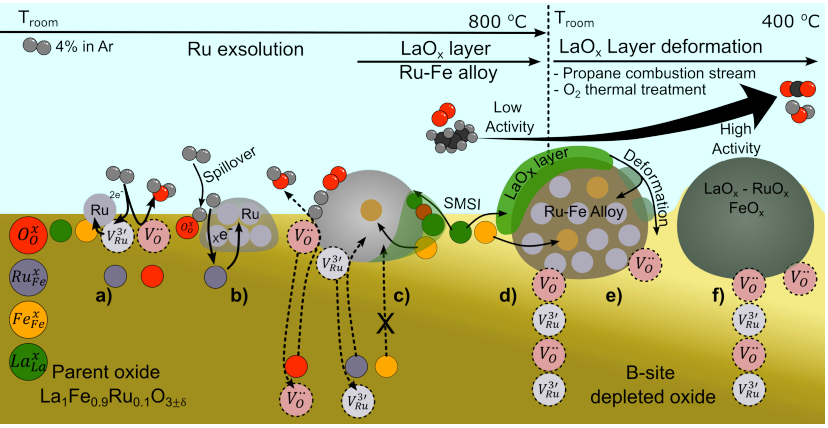

**Figure 1.** Schematic surface evolution of the $La_1Fe_{0.9}Ru_{0.1}O_3$ perovskite-like oxide. Under hydrogen atmosphere, a redox reaction takes place, oxidizing the $H_2$ to form $H_2O$ and transferring electrons to the surface, obtaining metallic Ru atoms (a). This process creates oxygen and ruthenium vacancies and metallic ruthenium over the surface, which are nucleation points for growing metallic nanoparticles (b). At the same time, the exsolution goes ahead with increasing the temperature. At higher temperatures (>500 °C), Fe from the near surface can exsolve into the Ru nanoparticles, forming $Ru_{Enriched}$-Fe alloy and letting a $LaO_{x\text{-enriched}}$ surface (c). Thus, in accordance with the SMSI phenomenon, $LaO_x$ species migrate along the metallic surface to cover them entirely (d) at high temperatures (800 °C). This $LaO_x$ overlayer negatively affects the catalytic activity for propane combustion. However, we found that the catalytic activity increases significantly after the first reaction cycle or oxidation treatment (400 (C). This change was attributed to a surface reconstruction (e), cleaning the NPs surface, and transforming them in a mix of $Ru_{Enriched}$ – Fe – La oxides (f).

# Metal phosphide nanoparticles for the hydrotreatment of methyl laurate

D. García Pérez[1*], M.C. Álvarez Galván[1], J.M. Campos Martín[1*], M.C. Capel Sánchez[1], S. Habas[2]

[1]*Instituto de Catálisis y Petroleoquímica (CSIC), Madrid, Spain.*
[2]*National Renewable Energy Laboratory, Colorado, USA.*
[*]***Corresponding Author** diana.garcia@csic.es*

**Introduction.**

Transition metal phosphide nanoparticles (NPs) are a promising active phase for hydrotreatment processes because of their advanced catalytic properties that result from a combination of metallic and acidic surface sites. This work aims to test the activity of catalysts based on NPs phosphide supported on silica in the hydrodeoxygenation of methyl laurate (a model compound for vegetable oil) to produce green liquid fuels.

**Experimental/methodology.**

$Ni_{1.6}Mo_{0.4}P$ and $Ni_1Mo_1P$ nanoparticles (NPs) were first synthesized by a facile molecular precursor route [1]. The NPs were incorporated into silica support. A reference $MoP/SiO_2$ catalyst was prepared by the direct reduction phosphite method [2]. Prepared NPs and catalysts were characterized by chemical analysis, XPS, TEM, and XRD. The prepared catalysts were tested in the hydrodeoxygenation (HDO) of methyl laurate to hydrocarbons. The reaction was performed at two different liquid space velocities (LHSV= 6 or 3 mL/g/h), and temperatures (300 or 350 ºC).

**Results and discussion.**

XRD results showed that the peaks of the $Ni_2P$ phase were shifted to a lower Bragg angle, indicating an expansion of the crystal structure due to the insertion of Mo in the structure and the reference sample $MoP/SiO_2$ did not show any diffraction peak. These results suggested the formation of bimetallic Ni-Mo phosphides NPs. HRTEM analyses confirm the expansion of the cell parameters, and the formation of spheric nanoparticles with a narrow distribution which is maintained after the incorporation in the support. The particle size in the $MoP/SiO_2$ sample was clearly lower (2.6 nm) with respect to the other NPs samples (9-13 nm). The catalytic activity in the HDO of methyl laurate of the samples with high contents of nickel ($Ni_2P$ and $Ni_{1.6}Mo_{0.4}P$) was low, whereas MoP and $Ni_1Mo_1P$ were very active catalysts (Figure 1). This trend was similar in both temperatures and liquid space velocity studied. The selectivity of hydrocarbons changed with the ratio Mo/Ni in the catalyst, the main hydrocarbon products were C11s with $Ni_2P$ sample, increasing the proportion of C12s with the amount of Mo. This fact, clearly indicates that $Ni_2P$ favors the decarbonylation/decarboxylation pathway while MoP species favored the hydrogenation path. In all cases, the most active catalyst is the reference $MoP/SiO_2$. The activity of $Ni_1Mo_1P$ was higher than expected for its dispersion in comparison with the reference sample. An analysis of the TOF clearly indicates that the $Ni_1Mo_1P$ presented higher intrinsic activity that points out synergy for the bimetallic catalyst in this reaction.

# Nickel alumina-based catalyst for sorption enhanced reforming: Effect of calcination temperature

Lj. Gavrilović[1*], S. S. Kazi[1], A. Oliveira[1], J. Meyer[1]

[1]*Institute for Energy Technology, Kjeller, Norway*
[*]*ljubisa.gavrilovic@ife.no*

**Keywords:** Ni catalyst, reforming, hydrogen

**Introduction.** The aim of the present paper is to develop a novel reforming catalyst tailored for Sorption-enhanced reforming process while withstanding multiple reforming-regeneration cycles to provide high $H_2$ yield and increased catalyst stability. This can be achieved by synthesizing a new Ni catalytic material with improved chemical and mechanical properties by formation of $NiAl_2O_4$ during catalyst calcination after synthesis [1] [2].

**Experimental/methodology.** A 15% Ni based catalysts was synthesized by the incipient wetness impregnation (IWI) method. The impregnated catalysts were dried and calcined at a different temperature (350°C-850°C) in presence of air (heating rate, 5 °C/min). The synthesized catalyst were characterized by XRD, BET, H2 chemisrotpion, TPR, TGA and SEM. Finally, their catalytic activity was evaluated in packed bed reactor-PBR, under relevant SMR process. The commercial type reforming catalyst was used as a reference for comparison to the in-house synthesized catalyst.

**Results and discussion.** The samples calcined at higher temperatures (750 and 850 °C) show shifting of the $Al_2O_3$ peak to a lower angle which indicates the formation of $NiAl_2O_4$[1], confirmed by XRD. The NiO crystallite size was impossible to detect for those calcined above 750 °C due to the formation of $NiAl_2O_4$. TPR results shows that reduction peaks are shifted towards higher temperatures for the catalysts calcined at higher temperature. This indicates that increasing calcination temperature enhances metal-support (Ni-$Al_2O_3$) interaction and leads to the formation of desired $NiAl_2O_4$ phase. The Ni dispersion decreases when increasing the calcination temperature due to the possible sintering of the Ni particles at higher temperatures. The activity of the two catalysts: commercial type and in-house synthesised, 15Ni/Puralox is presented in Figure 1. It can be seen that SER kinetics of commercial type is slower compared to in-house synthesised one after 100 cycles; this is due to some loss in catalytic activity of the commercial type of catalyst during SER cycles. The in-house synthesised catalyst shows much less deactivation due to the formation of $NiAl_2O_4$. Moreover, the in-house synthesised catalyst showed better resistant towards coking and sintering.

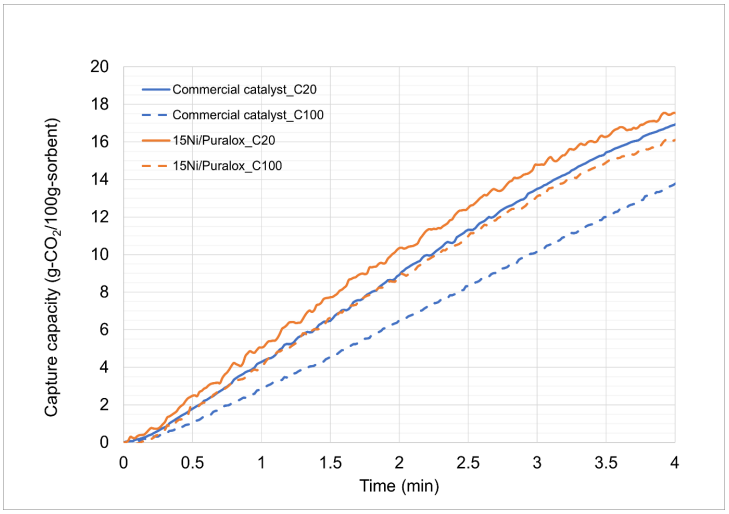

**Figure 1**. Comparison of catalytic activity of the commercial and 15%Ni/Puralox catalyst in SER TGA. multi-cycles

[*]*b.m.weckhuysen@uu.nl*

**Introduction.** Supported metal nanoparticles constitute important heterogeneous catalysts and it is well-known that the synthesis crucially determines the resulting, *inter alia*, structure, dispersion, and catalytic performance. Depending on support material, metal(oxide) nanoparticles, and the reaction of interest various synthesis approaches are reported.[1] While for monometallic catalysts syntheses yielding uniform and highly dispersed nanoparticles are reported, general guidelines for multi-metal catalyst systems are scarce. However, systems such as Ni- and Cu-based catalysts are excellent candidates for, e.g., $CO_2$ methanation and methanol synthesis from $CO_2$,[2] that is, thermocatalytic $CO_2$ valorization, which constitutes a promising approach for tackling the problem of continuously increasing global $CO_2$ emissions and related climate change. For converting $CO_2$ into other value-added products, Ni-based multi-metal catalysts are promising.[3] Hence, we chose the thermocatalytic $CO_2$ hydrogenation as showcase for the search of simple, reliable, cost-efficient, and adaptable synthesis protocols yielding highly dispersed metal nanoparticles in multi-metal catalysts. Importantly, this synthesis is easily adaptable, being essential in taking steps towards a more rational design of improved catalyst formulations and our journey towards a more circular society.

**Experimental/methodology.** Multi-metal solid catalysts were synthesized by an optimized incipient wetness co-impregnation technique. Citric acid (CA) and ethylene glycol (EG) were added to the aqueous nitrate precursor solution. Calcination was performed after the impregnated $SiO_2$ support was dried for 12 . Advanced characterization by operando infrared (IR) and X-ray absorption spectroscopy (XAS), and high-resolution transmission electron microscopy yielded new insights into the role of CA and EG additives.

**Results and discussion.** We successfully synthesized a set of small (< 2 nm) and highly dispersed transition metal nanoparticles (consisting of Ni, Fe, and Cu) without metal segregation in mono-, bi-, and trimetallic catalysts. The addition of CA as chelating agent induced an encapsulation of the central metal atoms by the citrate ligands, resulting in smaller and higher dispersed nanoparticles after the ligand removal during calcination.[4] Additionally, adding EG to the precursor solution resulted in enhanced interactions with the support surface, and finally, in smaller and higher dispersed nanoparticles. Importantly, this optimized synthesis was highly reproducible for mono- and multi-metal catalysts with varying metal ratio, demonstrating the great potential for a general guideline for transition metal catalysts. While the removal of EG yielded a minor but significant decrease in $CO_2$ conversion, that of EG and CA induced a drop in the $CO_2$ conversion by 25%, showing the importance of both additives.

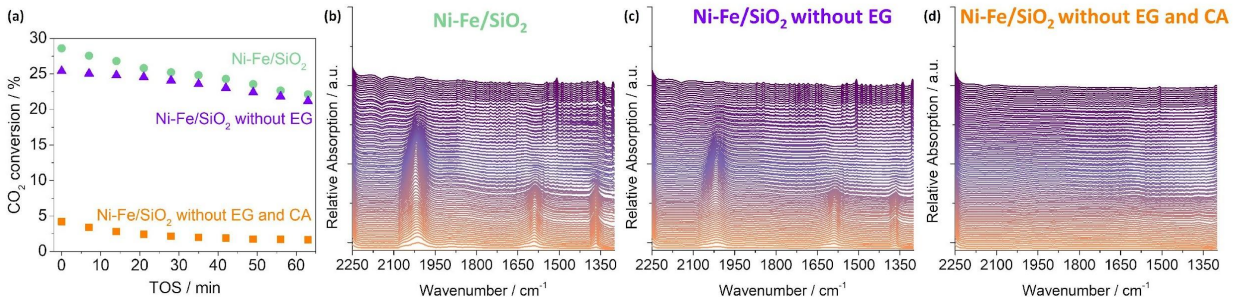

**Fig.:** Synthesis-dependent conversion during $CO_2$ hydrogenation at 400°C ($H_2/CO_2$=4, 1 bar, a) and operando IR spectra ($H_2/CO_2$=4, 1 bar, 100-400°C, b-d), demonstrating the effect of the addition of citric acid (CA) and ethylene glycol (EG).

Keywords: Atomic layer deposition, heterogenous catalysis, nickel acetylacetonate

Atomic layer deposition (ALD) is a powerful technique for making supported heterogenous catalysts. Due to its self-terminating nature, ALD can produce controlled and uniform metal contents down to single-atom catalysts [1,2]. While ALD has been gaining popularity in the catalysis community [2,3], the first reports of using it to prepare heterogenous catalysts date to early 1990s under the name atomic layer epitaxy and even 1970s under the name molecular layering [4]. Nickel is a known hydrogenation catalyst and owing to its versatility and abundance has also been used industrially in multiple other processes such as biomass gasification and $CO_2$ methanation [5,6].

This work reports an initial effort to obtain a uniform coating of nickel on mesoporous monoclinic zirconia (m-$ZrO_2$) using a fixed bed flow type ALD reactor. In an earlier work, it was shown that Ni catalysts can be supported on $Al_2O_3$ by ALD with Nickel(II) bis(acetylacetonate) as the ALD reactant [7]. Here, we used $Ni(acac)_2$ as the ALD precursor and m-$ZrO_2$ as the support. Thermogravimetric analysis (TGA) of the reactant $Ni(acac)_2$ confirmed its volatility and stability up to 300 °C. BET surface area of the m-ZrO2 was 60 $m^2g^{-1}$ and the mean pore size was 17 nm. The sample was prepared by calcination of the m-$ZrO_2$ at 600 °C in air after which it was loaded in a fixed bed ALD reactor. $Ni(acac)_2$ was vaporized at 165 °C (varied from 155 to 180°C) and carried by $N_2$ to the support. ALD reaction temperatures were varied from 200 to 240 °C. Also, the effect of the reactant exposure time on nickel loading was studied by changing the exposure duration between 120 min to 240 min. Ni loading on the $ZrO_2$ support was studied by X-ray fluorescence spectroscopy and inductively coupled plasma optical emission spectroscopy (ICP-OES). Acetylacetonate (acac) ligand removal was observed at 550 °C by in situ diffuse reflectance infrared Fourier transform spectroscopy (DRIFTS) combined with mass spectrometry (MS). The distribution of nickel within a m-$ZrO_2$ particle was analyzed by scanning electron microscopy-energy dispersive X-ray spectroscopy (SEM-EDS).

Ni loading increased with increasing reactant dose time from 120 to 240 min and with an increasing ALD reaction temperature from 200 to 240 °C. Nickel distribution by SEM-EDS within a m-$ZrO_2$ particle was seen although uniformity was not yet observed.

This initial study shows that $Ni(acac)_2$ is a promising ALD reactant to support Ni on mesoporous $ZrO_2$.

**Keywords:** Environmental catalysis, layered materials, double metal cyanide complexes, $CO_2$-utilization, copolymerization, epoxide.

**Introduction.** Square-planar tetracyanonickelate(II) anion ($[Ni(CN)_4]^{2-}$) has historically been used as a design element in the synthesis of cyano-bridged two-dimensional (2D) coordination compounds, including the well-known Hofmann-type clathrates and their analogues [1]. 2D structures are of considerable interest in catalysis because of their high surface-to-volume ratio and ease of access to the active sites. Thus, in this work, we report the synthesis, characterization and catalytic performance in the ring-opening copolymerization (ROCOP) of $CO_2$ and propylene oxide (PO), a green route to obtain biodegradable and biocompatible polypropylene carbonate (PPC) [2], of four 2D cyanide-bridged bimetallic complexes based on the tetracyanonickeltate(II) building block ($T[Ni(CN)_4]$; T= $Ni^{2+}$, $Co^{2+}$, $Fe^{2+}$, $Mn^{2+}$).

**Experimental/methodology.** The complexes were prepared by a *tert*-butanol (TBA)-assisted coprecipitation method. Their physico-chemical properties were thoroughly characterized by FT-IR, Raman, XRD, HT-XRD, TGA-MS, SEM, TEM, $N_2$ physisorption, $NH_3$-TPD, elemental analysis, and WDXRF. Catalytic activity tests were carried out in a 300 mL autoclave reactor using 2500 ppm of catalyst (vs PO), 20 bar pressure of $CO_2$, at 90 ºC and 120 ºC and over a 24 h run. A 100 mL Parr reactor equipped with a bottom-mounted Si-comp ATR probe was used for *in-situ* IR spectroscopy studies. Reaction products were characterized by $^1$H-NMR and GPC.

**Results and discussion.** Spectroscopic techniques confirmed the bimetallic nature of the synthesized complexes. TEM and SEM microscopy images corroborated their plate-like morphology. The topology and microstructure demonstrated to be dominated by the T atom ability to attract electrons. All complexes were active in the $CO_2$/PO ROCOP to produce PPCs with low-to-medium $CO_2$ content ($F_{Cu}$=13.1-42.4 mol%), medium-to-high molecular weight, ($M_n$=11000-36500 g $mol^{-1}$) and high dispersity values (Đ= 2.5-5.0). Undesired propylene carbonate (PC) was formed in all cases ($W_{PC}$= 0.2-75.9 wt%). Due to its high activity and remarkable selectivity, the kinetics and mechanism of the $Co[Ni(CN)_4]$ complex were further evaluated by *in-situ* IR spectroscopy. A rate law was proposed and determined from the initial rates (**Figure 1**).

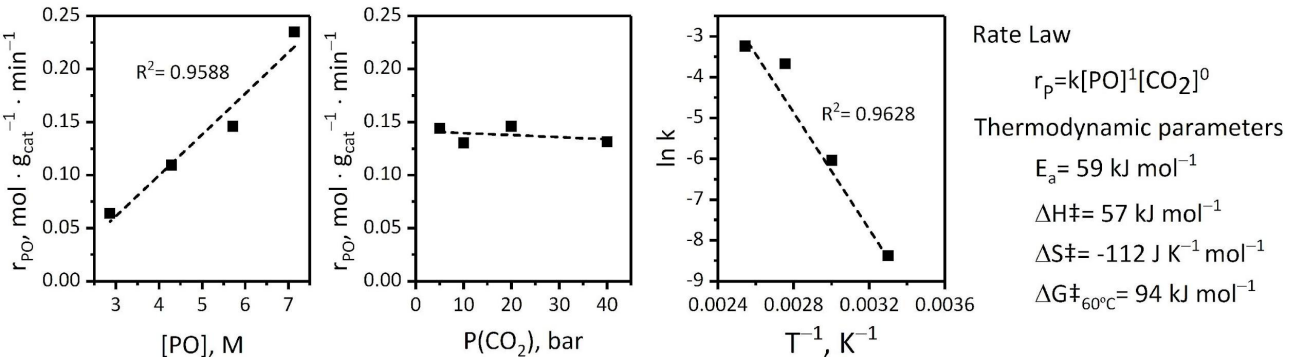

**Figure 1.** Kinetic study and thermodynamic parameters of the $Co[Ni(CN)_4]$ catalyzed $CO_2$/PO ROCOP.

**Keywords:** $CO_2$ hydrogenation, higher alcohols, single atom catalysts, C-C coupling reaction

**Abstract**

The ever-increasing population of the world and the improvement in living standards necessitates the production of more and more energy, which in the majority is still met by the combustion of finite fossil fuels. This in turn leads to an increase in the $CO_2$ concentration in the atmosphere, one of the main greenhouse gases, intensifing, thus, the phenomenon of global climate chanage.[1] A promising pathway to mitigate $CO_2$ emissions and its impact on the environment is by its catalytic transformation to fuels and other chemicals, such as CO, $CH_4$, $CH_3OH$, $C_{2+}H$ and $C_{2+}OH$. Carbon dioxide hydrogenation constitutes a promising reaction which can proceed via thermal-, photo- or electro- catalysis.[2] Among the aforementioned products, the investigation of the synthesis of higher alcohols (HAs), important chemicals in the fuel sector, is still at an early stage, in comparison with the other platform chemicals. This can be attributed to the difficulty of the reaction mechanism, as HAs consist of one C-O bond and at least one C-C bond and the success of C-C bond formation poses a formidable challenge.

Today the catalysts that are used the most in τηε industry are the conventional supported heterogeneous catalysts consisting of nanoparticles or clusters of the active metal dispersed on the surface of the support. However, these catalysts have two major limitations; firstly, their selectivity is low as only a part of the active sites participates in the reaction, and secondly the amount of noble metal needed is relatively high.[3] Therefore, in an effort to overcome these disadvantages researchers now turn their attention to reducing the size of the active phase to single atoms in order to increase catalytic performance and lower costs.

Single atom catalysts (SACs) have in the last decade emerged as a new class of materials combining the advantages of homogeneous and heterogeneous catalysts, i.e., well-defined sites, easy separation, high catalytic activity, selectivity and stability.[4] However, the most important feature of this kind of materials is that they contain only isolated metal atoms achieving, thus, a 100% atom utilization. Therefore, these catalytic materials provide the maximum possible metal dispersion taking full advantage of the metal active sites and minimizing the noble metal content needed. Until now, numerous SACs proved to have an outstanding catalytic performance in a variety of reactions such as CO oxidation, water-gas shift, selective hydrogenation, $CO_2$ reduction and C-C coupling.

For this reason, research regarding the $CO_2$ hydrogenation reaction has lately been focused on the development and investigation of new and innovative single atom catalysts for the enhancement of product yield. Thus, this review focuses on the recent advances in the use of single-atom catalysts for the thermo-, photo-, and electro- chemical hydrogenation of $CO_2$ and CO for the synthesis of a variety of chemicals (methanol, carbon monoxide, formic acid, higher alcohols) through the presentation, comparison and critical discusion of the different catalytic systems that have been used so far.

**Keywords:** cobalt catalysts, alkali doping, hydrogen production, ethanol steam reforming

**Introduction.** Hydrogen energy has received considerable attention due to its high specific energy density and environmental benefits. Among a variety of strategies for hydrogen production, ethanol steam reforming (ESR) is a promising route because $CO_2$ yielded during this reaction could be reused through the photosynthesis of plants, which can be used as feedstock for ethanol production by fermentation, thus forming a closed carbon loop cycle. Catalysts for ESR should have the ability to break the C–C bond. Noble metal catalysts, such as Rh, Ru, Pt, and Pd, are excellent catalysts for C–C bond cleavage. However, due to their high price, transition metal (Ni or Co) catalysts are frequently used for the ESR process. Their performance in the ESR process can be additionally enhanced by alkali promoters' application. Reportedly, the addition of alkali promoters to Co or Ni-based catalysts is effective for promoting ESR reaction and suppressing carbon deposition [1-4].

**Experimental/methodology.** The $Co/CeO_2$ catalyst with nominal metal loading of 10 wt% was prepared by wet impregnation of the commercial nano-dispersed ceria support (Aldrich, particle size: <25 nm particle size, DP:14 nm, VP: 0.14 mL/g, $S_{BET}$: 42.5 $m^2/g$) with the solution of $(CH_3COO)_2Co \times 4H_2O$ in ammonia solution, 25%. $KCo/CeO_2$ catalysts with nominal potassium loading of 0.5 and 1.4 wt% were prepared by wet impregnation method of finely grinded $Co/CeO_2$ solid with solutions containing $KNO_3$. Complementary characterization techniques, such as XRD, XRF, low-temperature nitrogen adsorption, SEM, TEM, and $H_2$-TPR, were used to correlate surface structure and functionality with the catalytic performance of catalysts. The ESR reaction for $EtOH/H_2O$ molar ratios of 1/4 and 1/12 and at temperatures from 420 to 540 °C was carried out over the pre-reduced (T = 500°C, p = 1atm) samples in the flow reactor.

**Results and discussion.** For $EtOH/H_2O$ molar ratio of 1/4, a temperature of 540 °C was sufficient to obtain complete ethanol conversion during 21 h of the ESR process with very high selectivity to hydrogen (92%) and carbon dioxide (60%) and only two by-products, methane and carbon monoxide, over $1.4KCo/CeO_2$ catalyst. In the case of the $Co/CeO_2$ sample, this temperature allowed obtaining the ethanol conversion of 90% after 21 hours of the ESR process. Moreover, C2 by-products, acetaldehyde and ethylene, were formed in the presence of this catalyst. Potassium doping of the $Co/CeO_2$ catalyst allowed not only to enhance steam reforming activity but also to suppress the aldol condensation of acetaldehyde to acetone. In addition, potassium doping inhibited the accumulation of carbon on the catalyst surface under the ESR conditions favoring the rate of the steam gasification of carbon formed during the process. Although the potassium addition did not influence the morphology of formed carbon, it seems to depend on the temperature of the ESR reaction. For 420 °C on the catalysts' surface mainly the polymeric carbon encapsulating the cobalt particles was formed, resulting in the immediate deactivation of $Co/CeO_2$ catalysts. Whereas the filamentous carbon, resulting from the methane decomposition and carbon monoxide disproportion reactions, was mostly formed during the ESR reaction carried out at 540 °C.

**Introduction.**

Air pollution is a major problem all over the world, affecting human health, ecosystems, and climate change. The transport industry has been recognised by the European Environment Agency as one of the first sources of air pollution in Europe[1]. The field of automotive catalysts is always under development, also to comply with more stringent emission regulations. In this framework, a fundamental understanding of the reactions occurring in a catalytic converter can help to reduce the amount of noble metals employed. The interest toward cerium oxide-based materials as supports for catalytically active nanoparticles has raised in the last decades due to oxygen storage properties of ceria[2], and it has recently been shown that using $CeO_2$ as supporting material instead of the conventional $Al_2O_3$ can significantly improve the activity for CO oxidation[3]. $CeO_2$ represents an example where fundamental studies can help in better understanding the contribution of active support materials, since morphological features can be tuned during its synthesis, with the aim to modify surface properties, influencing the catalytic performances[4].

**Experimental/methodology.**

The present work concerns the synthesis of well-defined anisotropically shaped $CeO_2$ nanostructures. Homogeneous and well-defined $CeO_2$ nanorods and nanocubes were successfully obtained through subcritical hydrothermal synthesis and consequently impregnated with small ($d < 5$ nm) and monodisperse PdPt bimetallic nanoparticles (NPs) produced *via* chemical reduction in a microfluidic reactor. A commercial $CeO_2$ with no preferentially exposed facets was used as a benchmark.

**Results and discussion.**

Through different analytical tools crystal structure (XRD), morphology and exposed facets (SEM, HRTEM), specific surface area and porosity ($N_2$ physisorption), noble metal loading (ICP-OES), and reducibility (TG-MS), have been determined. The catalysts were also tested for CO oxidation in a model gas mixture, under constant weight hour space velocity (WHSV), to reveal the effect of different exposed facets of the support in the catalytic performance. O*perando* XAS data were additionally acquired on Pd and Pt edges at ESRF. The catalytic activity data show clear differences between the performance of the bimetallic Pt-Pd catalysts supported on different anisotropically shaped $CeO_2$, which could be releted to their properties and redox behaviour.

**Keywords:** Ruthenium, magnetic catalyst, hydrogenation, hydroxymethylfurfural

**Introduction.** 5-hydroxymethylfurfural (produced from lignocellulosic biomass) shows immense potential for forming a vast range of platform chemicals for bio-polymers and biofuel production [1]. Therefore, selective and active catalysts for its transformation are critical for its utilization. Here we show that the choice of preparation method for deposition of a well known and active catalysts for hydrotreatments of biobased chemicals i.e., Ru [2] can have a profound effect on its activity and selectivity.

**Experimental/methodology.** A series of catalysts was prepared on a magnetic C support by a two-step procedure. In the first step of preparation the magnetic C support was prepared [3]. In the second step Ru was deposited: by impregnation, followed by drying and reduction in $H_2$ atmosphere at 250 °C. (Catalyst I); precipitation of $Ru^{3+}$ in presence of magnetic C, followed by drying (P) and reduction in $H_2$ atmosphere at 250 °C (PR) and by a solvothermal reduction of $Ru^{3+}$ by isopropanol in presence of magnetic C (ST). Prepared and spent catalysts were characterized and analyzed in great details by conventional methods. Catalytic hydrogenations of 5-hydroxymethylfurfural (HMF) were carried at 130, 150 and 170 °C at 5 MPa of $H_2$. Reaction rate constants and activation energies were determined by microkinetic modeling [4].

**Results and discussion.** TEM and STEM analysis showed that impregnation method followed by reduction of $RuCl_3$ to metallic Ru nanoparticles yielded the least homogenous dispersion of Ru over the surface of magnetic carbon. Such poor homogeneity of distribution can be associated to uneven deposition of $RuCl_3$ from aqueous solution in the impregnation step. The magnetic support is porous and therefore uneven drying and consequently uneven deposition is expected. Upon reduction the average size of Ru nanoparticles was 1.5 ± 0.3 nm. Solvothermal reduction of $Ru(acac)_3$ yielded relatively homogenous distribution of Ru nanoparticles of 1.7 ± 0.3 nm in diameter however, larger Ru platelets of 5 to 10 nm in size were frequently observed as well. Precipitation of $Ru^{3+}$ in presence of magnetic carbon results in homogeneous deposition of small approx. 1 nm sized Ru oxide/hydroxide nanoparticles. Those reduce to 1.3 ± 0.3 nm sized Ru nanoparticles when used for hydrogenation of HMF already at 130 °C. However, when reduced in $H_2$ in tubular furnace at 250 °C they grow to 3.2 ± 0.3 nm sized Ru nanoparticles. XRF determined content of Ru was comparable, approx. 4 wt.% for all of catalysts except for ST where 2.6 wt.% was determined. Their activity for HMF hydrogenation was markedly different. The PR catalysts showed the worst performance that could be related to the largest size of Ru nanoparticles found in that catalyst. The best performance in terms of activity, selectivity and stability was demonstrated by P catalyst. We attribute such behavior to the unique conditions of its reduction being conducted under reactive conditions.

# Efficient Catalysts for Methylcyclohexane Dehydrogenation: Dispersed Cluster Fe Decoration of $SiO_2$ Supported Pt Catalysts

H. Akhoundzadeh[1], R. Xu[*]

[1]*Nanyang Technological University, Singapore, Singapore*
[2]*Nanyang Technological University, Singapore, Singapore*
[*] *rxu@ntu.edu.sg*

**Introduction.**

Liquid organic hydrogen carriers (LOHCs) hold tremendous promise for hydrogen storage and transportation, with methylcyclohexane (MCH) being among the most favorable candidates. However, the dehydrogenation of MCH presents a significant challenge due to the lack of efficient catalysts. Traditionally, platinum (Pt) catalysts have been utilized for MCH dehydrogenation, but they suffer from rapid deactivation and low selectivity. The main objective of this study is to enhance the performance of Pt catalysts by incorporating Fe as a promoter while carefully controlling the size of Fe particles. To achieve this goal, we synthesized two different sizes of Fe particles and subsequently added Pt to the catalysts.

**Experimental/methodology.**

To synthesize $SiO_2$-supported Pt-Fe bimetallic catalysts, Fe-citric acid and $Fe(NO_3)_3$ were used as Fe precursors for which the resulting samples were designated as $Fe/SiO_2$-S (S for small Fe particles) and $Fe/SiO_2$-B (B for big Fe particles). Subsequently, $Pt(NH_3)_2(NO_3)$ was loaded.

**Results and discussion.**

In order to investigate the effect of Fe particle size and bimetallic formation, transmission electron microscopy (TEM) was used. As can be seen from Fig.1a and b, Fe particle size was around 1 nm in $Fe/SiO_2$-S sample while Fe size was much larger than $F/SiO_2$-B sample( 4nm). Fig1. shows the lattice fringe of PtFe samples is 0.21 nm which is lower than Pt(111) which is 0.23 nm, confirming Pt-Fe alloy formation.

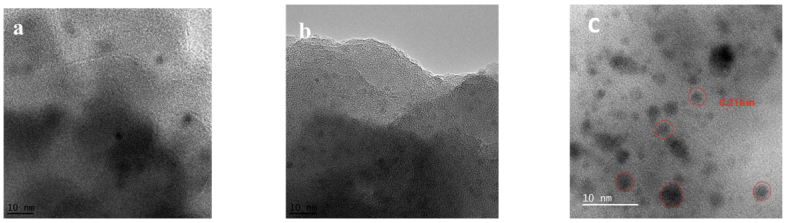

**Fig1.** TEM images of different supported Fe samples; a) $Fe/SiO_2$-B, b) $Fe/SiO_2$-S and $Pt\text{-}Fe/SiO_2$-S.

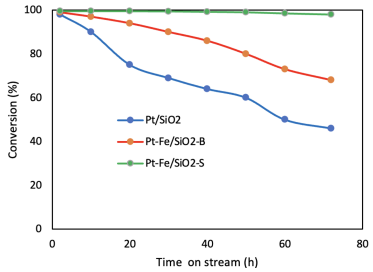

**Fig 2.** the catalytic performaance of different catalysts in MCH dehdyrogenation.

Fig. 2 illustrates the catalytic performance in MCH dehydrogenation, clearly indicating that the non-modified $Pt/SiO_2$ catalyst deactivated rapidly. However, with the addition of Fe, the performance improved, though to varying degrees depending on the size of the Fe particles. Notably, $Pt\text{-}Fe/SiO_2$-S exhibited significantly more stable performance than $Pt\text{-}Fe/SiO_2$-B, underscoring the critical role of promoter particle size. Smaller Fe particles provide a higher number of particles that can strongly interact with Pt. Remarkably, the $Pt\text{-}Fe/SiO_2$-B catalyst displayed an impressive hydrogen evolution rate of 2200 $mmol.gPt^{-1}.min^{-1}$, and even after 3 days, the conversion remained at around 98%. This research introduces a

pioneering technique for producing supported Pt-Fe catalysts, with a primary focus on precise control over the dimensions of Fe particles as a promoter.

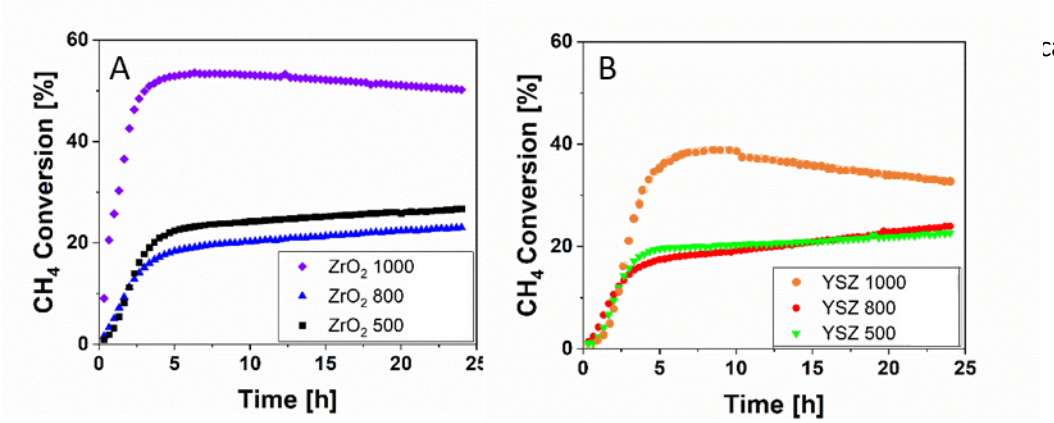
**Introduction**



Methane dry reforming is a well-studied reaction that have both scientific and industrial importance. It has gained much attention in recent years for its ability to convert two greenhouse gasses, $CH_4$ and $CO_2$, into syngas to produce a wide range of products.[1] The best-known catalysts for DRM are based on noble metals, which are not viable for an industrial process due to their high cost. This can be overcome by using transition-metal based catalysts such as nickel (Ni). However, Ni based catalysts suffer from strong deactivation, which can be caused by carbon deposition on catalyst's surface, sintering of the Ni particles and blockage of the catalyst support pores. Recent work within the Gazit group showed that a Ni catalyst supported on a hierarchical support, composed of a thin mixed metal oxide supported on a secondary underlying metal oxide, has great potential for the promotion of DRM reaction.[4] However, the nature and extent of interactions between the Ni and the hierarchical support and how they affect DRM catalysis is still not fully understood. In this work we evaluate the effect of the underlying $ZrO_2$ support morphology and phase on the hierachical Ni based catlayst catalytic performance.

**Experimental/methodology**

Nanofibers(NFs) of $ZrO_2$ and yittrium doped $ZrO_2$ (YSZ) were electrospun. The morphology of the NFs was characterized by high resolution scanning electron microscopy (HR-SEM), Temperature programed reduction experiments (TPR), powder X-ray diffracion (XRD) and ICP-OES. Catalytic activity was evaluated at 800 °C and atmospheric pressure in a fixed-bed quartz tubular reactor. The products were analyzed using an online GC.

**Results and discussion**

To induce morphological changes, the $ZrO_2$ YSZ NFs were calcined at different temperatures perior to hierarchical catalyst preparation. Using those materials as the underlying support for Ni we prepared 6 different catlayst and tested those in DRM. It was found that supporting the Ni on the hierarchical NFs calcined at 1000 °C produced a catalyst with the highest $CH_4$ conversion and $H_2$/CO ratio, Figure 1. comparing these resutls to structural parameter obtained by XRD we identify chnages in crystalline phase and in grain size. Furthermore, comparing the results to particular ZrO2 we find that the NFs geometry gives advantageous performance.

**Keywords:** Double perovskite, Electrocatalyst, Oxygen Evolution Reaction

**Introduction.**

The use of perovskite materials has been steadily increasing from the past to the present, and research is being conducted to find excellent durability and efficiency suitable for each field. [1] The characteristics of perovskite materials include high melting points, high hardness and strength, and considerable durability, but problems include low electrical and thermal conductivity and chemical inertness.[2]

Double perovskite structured material, $A_2BB'O_6$ is used in many electrochemical fields because of its good electrical properties, and its unique structure-property, of layer-by-layer, which is considered to have good structural advantages.

In this work, the electrocatalyst using tungsten (W) based double perovskite was designed. To make the stable structure, calcium (Ca) was used for stabilization, and a transition metal of nickel (Ni) was doped in the structure as an active site for improving electrocatalytic properties.

**Experimental/methodology.**

$Ba_2Ca_{1-x}Ni_xWO_6$ double perovskite catalysts were synthesized by the solid-state method. The mixed powder was calcinated in an alumina boat in the furnace at 800 ℃ for 24h and 1400 ℃ for 48 h.

**Results and discussion**

Prepared double perovskite structure catalysts of $Ba_2Ca_{1-x}Ni_xWO_6$ resulting in high crystallinity and good electrochemical properties. Each of the metals is finely positioned in certain rations, which was confirmed by the XRD, SEM & EDX analysis.

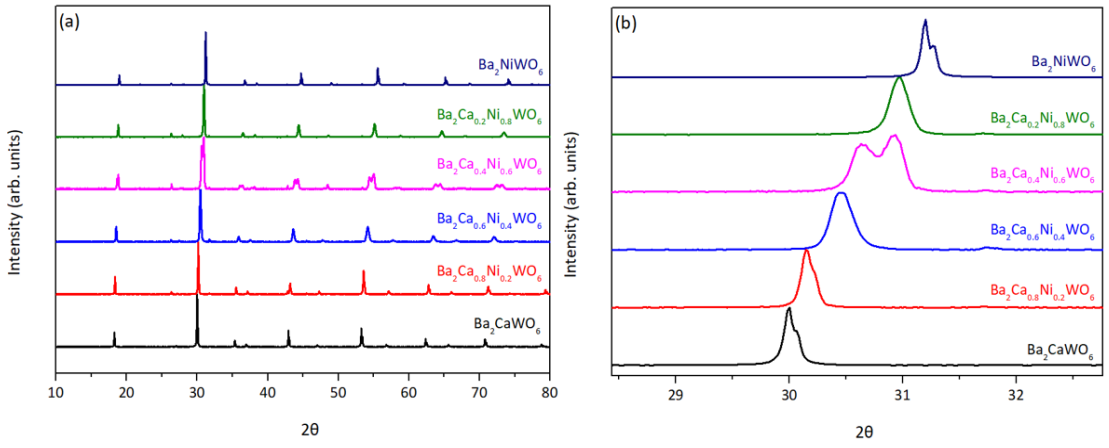

**Fig. 1. (a-b)** The XRD pattern of $Ba_2Ca_{1-x}Ni_xWO_6$ (x = 0, 0.2, 0.4, 0.6, 0.8, 1) shows the structure change when nickel doping amount becomes larger and the difference between calcium ion size and nickel ion size.

In XPS, there is a structural change when a portion of nickel increases depending on the calcium portion. From the electrochemical results, we can confirm that double perovskites with optimized Ni and Ca ration have great electrical properties, which indicates the importance of the structural design of the electrochemical catalysts.

# Hierarchical Hollow Al-Rich Nano ZSM-5 Crystals for Highly Selective Production of Light Olefins from Naphthene

Lei Han*, Ruoyu Wang, Peng Wang, Wei Lin
*Research Institute of Petroleum Processing, SINOPEC, Beijing 100083, China.*
*han-lei.ripp@sinopec.com*

**Keywords:** Al-rich ZSM-5, hierarchical zeolite, hollow structure, desilication, naphthene cracking

**Introduction.**

As one important member in crystalline aluminosilicates MFI family, ZSM-5 zeolites possess distinctive small microporous structure (~0.56 nm) and exhibit favorable shape-selectivity for enhanced light olefin yields in industrial catalytic cracking processes and many other fundamental petrochemical processes[1]. However, ZSM-5-catalyzed reactions may encounter with molecule diffusion problems due to limited pore size, leading to unwanted coke deposition and further deactivation, especially in the case of bulky cyclic compounds[2].

**Methodology.**

We report a facile Al-distribution regulated desilication approach to synthesize hierarchical Al-rich nano ZSM-5 crystals with hollow structures. Briefly, this approach involves (i) the synthesis of parent ZSM-5 zeolites with high percentages of local concentrated Al (Z5-LCA) domains and (ii) post-treatment of Z5-LCA with NaOH solution (Fig.1). The existence of LCA domains and their impacts on the selective desilication process were validated by diffuse reflection UV spectra and filtrate analysis, and approximately 49% of Al atoms emerged in Z5-LCA samples as Al species in close contact.

**Results and discussion.**

The as-synthesized Z5-LCA is primarily in round pancake shape with uniform sizes of around 600~1000 nm. Distinct hollow ZSM-5 zeolite can be obtained using more concentrated base (0.6 M of NaOH) in the post-treatment procedure. The hollow ZSM-5 zeolite is characteristic of type IV BET isotherm curves, and pronounced H4 hysteresis loops in the relative pressure range of $p/p_0$ = 0.45~0.85, indicating the generation of mesoporous cavities. Compared with its parent zeolite, the hierarchical hollow nano ZSM-5 crystal exhibited increased catalytic activities as well as ~ 2-fold improved selectivities for high-value light olefins ($C_2H_4$ and $C_3H_6$) in the catalytic cracking of decalin (a model bulky naphthene molecule) (Fig.2). These findings expand our knowledge on achieving desirable zeolite structures by regulating framework Al distribution, and suggest a promising new catalyst toward highly selective production of light olefins from naphthene feedstocks.

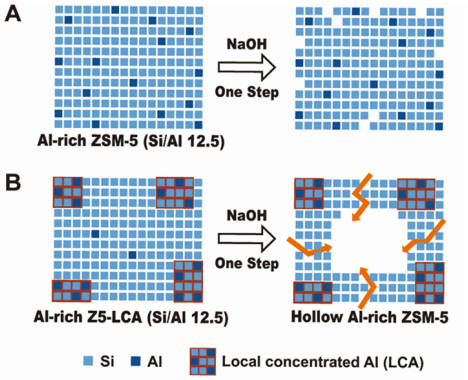

**Fig. 1 (A)** Schematic illustration of the solid mesoporous ZSM-5 obtained after one-step alkaline treatment of regular Al-zoned ZSM-5 with a low Si/Al molar ratio. **(B)** Hierarchical hollow Al-rich ZSM-5 obtained after one-step alkaline treatment of parent Al-rich ZSM-5 with local concentrated Al atoms (Z5-LCA).

**Keywords:** Alumina carrier, Heat resistance, Coking, Steam reforming

**Introduction.**

Catalysts for steam reforming reactions must maintain a high specific surface area in a steam atmosphere at high temperature and high pressure, and must also suppress coking. We have reported that silica-doped alumina prepared by coprecipitation exhibits extremely high heat resistance. However, the addition of silica tends to induce coking [1]. Therefore, in the present study, silica and barium oxide were added to alumina to prepare an alumina carrier with both heat resistance and coking resistance.

**Experimental.**

Ethyl silicate was added to the aluminum nitrate solution and stirred to obtain a homogeneous solution. Ammonia water was then added to this solution to form a precipitate. After filtration and washing of the precipitate, an aqueous barium nitrate solution was added and evaporated to dryness at 150°C. The dried powder was calcined at 1000-1200°C to obtain the alumina carrier. Nickel-supported catalysts were prepared on the resulting alumina supports by the impregnation method, and the amount of coking was evaluated by a steam reforming reaction using propane.

**Results and discussion.**

We prepared alumina samples with silica, barium oxide, and lanthanum oxide, and evaluated their heat resistance. The silica-doped alumina exhibited the highest heat resistance [2]. The specific surface area of the alumina carrier increased with increasing silica content, indicating that silica is effective for improving heat resistance [3]. However, the solid acidity of the alumina carrier was evaluated by $NH_3$–temperature-programmed desorption and was found to increase with increasing silica content. The amount of coking was evaluated by a steam reforming reaction with propane using a Ni-$SiO_2$/$Al_2O_3$ catalyst. For catalysts with 3% or more of added silica, the amount of coking increased rapidly with increasing silica content. Therefore, alumina supports were prepared with various amounts of added silica and barium, and the specific surface area and solid acid content were evaluated. As shown in Figure 1, the 7% BaO-1% $SiO_2$/$Al_2O_3$ carrier showed a specific surface area of 34 $m^2 \cdot g^{-1}$ after heat treatment at 1200°C for 30 h, while the solid acidity was comparable to that of alumina without silica. These results indicate that BaO-$SiO_2$/$Al_2O_3$ exhibits high heat resistance but suppressed solid acidity.

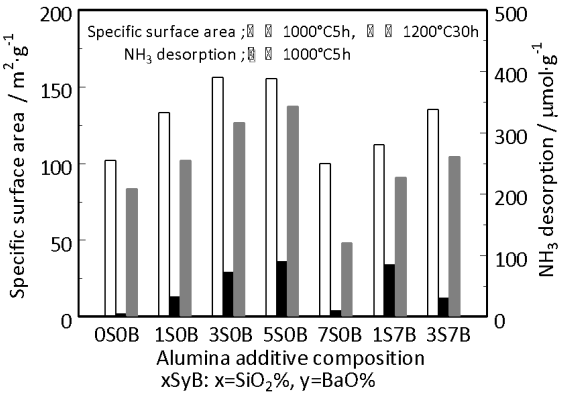

Figure 1. Specific surface area and solid acid content of alumina carriers with various amounts of added silica and barium oxide.

# Carbon Neutral Isobutanol – Development of high performance catalysts based on dilute alloys

J. Häusler[1*], J. Pasel[1], R. Peters[1]

[1]*Forschungszentrum Jülich GmbH, Jülich, Germany*
[*]*j.haeusler@fz-juelich.de*

**Keywords:** Guerbet Reaction, Carbon Neutral Fuels, d-Band Center, Catalytic Activity, C-Methylation

**Introduction.** To mitigate CO2 emissions in society, it is imperative that products utilized on a large scale are produced utilizing CO2 sources. The primary contributors to CO2 emissions are fossil fuels, accounting for 18% of the worldwide CO2 emissions in 2019 due to road traffic[1]. Carbon-neutral fuels can reduce the climate impact but to be used in existing consumer cars, they have to match the characteristics of fossil fuels. Methanol can easily be synthesized from CO2 and renewable hydrogen but does not meet these requirements. Because direct usage of methanol or even ethanol in higher concentrations is incompatible and restricted by the DIN EN 228 and ASTM D7862 in cars, the efficient synthesis of C4 alcohols is a central part of the project. These C4 or "higher alcohols" prove to meet preceding regulations and burning characteristics.

Because of this a lot of research nowadays deals with the upgrading of ethanol into 1-butanol through the Guerbet reaction, since 1-butanol has a higher caloric value, is less aggressive and more hydrophobic than ethanol[2,3]. Since 1-butanol has a higher caloric value, is less aggressive, and is more hydrophobic than ethanol[2,3]. A huge disadvantage of this reaction is the low conversion of ethanol and low selectivity towards 1-butanol. Using methanol for the methylation of ethanol and NaOH as a cheap and abundant base allowed the selective synthesis of 2-methyl-1-propanol (iso-butanol)[4,5]. In the context of a CO2-neutral methanol-based fuel synthesis, this is advantageous, as 50% of the carbon atoms are methanol-originated, and by using bio-ethanol a carbon-neutral product can be achieved.

For our research, we decided to build upon this C-methylation protocol for the synthesis of iso-butanol, because i-butanol is not only suitable as a drop-in fuel but also as an educt for octane enhancers and monomer for polymers and thereby offers a product suitable to exchange fossil based iso-butanol[6]. In this study, we aim at understanding the underlying influences of the active metal in the synthesis of i-butanol.

**Experimental/methodology.** For the search of activity trends in the metals we used monometallic catalysts and correlated their activity against the d-Band center. After identification of the best-performing catalyst based on isobutanol yield, we synthesized bimetallic catalysts with calculated d-Band values near the optimal catalytic metal. Further, the bimetallic catalyst with the highest catalytic activity was chosen for further optimization experiments, by varying metal loading and metal-to-metal ratio.

The catalysts for the reaction were prepared by impregnation and precipitation methods on activated carbon, drying, and where necessary subsequent impregnation with the appropriate amount of platinum precursor. All of the catalysts were characterized through STEM, ICP-OES, H2-Chemisorption, XRD, and N2-Physisorption. Catalytic tests were performed in a Parr batch Autoclave reactor of 70mL Volume. Product analysis and quantification of liquid samples were performed with GCMS.

**Results and discussion.** For the monometallic catalysts a volcano plot was achieved when the TOF calculated from STEM and chemisorption experiments was correlated with the d-band-center value of the transition metals, Cu (-2,67 eV), Pt (-2,25 eV), Ir (-2,11 eV), Pd (-1,83 eV), Rh (-1,73 eV) and Rh (-1,41 eV). Platinum reached the maximum TOF of 16,25 h-1 while there was a monotonic decrease of TOF for the metals with higher or lower d-band center values. This result led us to the assumption that an optimal adsorbate-adsorbent interaction was reached at the d-band center value of -2,25 eV, following the Sabatier-Principle [7]

Synthesis, characterization, and experimental testing of the highly diluted bimetallic alloys Cu99Ni1/C, Cu99Fe/C, Fe99Pt1/C, Fe99Pd1/C, Ni99Pt1/C resulted in much lower TOFs and did not match the predicted volcano plot when calculating the TOF based on the metal surface area from STEM and XRD measurements. Nevertheless, the Ni99Pt/C catalyst was not deactivated under reaction conditions, while the corresponding Pt/C catalyst deactivated within 1-2 hours depending on the reaction temperature. Optimizing the Ni: Pt

ratio and metal loading, allowed us to reach a 12% yield of i-butanol with a selectivity of 95% after 4h reaction time, while the Pt catalyst only achieved a 2% yield under similar reaction conditions.

# Non-Symmetrical Triphos Derivatives and their Application in Ruthenium Catalyzed Hydrogenation Reactions

Johanna Henkel[1], Ole Osterthun[1], and Jürgen Klankermayer[1*]

[1]RWTH Aachen University, Institute of Technical and Macromolecular Chemistry, Aachen, Germany
*henkel@itmc.rwth-aachen.de and jklankermayer@itmc.rwth-aachen.de*

**Introduction.** Ruthenium triphos complexes, with [Ru(triphos)(tmm)] (triphos = 1,1,1-tris(diphenylphosphino)ethane; tmm = trimethylenemethane) as the main representative, have been extensively studied for various reactions with a focus on the hydrogenation of carbonates, amides, polyesters, polycarbonates and carbon dioxide ($CO_2$).[1-3] While mainly [Ru(triphos$^{R_3}$)(tmm)] complexes with the same substituents on the phosphines have been studied in catalytic hydrogenations, little work has been done to understand the effects of triphos systems with altered phosphine arms of the form [Ru(triphos$^{RR'_2}$)(tmm)]. However, this increased complexity allows the tailoring of the ligand environment specifically to the substrate, paving the way to catalytic systems with unprecedented activity and selectivity.
**Experimental/methodology.** Based on the protocol of Tuczek *et al.*[4], the synthesis of a wide range of triphos ligand derivatives using diisopropylphosphine or dicyclohexylphosphine and two aromatic phosphines is presented here (Figure 1). The corresponding [Ru(triphos$^{RR'_2}$)(tmm)] complexes can be tested for selected hydrogenation reactions.
**Results and discussion.** The catalytic activity of the synthesized catalysts was tested in the hydrogenation of $CO_2$ to methanol. For the symmetry broken ligands obtained by introducing electron donating isopropyl groups, an increase of the initial TOF by a factor up to 2 could be observed for all tested catalysts in comparison to the symmetrical [Ru(triphos)(tmm)]. With the introduction of cyclohexyl groups, an increase by a factor up to 2.3 could be achieved. The largest increase in activity could be observed for the ruthenium triphos derivative with one $PCy_2$ (Cy = cyclohexyl) group and two P(*m*-OMe)$_2$ (*m*-OMe = 3,5-dimethoxyphenyl) groups, resulting in a $TOF_{ini}$ of 327 and a TON for methanol of 1193. We further plan to use the described catalysts for the hydrogenation of selected other substrates.

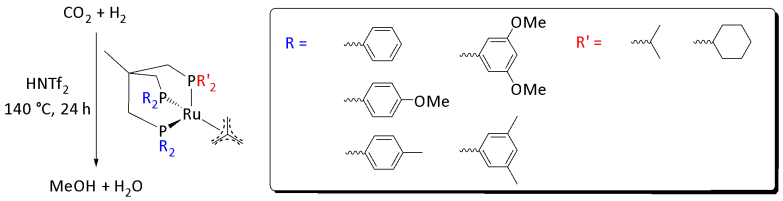

**Figure 1:** Different [Ru(triphos$^{RR'_2}$)(tmm)] complexes tested in the hydrogenation of $CO_2$ to methanol.

Classical experimental testing of all candidates for each substrate is impossible due to the expansion of chemical space through symmetry breaking, which leads to a multitude of complex combinations. Therefore, this class of complexes will be studied more closely and explored through the development and application of computational and modern machine learning methods in collaboration with Prof. Bannwarth's group (RWTH Aachen University).

# Influence of Support on the Dehydrogenation of Perhydro Benzyltoluene with Platinum-based Catalysts

E. Herzinger[1], M. Wolf[1*]

[1]*Karlsruhe Institute of Technology, Karlsruhe, Germany*
[*]*moritz.wolf@kit.edu*

**Keywords:** Chemical hydrogen storage, LOHC, dehydrogenation, catalyst preparation, support material

**Introduction.** Hydrogen as an energy carrier offers many benefits for the environment, energy security, economy and end users.[1] However, cost-effective, compact, safe and convenient storage of hydrogen are essential for large-scale implementation. Further, the volumetric energy density of hydrogen is relatively low compared to other energy carriers.[2] One approach to address this challenge is the use of liquid organic hydrogen carriers (LOHCs) for chemical hydrogen storage. LOHCs are organic liquids that can chemically bind hydrogen in a reversible manner, which allows for long-term storage and safe transportation of hydrogen under ambient conditions.[3] Benzyltoluene/perhydro benzyltoluene (H0-BT/H12-BT) is a technical LOHC system that is thermally stable, has low toxicity, and has a wide liquid range. It has a hydrogen storage capacity of 6.2 wt%, which is equivalent to 2.1 kWh $kg^{-1}$ or 1.9 kWh $L^{-1}$.[4] However, to maximize the hydrogen storage capacity and the number of repeated loading and unloading cycles via catalytic hydrogenation and dehydrogenation, respectivly, a superior catalyst selectivity and high conversions are of utmost importance.

**Experimental/methodology.** In this study, the influence of the support material on the dehydrogenation activity of platinum-based catalyst systems is investigated. Therefore, platinum was supported on a range of materials and the resulting catalysts as well as the support materials were thoroughly characterized by means of X-ray diffraction (XRD), transmission electron microscopy (TEM) and $N_2$ physisorption. The dehydrogenation activity was evaluated in semi-batch laboratory-scale dehydrogenation experiments using stirred round-bottom flasks to compare key performance indicators, such as the degree of dehydrogenation (DoDH) of perhydro benzyltoluene and the platinum-based productivity of the catalysts.

**Results and discussion.** The dehydrogenation performance and catalyst productivity of the prepared catalysts strongly depends on the utilized supports (Fig. 1). These results indicate that the composition, morphology and surface chemistry of the support significantly influence the catalyst activity. Limited pore diffusion and/or insufficient distribution of the active metal over the support surface as well as strong interaction with material additives might hamper the catalysts activity. Overall, this research highlights the importance of understanding how the support material can potentially affect catalyst activity in order to develop more efficient systems in the future.

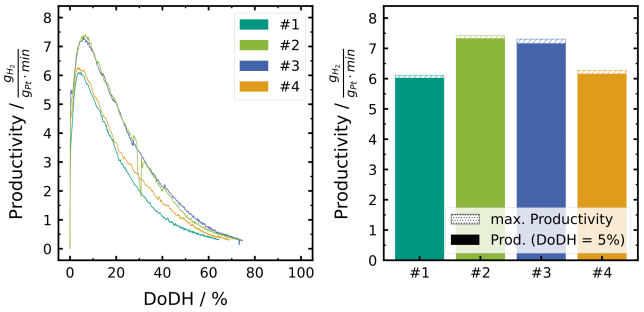

**Fig. 1: Productivity (left) and maximum productivity as well as productivity at a DoDH of 5% (right) during semi-batch dehydrogenation of perhydro benzyltoluol with $Pt/Al_2O_3$ catalysts at 250 °C**

# Are zeolites promising supports for diesel oxidation catalysts?

Phuoc Hoang Ho, Derek Creaser, and Louise Olsson*

*Chemical Engineering, Competence Centre for Catalysis, Chalmers University of Technology, S-412 96 Gothenburg, Sweden*

* *louise.olsson@chalmers.se (Louise Olsson)*

**Keywords:** Diesel Oxidation Catalysts, Zeolites, High SAR zeolite, Pt-based catalysts

**Introduction.** Diesel oxidation catalysts (DOC) primarily oxidize CO, unburnt hydrocarbons (HCs), and NO and thereby play a crucial role in meeting emission regulations [1]. Investigating the impact of sulfur poisoning is essential to extend the lifetime of the DOC. Most studies have focused on alumina supports but not zeolites, although zeolites are widely used for other applications in exhaust gas after-treatment systems and are claimed to be promising materials for DOCs in some patents. This work investigates two main aspects on the use of zeolites as supports for DOCs i) different types of zeolites with high siliceous contents in comparisons with alumina support and ii) the effect of Pt/Pd ratio. The activity tests focused on i) the catalytic oxidation of CO, NO, and hydrocarbons ($C_3H_8$ and $C_3H_6$) and ii) the deactivation of the oxidation activity of the catalyst during poisoning with $SO_2$.

**Experimental/methodology.** High siliceous zeolites (ZSM-5, BEA, and Y zeolites) were used as supports. Monometallic catalysts containing Pt were prepared with a wet impregnation method. A series of Pt-Pd bimetallic catalysts with different Pt/Pd ratios (same amount of total moles of noble metals) was also prepared. Each powder material was subsequently coated on a honeycomb monolith with a dip-coating method. The catalysts were characterized by many techniques including ICP-SFMS, XRD, HRTEM, $N_2$ physisorption, CO chemisorption, and DRIFTS.

**Results and discussion.** Pt dispersion was ranked in the order of Pt/Y (4.6%) < $Pt/Al_2O_3$ (6.5%) < Pt/BEA (7.3%) ~ Pt/ZSM-5 (7.4%), resulting in an average particle size range of 15 – 24 nm. The Pt/BEA catalyst not only decreased the $T_{50}$ for CO and $C_3H_8$ oxidation compared to the benchmark $Pt/Al_2O_3$ catalyst (Fig. 1a) but also showed a more stable conversion. All zeolite-based catalysts had significantly lower $T_{50}$ values for $C_3H_8$ oxidation, perhaps due to better confinement of $C_3H_8$ in the zeolite pores than in alumina. During the $SO_2$ poisoning, the Pt/BEA showed more stable conversions than $Pt/Al_2O_3$ for CO and $C_3H_6$ but faster deactivation partially for NO oxidation, due to the low sulfur adsorption capacity of the support. The addition of 20 ppm $SO_2$ promoted $C_3H_8$ oxidation for both $Pt/Al_2O_3$ and Pt/BEA, but the $SO_2$ promotion for $C_3H_8$ oxidation occurred faster on the latter than the former (data not shown here). The addition of a small fraction of Pd improved the oxidation resistance of Pt and this enhanced the oxidation of CO and $C_3H_6$ as well as the reduction of NO with hydrocarbon. The Pt3Pd1/BEA showed also better sulfur resistance for CO oxidation than the monometallic Pt catalyst (Fig. 1b).

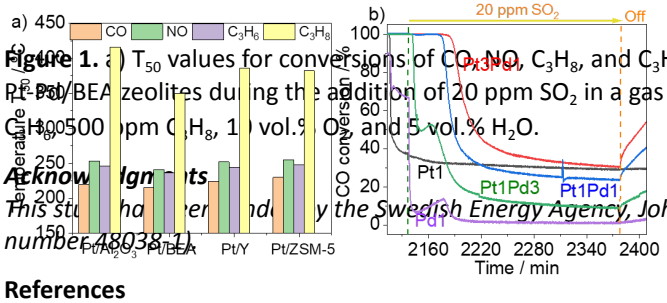

**Figure 1.** a) $T_{50}$ values for conversions of CO, NO, $C_3H_8$, and $C_3H_6$ with different catalysts and b) effect of Pt/Pd ratios on Pt-Pd/BEA zeolites during the addition of 20 ppm $SO_2$ in a gas mixture containing 1000 ppm CO, 500 ppm NO, 500 ppm $C_3H_6$, 500 ppm $C_3H_8$, 10 vol.% $O_2$ and 5 vol.% $H_2O$.

**Keywords:** Catalysis, Palladium, Carboxylation, $CO_2$

**Introduction**

Targeting a circular and sustainable production of chemical goods, the utilization of the nonfossil and nontoxic low value "waste" material carbon dioxide ($CO_2$) has the potential to play a key role in designing future processes and chemicals. Among the many interesting and challenging reactions with $CO_2$ the direct C-H carboxylation of arenes, enabled by only catalytic amounts of organometallic compounds, remained unsolved so far. This reaction, which is therefore often referred as *dream reaction*, represents a highly atom efficient procedure for the generation of aromatic carboxylic acids - the latter being a frequent motive in high value chemicals. Accordingly, this catalytic reaction provides the potential to satisfy most of the principles of green chemistry; especially when achieving high turnover numbers, chemo- as well as regioselectivity and the avoidance of additional solvents and additives.

**Experimental/methodology**

In recent years we have conducted various computational and experimental studies[1] to develop active molecular catalysts for the carboxylation of arenes with $CO_2$ and have recently reported on a stochiometric reaction.[2] In this work, we present a thorough experimental study on the direct carboxylation of a variety of arenes together with detailed DFT studies for one exemplified substrate.[3]

**Results and discussion**

We show that with sulfonamidophosphane ligands surprisingly active Pd-catalysts can be synthesized and applied in direct carboxylations of $CO_2$. The results of catalytic carboxylations for various arenes are reported. Both experiments and DFT studies show that electron rich arenes are carboxylated easily, while electron poor substrates undergo the reaction with low conversion.

# Synthesis of graphene supported efficient nano-catalysts for biomass applications

Will Chartier

*Loughborough University, Loughborough, United Kingdom*
*w.chartier@lboro.ac.uk*

**Keywords:** Net zero carbon, graphene oxide

**Introduction.** Biotechnology needs to play a major role in the transition from our current fossil-fuel reliant society towards a lower-carbon and sustainable economy. The grand challenge centres around the fundamental science differences between dilute aqueous biorefinery streams containing organic/biological molecules and concentrated long chain species in crude oil. For materials at nanoscale, novel electronic structures are strongly impacted by the dimension and morphology of the materials generated. Metallic nanoparticles contained in a 2D membrane allows the study of catalysis under nanoconfinement and realization of the dual system for both precise molecular separation and nano scale catalysis.

**Experimental/methodology.** Synthesise graphene oxide supported catalysts including Ni, Pt, Ni-Pt alloys with controlled particle size and morphology for biomass applications via microwave and hydrothermal approaches. Understand the mechanisms of the synthesis and catalysis of these developed graphene supported catalysts. Investigate the effects of reaction conditions of both microwave and hydrothermal synthesis with a combination of both methods on the particle size and morphology of Ni, Pt and alloy particles with the reduction of graphene oxide. Investigate the effects of reaction conditions on the formation of graphene oxide supported Ni, Pt and alloy catalysts, to characterise particle size, morphology, crystal structures distribution of particles on graphene oxide, catalytic activity of the catalysts, reduced graphene oxide (rGO) and rGO supported catalysts synthesised.

**Results and discussion.** Graphene oxide supported metal catalysts investigated under SEM and EDX microscopy where nickel nanoparticle aggregations were found. The crystallite size varies depending on the reducing agent used and their sizes vary between 15 and 21nm. Further characterisation by XRD and UV-Vis show the sucessful synthesis of nickel from precursors. 4- Nitrophenol to 4- Aminophenol catalytic conversion experiments characterised by UV-Vis show good catalytic reduciton of graphene oxide suppported platinum and nickel catalysts.

# Mesoporous Silica Monoliths as Porous Scaffold for Heterogeneous Organocatalysis in Continuous-flow

U. Ali[1], Peter R. Schreiner[2], Bernd M. Smarsly*[1]

[1]*Institute of Physical Chemistry, Justus Liebig University, Giessen, Germany*
[2]*Institute of Organic Chemistry, Justus Liebig University, Giessen, Germany*
[*]*Bernd.Smarsly@phys.chemie.uni-giessen.de*

In organic chemistry for synthesis of organic compounds, we need a lot of apparatus, reagents, catalysts and specific conditions so that at the end we get mixture of products, side products, mixed catalysts and then we need to separate this mixture from each other. This complicated and time-consuming process is known as batch synthesis. To minimize all these flaws and synthesizing product through simple and straight forward way to get maximum yield that can be collected easily without further purification, the concept of "Synthesis in Continuous-Flow" is established and attracted great attention in chemical societies. In this project we worked on tuning of mesoporous space in silica monoliths that are being used as porous scaffold for heterogeneous catalysis in continuous-flow. We carefully tuned the hydrothermal temperature during synthesis of silica monoliths and exclusive but detailed physisorption studies confirmed the orderly tuning of mesopore space from restricted mesopores to well-connected open mesoporous system. The mesopore size is controlled form 11nm to 15nm with difference of 1 nm by changing hydrothermal temperature 80°C to 95°C by gape of 3°C. The further change of mesopore size from 15nm to 27nm is controlled by using hydrothermal temperature range of 95°C to 110°C with change of 5°C. The resulting monoliths with known mesopore space were functionalized with thiourea catalyst and heterogeneous flow catalysis performed on a very classic reaction used for protection of alcohols and phenols with 3,4-dihydro-2*H*-pyran. By using immobilized thiourea catalyst on silica monoliths, very fine yields were achieved in number of reactions by varying different alcohols protection by 3,4-dihydro-2*H*-pyran.

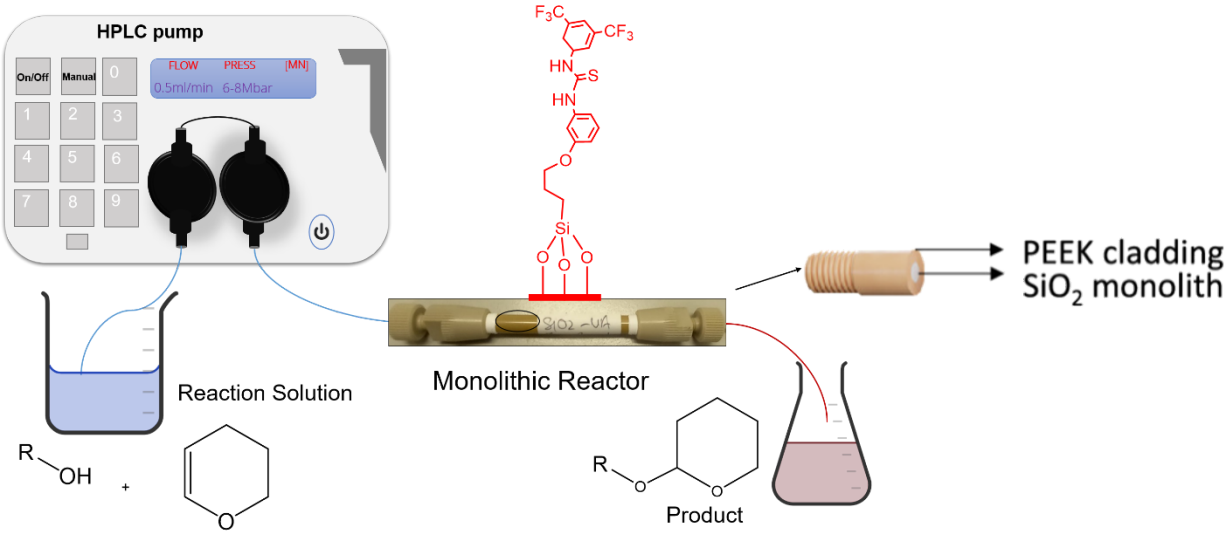

*Figure 1: Flow catalysis setup for protection of alcohol with 3,4-dihydro-2H-pyran by using thiourea catalyst immobilized on silica monolith.*

# Ammonia decomposition over transition-metal/carbon catalyst for on-site generation of hydrogen

Zongkun Chen*, Michael Poschmann, Natalia Kowalew, Marius Heise-Podleska, Tobias Stamm, Robert Schlögl, Saskia Heumann*

*Max Planck Institute for Chemical Energy Conversion, Mülheim an der Ruhr/Germany*

**Keywords:** ammonia decomposition, carbon, hydrogen

**Introduction.** The Catalytic decomposition of ammonia with complete conversion to hydrogen production at low temperature has received extensive attention because on-site hydrogen production from ammonia bypasses the challenges of hydrogen storage and transportation. Among various technologies for the production of hydrogen via ammonia decomposition, thermal decomposition is the most common technique [1], which is usually carried out at higher temperatures. Considering that decreasing the conversion temperature to increase the conversion efficiency is beneficial for facilitating the further development of this field, numerous efforts have been devoted to the development of highly active and robust catalysts [1, 2]. State-of-the-art ammonia decomposition catalysts are ruthenium doped with potassium, barium, and cesium and supported on various oxides and carbon supports [3]. However, these catalysts are still insufficiently active for low-temperature $NH_3$ decomposition and, more importantly, for large-scale applications it is not economically feasible. Considering that a satisfactory performance-to-cost ratio could make the catalysts stand out from the competition with their counterparts, it is urgent to incorporate both performance and cost into their design and fabrication. In our study, transition-metal oxides or transition-metal have been supported onto carbon materials as the potential catalysts for the decomposition of ammonia by a facile freeze-drying and calcination method.

**Experimental/methodology.** Figure 1A schematically illustrates the facile freeze-drying and calcination method that could effectively fabricate transition-metal/carbon catalyst with a hierarchical structure, which mainly involves freezing a mixture of glucose and $Na_2CO_3$ in aqueous solution, followed by the freeze-drying of the mixture and subsequent pyrolysis at certain temperatures to obtain the desired carbon materials with hierarchical structure.

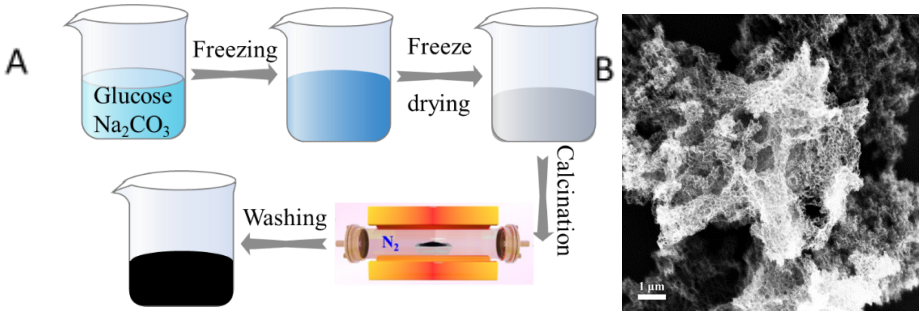

Figure 1. (A) A schematic illustration of the synthetic strategy for carbon materials with a hierarchical structure. (B) SEM image of the obtained carbon materials.

**Results and discussion.** As shown in Figure 1B, the structure of the obtained carbon materials can be considered as the aggregation of numerous interconnected hollow carbon bubbles with a size of 100-200 nm, leading to a 3D porous carbon with very open access. The material properties of the hierarchical carbon materials are modified by systematically varying the synthesis parameter, such as temperature or reactant ratios. The structure-property correlations are investigated in dependence of ammonia decomposition with the focus on activity, selectivity and stability.

# Activity and stability of the catalytic oxidation of methane with Pd/$CeO_2$ nanorods, nanocubes, and octahedra

M. C. Policano*, L. Lefferts, J. A. F. Albanese

*Catalytic Processes and Materials Group, Faculty of Science and Technology, MESA+ Institute for Nanotechnology, University of Twente, PO Box 217, 7500 AE Enschede, The Netherlands*

**Keywords:** Methane oxidation, $CeO_2$, structure, activity, poison resistance

**Introduction.** More restrictive regulations aimed at drastically reducing the emissions of harmful and greenhouse gases (GHG), triggering a shift in the maritime industry. Given this, the use of liquified natural gas (LNG) powered vessels instead of e standard heavy fuel oil (HFO) can contribute to reductions in $SO_2$, $NO_X$, $CO_2$, CO, and toxic particles[1]. However, this reduction comes with an increase of around 5 times in methane emissions[1], which is highly undesirable as the methane global warming potential (GWP) is 37±10 in a 100-year horizon[2]. Oxidation of unburnt methane on palladium-based catalysts is an attractive proposition for the reduction of GHG emissions in LNG engines as it can achieve high conversion levels at low temperatures and short contact times[3]. Despite the high activity of palladium-based catalysts in dry conditions, the addition of water can deactivate the catalyst due to the formation of $Pd(OH)_2$ and hydroxyl accumulation on the support, which consequently hinders oxygen mobility[4]–[6]. Considering that water is generated during methane combustion, the development of water-resistance catalysts is key for large-scale deployment. To overcome this challenge one can leverage the high oxygen mobility of supports such as $CeO_2$ that can increase the activity of oxidation catalysts, reducing the impact of water on oxygen availability[6]. Different morphologies of $CeO_2$ create different facet terminations affecting the Pd oxidation state and $CeO_2$ reducibility[7]. This work aims at studying the methane oxidation activity and water resistance of different $CeO_2$ facet terminations: nanorods {111}, nanocubes {100}, and octahedrons {110} and {111}.

**Experimental/methodology.** The $CeO_2$ supports with different morphologies were synthesized using a hydrothermal method[8] followed by wet impregnation of Pd to achieve a 5 wt. % loading. Methane (400-4000 ppm) and water (0-10 %) concentrations were varied at 10 vol. % oxygen. Product distributions were measured using on-line gas chromatography (Varian CP-3800). Detailed catalyst characterization vias: TEM, SEM, XRD, and Raman were conducted to build property-structure-activity-stability relationships.

**Results and discussion.** Reactions with different methane and water concentrations at different temperatures allow the unveiling of reaction orders of methane and water with each $CeO_2$ support. Moreover, time-on-stream experiments provided information about the stability of the catalysts in dry or wet conditions. By combining the reaction kinetics data with the catalyst characterization it will be possible to elucidate the factors that control the activity and stability of facetted Pd-$CeO_2$ catalysts.

# Selective oxidation reaction using MAX phases as heterogeneous catalysts

Iuliana M. Chirica[1,2*], Mihaela M. Trandafir[1], Anca G. Mirea[1], Florentina Neațu[1], Ștefan Neațu[1], Michel W. Barsoum[3], Mihaela Florea[1]

**Introduction.** A focused research in the last decades showed that the scientific community handled an important challenge to identify the next generation of sustainable, cost-effective and energy efficient catalytic materials [1]. Selective oxidation reactions of hydrocarbons continue to be in the spotlight of both academia and industry [2] and play a key role for the production of valuable compounds [3] used in important fields, ranging from polymer synthesis to medicinal chemistry. [4]

**Experimental/methodology.** In this line, selective oxidation of *p*-cymene is an important green industrial chemical process due to the fact that represent a viable alternative to the oxidation of *p*-xylene to terephthalic acid (TA), one of the monomers used for the production of polyethylene terephthalate (PET) [5]. Moreover, other reaction oxidation products, such as *p*-methylacetophenone (MAP), *p*-toluic acid (TOA) and *p*-isopropylbenzoic acid (IBA) have applications in various fields [6].

**Results and discussion.** In this study, the catalytic properties of different MAX phases ($Ti_3AlC_2$, $Ti_2AlC$, $V_2AlC$, $Ti_3SiC_2$, $Mo_2Ga_2C$ and $Mo_2Ti_2AlC_3$) were investigated in catalytic oxidation reaction of *p*-cymene (see Scheme 1), with remarkable results obtained only in the case of $Ti_3AlC_2$, $Ti_2AlC$ and $Ti_3SiC_2$, respectively. The highest obtained yield of ~41% in terephtalic acid was achieved at 140 °C and 2.3 MPa $O_2$ pressure on $Ti_3AlC_2$. With the MAX phase acting as catalyst, the selective oxidation occurred at the methyl substituent as well as at the isopropyl substituent through two different reaction pathways (***Scheme 1***, ***a)*** and ***b)***), generating several reaction products, identified by $^1$H–RMN. Therefore, MAX phases present good activity in p-cymene oxidation reaction, and moreover MAX phase compositions are stable in the reaction conditions used, as evidenced by the Raman and X-ray diffraction data recorded before and upon testing.

**Introduction.**

Surface defects, such as oxygen vacancies, of perovskite oxides can be easily controlled through various methods due to their high design flexibility [1]. Particularly, when using perovskites as heterogeneous catalysts for various oxidation reactions, formation of the surface oxygen vacancies strongly affect their catalytic activity. In this study, we synthesized $LaCoO_3$ catalysts and induced oxygen vacancies through post-treatments (acid or reductive thermal treatments). Additionally, non-stoichiometric $LaCoO_3$ perovskites were also prepared to control their oxygen vacancies. Through this work, the effect of the post-treatments and non-stochiometry on the surface properties and the catalytic activities of $LaCoO_3$ perovskites in CO oxidation was systematically investigated using various characterizations.

**Experimental/methodology.**

$LaCoO_3$ perovskite was synthesized through a citrate sol-gel method. Then, as-prepared $LaCoO_3$ was soaked in diluted $HNO_3$ solution for 1, 5, and 12 h, respectively, for the acid treatments. In the reductive thermal treatment procedure, $LaCoO_3$ was loaded in a continuous-flow fixed-bed reactor and heated under 4% $H_2/N_2$ flow at 200 and 400 °C, respectively. Non-stoichiometric $LaCoO_3$ perovskites with Co/La ratios of 0.9 and 0.95 were also prepared through the citrate sol-gel method.

**Results and discussion.**

According to previous studies, the properties of surface oxygen species (surface lattice oxygen ($O_{lat}$) and adsorbed oxygen species ($O_{ads}$) on oxygen vacancies) significantly influence the catalytic behavior in CO oxidation [2]. Therefore, the effect of post-treatments and non-stoichiometry on the chemical species of $LaCoO_3$ was examined through X-ray photoelectron spectroscopy. Based on the experimental results, we investigated the correlation between the surface chemical state ($O_{ads}/O_{lat}$ and $Co^{2+}/Co^{3+}$) and the reaction temperature at which the CO conversion reaches 50% ($T_{50}$) to elucidate their relationship. As shown in Fig. 1, the catalytic activity of the prepared catalysts in CO oxidation enhanced as the $O_{ads}/O_{lat}$ and $Co^{2+}/Co^{3+}$ increased. Consequently, we confirmed that surface oxygen vacancies formed in post-treated and non-stoichiometric $LaCoO_3$ catalysts facilitate the conversion of CO to $CO_2$.

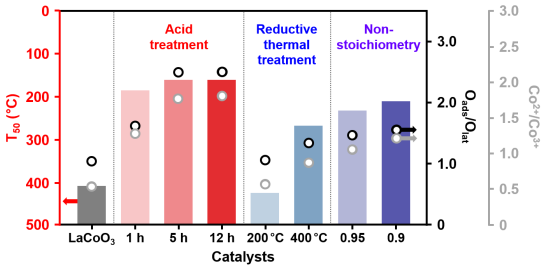

**Fig. 1.** Correlation between the surface chemical state ($O_{ads}/O_{lat}$ and $Co^{2+}/Co^{3+}$ ratio) and the catalytic activity ($T_{50}$).

**Keywords:** metal oxide cluster, base catalysis, $CO_2$ fixation

**Introduction.** Recently, the application of metal oxide clusters as base catalysts has been reported, while those materials have been known for acid catalysts, photocatalysts, and redox catalysts[1],[2]. We have reported the base catalysis of Lindqvist-type V-group metal oxide clusters $[M_6O_{19}]^{8-}$ (M = Nb, Ta) for Knoevenagel condensation reaction and $CO_2$ fixation reaction due to the highly negative natural bonding charge of the surface O atoms[3]. In this study, tetrabutylammonium (TBA) salts of $[Ta_xNb_{6-x}O_{19}]^{8-}$ (TBA-$Ta_xNb_{6-x}$, $x$ = 0−6), were prepared and applied as the catalysts for $CO_2$ fixation to styrene oxide (**SO**) for tuning the selectively toward styrene carbonate (**SC**).

**Experimental/methodology.** TBA-$Ta_xNb_{6-x}$ were synthesized by a microwave-assisted hydrothermal method in tetrabutylammonium hydroxide aqueous solution according to the literature[4],[5]. The fabricated clusters were characterized by ESI-MS, FT-IR, elemental analysis, and XAFS analysis, and the adsorption energy was calculated by DFT calculation. $CO_2$ fixation to **SO** were carried out in a batch-type reactors under atmospheric gas pressure. The reaction solutions were analyzed by GC-FID and GC-MS using an internal standard.

**Results and discussion.** The clusters were employed as the catalysts in $CO_2$ fixation to **SO** (Figure 1). **SO** conversion increased with higher Ta content, however, the selectivity toward **SC** depended on the composition of the clusters. The viscosity of the product solution gradually increased with higher Ta content, indicating the polymerization of **SO** as a side reaction. Interestingly, single-Ta-substituted TBA-$Ta_1Nb_5$ maintained the high **SC** selectivity even at a high **SO** conversion. XAFS and DFT studies revealed that the adsorption of **SO** and $CO_2$ preferentially occurred on the terminal O coordinated to Ta over that of Nb and the adsorption energy of $CO_2$ was lower than that of **SO**. Thus, the undesiable polymerization occurred over Ta-rich TBA-$Ta_xNb_{6-x}$, while the single Ta site promoted $CO_2$ activation and the following nucleophilic attack to **SO** to form **SC.** In this work, the highest selectivity of **SC** could be achieved using single-Ta-substituted TBA-$Ta_1Nb_5$ as the catalyst.

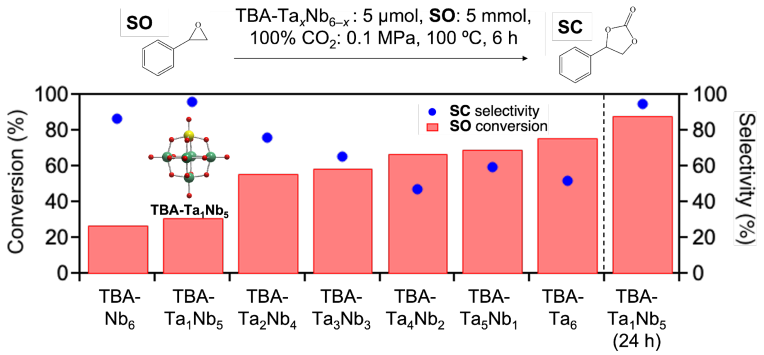

**Figure 1. $CO_2$ fixation to SO over TBA-$Ta_xNb_{6-x}$. Bars and dots represent SO conversion and SC selectivity, respectively.**

**Keywords:** Hydrogenation, Adaptive Catalysis, Hydroxylamines, Anilines, Nitroarenes

**Introduction.** Catalysts and catalytic systems are typically used to transform substrates selectively into a single product.[1] Alternatively, one could imagine dynamic catalytic systems that adapt to the reaction conditions—allowing precise control over bond activation processes and catalytic sequences—to yield distinct products.[2] In this context, reducing nitro compounds on the way to fully reduced aniline might lead to several potentially useful platforms, provided selectivity can be controlled.[3,4]

**Experimental/methodology.** Experimental mechanistic studies and DFT calculations revealed: 1) the importance of the designed ligand environment for providing the catalyst with adaptive properties; 2) the role of the solvent medium in controlling the selectivity of the catalyst; 3) the formation of a rhodium-hydride intermediate capable of 4) transferring the hydride to the boron-activated substrate site.

**Results and discussion.** An adaptive rhodium-based catalytic system for the controlled hydrogenation of nitro-containing substrates to anilines and hydroxylamines will be presented. The system employs a rhodium(III) center with a Lewis acidic boron arm in the secondary coordination sphere to control the catalytic network.[5]

**Keywords:** dye-sensitized, photocatalyst, visible light, photocatalytic oxidation

**Introduction.** Photocatalytic reaction is redox reaction caused by only photoirradiation, i. e., photocatalytic reaction proceeds at room temperature and under atmospheric pressure. Therefore, many researcher have been studied have been studied application of photocatalytic reaction to organic synthesis. Most of them, titanium(IV) oxide ($TiO_2$), which have high photocatalytic activity and chemical stability, was used as photocatalyst. However, $TiO_2$ is driven only by ultraviolet light, which is rarely contained in sunlight. For using sunlight effectively, visible-light driven photocatalyst is favorable. Dye-sensitized TiO2, in which a dye is adsorbed on the surface of $TiO_2$, is a visible light responsive photocatalyst [1]. Generally, expensive noble metals such as ruthenium (Ru) and iridium (Ir) are used as dyes for sensitizer. In addition, leaching of them causes a environmentally problem. In this study, dye-sensitized photocatalysts using fluorescein, non-toxic dye to the environment and human, have been prepared and successfully applied to the photocatalytic oxidation of 1-phenylethanol to acetophenone.

**Experimental/methodology.** Bare $TiO_2$ was suspended in ethanol solution containing fluorescein and stirred at room temperature for overnight. Fluorescein adsorbed $TiO_2$ (Fl-$TiO_2$, 50 mg) was suspended in acetonitrile solution (5 $cm^3$) containing 1-phenylethanol (ca. 50 μmol) in a test tube. After gas phase was replaced by dioxygen ($O_2$) and sealed with a rubber septum, the test tube was photoirradiated by Green LED ($\lambda_{max}$ = 550 nm). After photoirradiation, the catalyst was removed by filtration, liquid phase was analyzed by liquid chromatography.

**Results and discussion.** Fig. 1 shows time courses of the amount of 1-phenylethanol remained and acetophenone formed. The amount of 1-phenylethanol decreased with photoirradiation, while the amount of acetophenone increased. After 1.5-h photoirradiation, acetophenone was obtained in a high yield 94 %. After the reaction, photocatalyst was eliminated by centrifugation from reaction mixture. Recovered photocatalyst was reused at least three times without loss of activity.

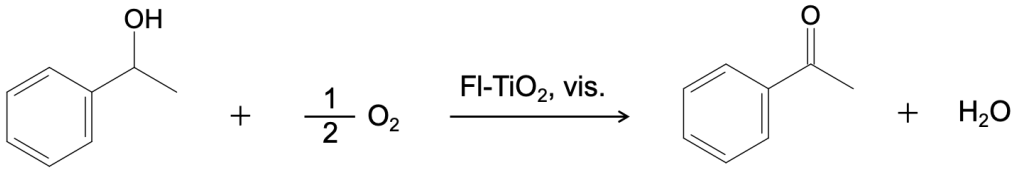

**Figure 1. Photocatalytic oxidation of 1-phenylethanol to acetophenone over fluoresceine-modified $TiO_2$ (Fl-$TiO_2$) under visible light.**

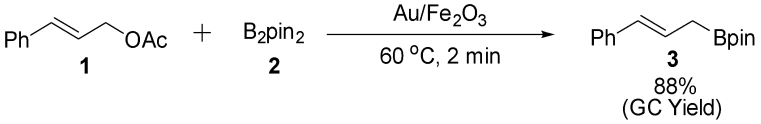
**Keywords:** Au Nanopariticle, Cooperative Catalysis, Borylation

**Introduction.**



Cooperative catalysis between metal nanoparticles and the support enables the efficient transformation of organic molecules. Therefore, elucidation of the relationship between catalytic activity and the cooperation of metal nanoparticles and supports is important for catalyst design. We reported that supported Au nanoparticle catalysts showed high activity for borylation of allylic C($sp^3$)–O bond to give allyl boronates.[1] In this study, we investigated the relationship between catalytic activity for borylation of C($sp^3$)–O bond over supported Au catalysts and their physical properties.

**Experimental/methodology.**

Supported Au catalysts were prepared through deposition-precipitation method by using tetrachloroauric acid as an Au precursor and urea as a pH adjust reagent. The specific surface area and acidity of the catalysts were determined from nitrogen adsorption/desorption isotherms and pyridine adsorption FT-IR spectra, respectively.

**Results and discussion.**

The allylic borylation of cinnamyl acetate (**1**) with $B_2pin_2$ (**2**) at 60 °C in the presence of $Au/Fe_2O_3$ catalyst completed within only 2 min to give the desired cinnamyl boronate (**3**) in high yield (Scheme 1). Kinetic study revealed that carbocations formed as intermediates, and that the activation of $B_2pin_2$ by Lewis acid on support was the rate-determining step. Moreover, a positive correlation was observed between the amount of Lewis acid per unit surface area (acid density) and TOF (Fig. 1). These results suggest that both Au nanoparticles and Lewis acid at the surroungings of Au nanoparticles cooperatively activated the substrates. Therefore, the use of catalysts with high Lewis acid density is essential for efficient cooperative activation of organic molecules.

**Scheme 1. Borylation of cinnamyl acetate by $Au/Fe_2O_3$**

# Decoration of $Au/SiO_2$ by Thin Metal Oxide Layer Derived from Layered Double Hydroxides

K. Okayama[1], A. Nakayama[1], T. Murayama[1], N. Sakaguchi[2], T. Shimada[1], S. Takagi[1], T. Ishida[1,*]

**Keywords:** Gold nanoparticles, Layered Double Hydroxide, CO oxidation, PROX

**Introduction.** Recently, decoration of metal nanoparticle (NP) surface by thin metal oxide (MOx) layers has been intensively studied to create new Au–MOx interface on metal NPs. However, the conventional methods have some problems such as limitation of the types of MOx, difficulty in controlling the thickness of the MOx layer, and the need for expensive apparatus. In this study, we focused on layered double hydroxides (LDHs) as a coating material for supported Au catalysts. LDHs ($[M(II)_{1-x}M(III)_x(OH)_2][(A^{n-})_{x/n}\cdot yH_2O]$) are consisted of a divalent metal hydroxide and M(III) is partly replaced. LDHs can be exfoliated into LDH monolayer nanosheets (NS) and is converted to a mixed metal oxide (MMO) by calcination. In this work, LDH NS is used as a precursor for the decoration of Au surface by thin MMO layer (Fig. 1). We found that the modification of Au NPs by LDH NS can create effective Au–MOx interface on Au NPs, and the catalytic activity of the obtained catalysts for CO oxidation was greatly improved.

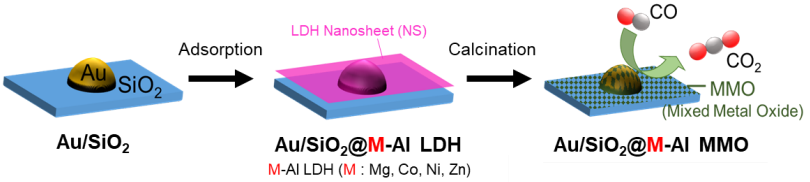

Fig. 1 Schematic image of mixed metal oxide-decorated $Au/SiO_2$ using LDH nanosheets.

**Experimental.** $Au/SiO_2$ (1 wt% of Au loading, 5.8 nm of Au NPs) was purchased from Haruta Gold Inc. Four kinds of LDHs (Mg-Al, Zn-Al, Co-Al, Ni-Al) were prepared by homogeneous precipitation method using urea according to the previously report.[1] The LDHs were exfoliated according to the literature to give LDH NS. The monolayer LDH NS was adsorbed on $Au/SiO_2$ ($Au@SiO_2@LDH$) followed by calcination in air to give $Au/SiO_2$@M-Al MMOs. For comparison, Co-Al oxides were deposited on $Au/SiO_2$ by impregnation to give Co-Al/$Au/SiO_2$-imp. Catalytic performance of the catalysts was evaluated by CO oxidation in a fixed bed flow reactor (1 vol% CO in air, SV=20,000 mL $g_{cat}^{-1}$ $h^{-1}$).

**Results and discussion.** Structures of LDHs and exfoliation of LDHs were confirmed by XRD. TEM-EDX analysis of $Au/SiO_2$@M-Al LDHs revealed that the metals derived from LDHs were highly dispersed on the entire catalyst surface. TEM images also confirmed the formation of the overlayer with the thickness of ca. 1 nm on $Au/SiO_2$. The CO oxidation was carried out using $Au/SiO_2$@Co-Al LDH. The CO conversion increased rapidly at about 250 °C in the first run, which coinsides the conversion of LDH to MMO (Fig. 2). While cooling the catalyst from 330 °C, the full conversion was maintained even at 50 °C. Given that the CO conversion of $Au/SiO_2$ was only 24 % at 303 °C, the activity was significantly improved by modification of $Au/SiO_2$ with Co-Al MMO. The catalytic activity order of $Au/SiO_2$@M-Al MMO was M=Co> Ni>Zn>Mg. $Au/SiO_2$@Co-Al MMO showed higher activity than Co-Al/$Au/SiO_2$-Imp. The results suggest that covering Au surface by thin MMO layer was more efficient to create new Au-CoOx interface than the deposition of Co-Al oxides by impregnation.

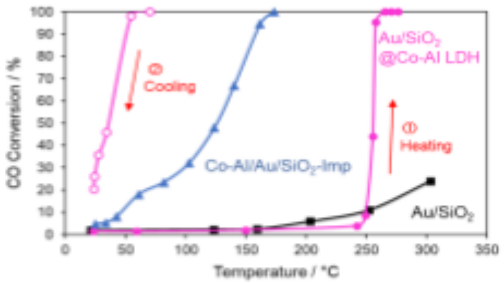

Fig. 2 CO oxidation of $Au/SiO_2$@Co-Al LDH.

**Keywords:** sulfated zirconia catalyst, local structure, acid catalysis

**Introduction.** Sulfated zirconia (ZrS) is widely known to exhibit an excellent catalytic activity for various acid reactions. Fundamental understanding of its outstanding acidity can offer a way for rational catalyst design. However, its catalytically active structure has yet to be identified to date, due to the inhomogeneity of the catalyst state. In this study, we focused on the crystalline $Zr_3SO_9$ catalyst reported 30 years ago by Kato *et al.*[1]

**Experimental/methodology.** Crystalline $Zr_3SO_9$ was synthesized by hydrothermal method according to the procedure reported by Kato *et al*.[1] Briefly, the precursor solution prepared by dissolving $ZrOCl_2 \cdot 8H_2O$ (Zr: 7.5 mmol) in $H_2SO_4$ (15 mmol) containing 14 mL distilled water was hydrothermally treated at 240 °C for 72 h to obtain $Zr_3SO_9$.

**Results and discussion.** The Crystal structure of $Zr_3SO_9$ was solved by combining the results of elemental analyses, microscopic analyses, and *ab-initio* structural analysis using the powder XRD pattern. $Zr_3SO_9$ consisted of the sheet having the same structural arrangement of (101) plane of the tetragonal $ZrO_2$, and $SO_4^{2-}$ was uniformly isolated on the Zr trimer (Fig. 1). This material exhibited outstanding catalytic activity for various acid reactions, and the activity was far better than those of typical acid catalysts including ZrS. In the isomerization of *n*-butane in which super acidity is needed for catalysis, the catalytic activity of $Zr_3SO_9$ was 2.5/7.5 times higher than those of ZrS in the catalyst amount/S amount basis.

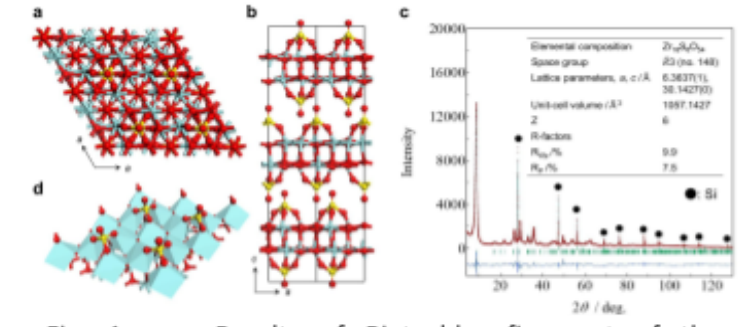

Fig. 2. Local structure of the crystalline $Zr_3SO_9$ in generating acidity.

Spectroscopic analyses and DFT calculations revealed that the Zr site adjacent to $SO_4^{2-}$ acts as the Lewis acid site, and $H_2O$ coordinated on this Zr site acts as the Brønsted acid site (Fig. 2).

**Keywords:** 3D printing, Gyroid, Methanation, $CO_2$ conversion

**Introduction:** The utilization of 3D printing in catalyst production for $CO_2$ methanation has emerged as a response due to the challenges posed by the highly exothermic reaction and high gas space velocity. These conditions necessitate enhancedmore efficient heat and mass transfer,, while maintaining optimal catalytic performance. In this study, we developed a 3D-printed a Ni/$Al_2O_3$ catalyst and evaluated its effectiveness for $CO_2$ methanation at various temperatures.

**Experimental/methodology:** To synthesize Printable $Al_2O_3$ resin, a carefully optimized blend of the latter commercial photopolymer resin and $Al_2O_3$ was prepared. The resulting resin was then employed to 3D print cylindrical gyroid sheet lattices, characterized by aa high surface area to volume ratio. Elegoo's Mars 3 Pro printer (3DPPAL) was utilized for this purpose. Subsequently, the printed samples were subjected to controlled heating in a furnace to facilitate debinding and the removal of photopolymer. They were then sintered at 650°C (3DPAL). In order to achieve the desired loading, the 3DPAL sample was impregnated with Nickel (Ni) using the wet impregnation technique [1]. For comparison purposes, Ni/$Al_2O_3$ powder with identical loading was also prepared, for comparison and the powder was also coated onto 3D-printed aluminium (Ni/$Al_2O_3$-3DAL) for comparison. Both the powder and printed catalysts underwent BET analysis, SEM-EDX, $H_2$-TPR, $CO_2$-TPD, and $CO_2$ methanation tests.

**Results and discussion:** The higher sintering temperature was seen observed to cause a further reduction in the surface area of Ni-3DPAL. To optimize further the process, it is recommended to increase the sintering temperature can be increased to remove the to eliminate any residual polymer, and raise the Ni loading in both the powder and printed samples can be increased. Comparatively, Ni/$Al_2O_3$-3DAL exhibited higher $CH_4$ selectivity, $CH_4$ yield, and $CO_2$ conversion than /$Al_2O_3$-3DAL Ni/$Al_2O_3$ powder and Ni-3DAPL. This was attributed to the apparent occurrence of reverse water gas shift in the latter. A reduction in surface area was observed in 3DPAL as compared to $Al_2O_3$ powder Notably, the CO yield was also the lowest for Ni/$Al_2O_3$-3DAL. The higher sintering temperature was seen to further reduce the surface area It is proposed that the improved activity is attributed to Enhanced heat dissipation due toresulting from the metal support utilized.is proposed to be responsible for the improvement in activity. After Ni loading, the surface area decreased further, as seen from the liquid nitrogen adsorption isotherms.

a) Resin synthesis and 3D printing, b) Washing and drying, c) Debinding and sintering, d) Ni-impregnation

# Understanding Titania Crystallization to Generate Engineered Anatase Particle Architecture

A. Jain[1], M. Kumar[1*]

[1]*Indian Institute of Technology Delhi, New Delhi, India*
[*]*manjeshkumar@chemical.iitd.ac.in*

**Keywords:** Catalysis, Crystal growth, Nonclassical mechanism, Growth modifiers

**Introduction.** Modulating the crystal shape and size with desirable exposed/terminating reactive facets is significant for fundamental studies and various technological applications [1]. Anatase phase of $TiO_2$ has been widely studied due to its extensive industrial applications [2], [3]. Here we present a novel, economically feasible and simplistic wet chemistry approach to synthesize titania crystals with high index facets with particle size control over 3 orders of magnitude (5 nm-3000 nm).

**Experimental/methodology.** The synthesis of titania particles was carried out using a hydrothermal method. Titanium Isopropoxide (TTIP) was mixed with alkyl ammonium hydroxide and DI water in stoichiometric ratio. Subsequently, the pH of the growth solution was adjusted in the range of 3-11 using various protic acids. The pH adjusted growth solution and pH adjusted solutions with modifiers (organic and inorganic) were subjected to hydrothermal treatment at 200 ˚C for 12h in dynamic conditions.

**Results and discussion.** In this study, we conducted the comprehensive investigations generating the crystals from a few nanometers to few microns with varied surface architecture and varied dimensionality (0-3 Dimensions) via modulation of physicochemical growth conditions. Unique structures generated here such as coral -shaped structure (Figure 1B and P4) provide high surface area while faceted crystals (Figure 1D and P2) formed serve as host for active metal sites. Further, we have also explored the crystallization pathways of anatase crystals, which shows that growth solutions with similar initial precursor phase traverse 4 different paths to generate these structures (shown in Figure 1). We observed different precursor phases such as nanosheets (Figure 1 P1), partially ordered domain (Figure 1 P2), rod-shaped microcrystalline (Figure1A), needle-shaped crystallite (Figure 1 P4), among others that generate an array of bulk crystals. These uncontrolled pathways were intervened using modifiers (organic molecules and inorganic salts) to generate more desired faceted crystals. Complete blueprint will be presented for rational design of titania crystals.

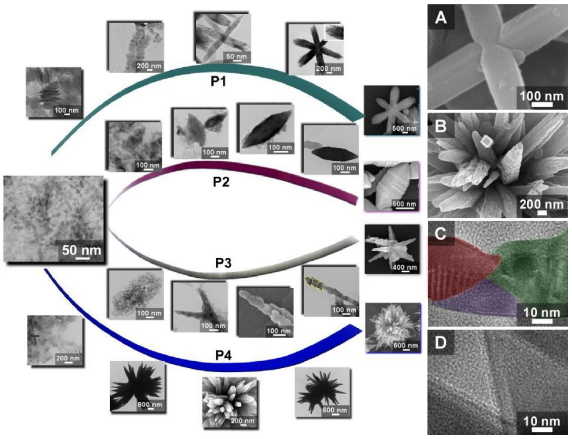

**Figure 1|** Palette of Anatase Crystallization. P1. The first curved path (green) represents formation of flower-shaped titania particle at high pH. All the paths show time-elapsed data from 0 min to 12h of hydrothermal treatment. P2. Represents the formation of a faceted particle at high pH using salt as modifier. P3. Shows the formation of highly branched star-like agglomerate at high pH using a different salt as modifier. P4. Shows the formation of coral-shaped titania particle at low pH. A. Cojoined rods at medium pH. B. Needle-like particle obtained at low pH. C. Oriented attachment of particle using modifier. D. faceted particle obtained using modifier

**Keywords:** recyclable, catalyst, deuterium-labelling, circular, immobilization, isotope exchange.

**Introduction.** Deuterium-labelled organic compounds are used in many applications.[1-4] The preparation of such compounds relies on catalysts such as bio-, organometallic or organo- catalysts. These catalysts are typically made using lengthy and expensive procedures. Some contain precious metals (e.g., Ir, Pd).[5] Furthermore, they are frequently used in a linear 'make-use-dispose' approach. The use of recyclable forms of these catalysts represents an advance towards circular chemistry,[6] and various strategies have been explored for the development of recyclable catalysts for the synthesis of deuterium-labelled organic compounds.[7-9]

**Experimental/methodology.** One approach to creating a recyclable catalyst involves immobilization of the parent catalyst on a polymer-based support. In this presentation, I will report on the design and synthesis of recyclable catalysts featuring a stimuli-responsive polypropylene imine (PPI) dendrimer matrix functionalized with reactive iridium-N-heterocyclic carbene centers (Kerr's catalyst, **1**), scheme, part (a). I will also present a comparison between the activity of the immobilized catalyst (**2**) *versus* the parent catalyst (**1**). Finally, I will discuss approaches taken for the recovery and reuse of the dendrimer catalysts.

**Results and discussion.** I will present evidence for the formation of the dendrimer-based catalysts and the effectiveness of their recovery and reuse. I will also highlight preliminary results obtained when comparing the activity of the dendrimer catalysts *versus* the parent catalyst in the deuterium-labelling of acetophenone, a simple model organic substrate, part (b), below.

**1**, Kerr's catalyst

**2**, Kerr's catalyst, immobilized on PPI either via the $PPh_3$ or the NHC group

**Keywords:** Platinum, Perovskite, Emergent nanoparticles, Catalytic applications

**Introduction.**
Platinum catalysts demonstrate exceptional ability in many important fields, e.g. in removing atmospheric pollutants. Typically, these are dispersed on a porous support, such as γ-$Al_2O_3$, with low loading of 0.5−2.0 wt% and have been extensively used in ECT (Emission control technology) applications [1,2]. However, it is expensive and not always sufficiently durable, due to Pt agglomeration and even sublimation at high temperature operation [3,4]. Here, we present a perovskite system in which 0.5 wt% of Pt is integrated into the support, and its subsequent conversion through exsolution to achieve a resilient catalyst.

**Experimental/methodology.**
Due to the instability of most Pt oxides at high temperature, a thermally stable platinum oxide precursor, Barium Platinate, is utilised to preserve the platinum as an oxide through the solid-state synthesis in an approach inspired by the Trojan horse legend [5].

**Results and discussion.**
A uniform equilibrated structure with active emergent Pt nanoparticles strongly embedded at the perovskite surface (Figure 1) was produced. The nanoparticles were also controllable in size and distribution by optimizing the procedure, yielding modified performance in CO oxidation activity with greatly improved stability [5]. This catalysts were further evaluated under a variety of reactions under realistic test environments, for example, Diesel Oxidation Catalysis.

# $SiO_2$@Ni@$ZrO_2$ core-shell catalyst for combined steam and dry reforming of methane

Seorin Ji[1], Eun Jun Lee[1], Hyoseong Woo[1], Kwan-Young Lee[1*]

[1]*Department of Chemical and Biological Engineering, Korea University, 145 Anam-ro, Sungbuk-ku Seoul 02841, Republic of Korea*

[*]*Corresponding author (kylee@korea.ac.kr)*

**Keywords: core-shell, combined steam and dry reforming of methane**

**Introduction.** Hydrogen Energy is an alternative energy sources which is capable of large-scale, long-term storage and can be produced by various types of energe resources. Reforming of methane is a process that can produce hydrogen from methane, and this process is most widely used in industry. Recently, combined steam and dry reforming of methane (CSDRM) attracts much attention among various methane reforming. CSDRM is a combination of steam reforming of methane (SRM) and dry reforming of methane (DRM), and it produces hydrogen and carbon monoxide by using methane, carbon dioxide, and water. It has advantages that it consumes two main green house gases ($CO_2$, $CH_4$), and it exhibits higher coke resistance than DRM. Additionally, CSDRM produces syngas with $H_2$/CO ratio of 2, which has advantages in sequential processes such as Fisher-Tropsch synthesis.

In CSDRM, Ni based catalyst is most widely used for its high activity and reasonable price. However, it has serious problem in metal sintering and coke deposition compared to noble metal based catalyst. Catalyst with core-shell structure can prevent catalyst deactivation by physically suppressing metal sintering and inhibiting coke deposition [1,2]. So, we suggest core-shell $SiO_2$@Ni@$ZrO_2$ catalyst for the long-term stability of CSDRM.

**Experimental/methodology.** Ni nanoparticle was synthesized by ammonia-Borane Hydrolysis. $SiO_2$ was synthesized by modified stöber method. Ni nanoparticle and $SiO_2$ were mixed in room temperature with hexane overnight to form Ni@$SiO_2$ sphere. $ZrO_2$ shell was formed above the sphere using zirconium butoxide solution.

Ni/$SiO_2$ was synthesized by incipient wetness impregnation method as a reference catalyst.

CSDRM reaction was conducted using a tubular quartz fixed bed reactor at 800 °C, atmospheric pressure to examine catalyst activity. Catalysts were reduced at 500 °C for 3 hours in 10% $H_2$/$N_2$ gas mixture with flow rate of 100 mL/min before reaction. Feed gas mixture consisted of $CH_4$, $CO_2$, $H_2O$, $N_2$ in a molar ratio of 10:4:8:78 with flow rate of 100 mL/min.

**Results and discussion.** In XRD, it is confirmed that highly dispersed Ni was formed through the crystal structure of Ni/$SiO_2$ and $SiO_2$@Ni@$ZrO_2$. Also, $SiO_2$@Ni@$ZrO_2$ formed a core-shell structure through TEM and EDS mapping. $ZrO_2$ shell structure was estimated to prevent sintering of Ni nanoparticles.

As a result of comparing the CSDRM activity at 800 °C, the $SiO_2$@Ni@$ZrO_2$ catalyst showed higher activity and stability than Ni/$SiO_2$. The $SiO_2$@Ni@$ZrO_2$ catalyst maintained constant $CH_4$ and $CO_2$ conversion for more than 30 hours, meanwhile, $CH_4$ conversion and $CO_2$ conversion of Ni/$SiO_2$ have significantly decreased for 30 hours. In addition, various catalyst characterization analysis was performed to identify the cause of higher activity and stability of $SiO_2$@Ni@$ZrO_2$ than that of Ni/$SiO_2$. As a result, we suggest that core-shell structure of $SiO_2$@Ni@$ZrO_2$ improved its stability in long-term reaction.

**jiwj@nju.edu.cn*

**Introduction.** Considerable efforts have been devoted to the kind of renewable energy.[1] Hydrogen is regarded as a green energy carrier and a key to achieve low-carbon energy economy. [2] Formic acid (FA) has been recognized as one of the promising hydrogen carriers due to its high energy density (1.22 g/cm$^3$). The water gas shift (WGS) is another critical process to increase hydrogen production. It is well known that the size of metal entities can considerably determine catalyst activity. In application of noble metal catalysts, how to improve utilization efficiency of noble metals meanwhile to enhance catalyst efficiency is always a hot topic in the field of catalysis [3,4].

**Experimental/methodology.** Our catalysts were designed and fabricated according to the following tatics: first, the ion liquid-assisted synthesis of alumina is conducted to obtain regularly shaped hexagonal $Al_2O_3$ plates, so that the majority of desirable (110) facet is exposed; secondly, the Pt nano-clusters ranging from ca. 0.58 nm to 0.74 nm and 1.20 nm are preciously deposited onto the (110) facet of alumina support through the atomic-layer-deposition approach. The Pt clusters were also deposited on the polycrystalline $Al_2O_3$ for comparison. DFT simulations, characterizations, and activity evaluations were conducted to explicate the role and significance of the unique metal-oxide interfacial structure for the target reactions.

**Results and discussion.** We have precisely deposited the size-tunable Pt clusters onto the $Al_2O_3$ (110) facet and $Al_2O_3$ rods through atomic-layer-deposition strategy as well as deposition-precipitation method. The resulting materials were applied for WGS and FA decomposition. Compared to the Pt nanoparticles on the $Al_2O_3$ (110) facet or Pt fine clusters on the polycrystalline rod-like $Al_2O_3$, those ultrafine Pt clusters on the $Al_2O_3$ (110) facet with very low Pt loading (0.07wt%) exhibit exceptional low-temperature CO conversion for WGS, with a $TOF_{CO}$ of 2.1 $s^{-1}$ at 210℃ and a CO conversion rate of 10.2 mmol $g_{Pt}^{-1}$ $s^{-1}$, 4.7, 7.7, and 9.7 times higher than that on 0.34%Pt/$Al_2O_3$-AD, 0.56%Pt/$Al_2O_3$-AD and 0.46%Pt/$Al_2O_3$-DP. The current 0.07%Pt/$Al_2O_3$-AD catalyst also outperforms the Pt/Ir-based single atom catalysts. For FA decomposition, 0.07%Pt/$Al_2O_3$-AD affords the highest TOF of 1.02 $s^{-1}$ at 200℃ with almost full FA conversion, and the $H_2$ formation rate is 4.5 times higher than that obtained on 0.46%Pt/$Al_2O_3$-DP. The unique synergism involved between the ultrafine Pt entity and the specific (110) facet of $Al_2O_3$ brings about significant modification in electron state and local geometry of Pt atoms in the ultrafine Pt clusters which are further supported by the DFT simulations, accounting for the superior performances in both FA decomposition and WGS.

# Novel Oxyhydride Electride Activating Co Catalyst for Ammonia Synthesis

Yihao Jiang[1], Masayoshi Miyazaki[1], Hideo Hosono[1], Masaaki Kitano[1,*]

[1] *International Research Frontiers Initiative MDX Research Center for Element Strategy, Tokyo Institute of Technology, 4259 Nagatsuta, Midori-ku, Yokohama 226-8503, Japan*

**Keywords:** Oxyhydride, Electride, Ammonia synthesis, Catalysts

**Introduction.**

Ammonia is one of the most important chemicals due to its broad application in industrial production. Co is studied as a practical catalyst for ammonia synthesis to replace noble metal Ru. However, the weak Co−N interaction makes Co inactive for ammonia synthesis using conventional supports especially under mild reaction conditions.[1] Previous research demonstrates that hydride materials like LiH and $BaH_2$ are very effective supports for Co-based catalysts.[2,3] However, the reported hydride-based catalysts are very sensitive toward air and readily deactivated due to the irreversible decomposition by the reaction with ambient atmosphere. Therefore, the major challenge of catalyst design for green ammonia synthesis is to be Ru-free with high catalytic performance and chemically-robust. Here, we report a novel oxyhydride electride material $BaAl_2O_{4-x}H_y$ as an efficient and chemically-durable support for Co catalyst in ammonia synthesis.

**Experimental/methodology.**

$BaAl_2O_{4-x}H_y$ was synthesized by solid-state reaction of γ-$Al_2O_3$, $BaH_2$ and $BaCO_3$ mixed in an agate mortar under $H_2$ gas flow. $BaAl_2O_{4-x}H_y$ and $Co_2(CO)_8$ were physically mixed and heated at 500°C under $N_2/H_2$ mixed gas flow to load Co. The ammonia synthesis reaction was evaluated using a fixed-bed flow reactor.

**Results and discussion.**

$BaAl_2O_{4-x}H_y$ has a stuffed tridymite structure that provides interstitial cage sites (Figure 1) to accommodate anionic electrons and $H^-$ ions. The existence of anionic electrons is confirmed by iodometric titration and magnetic susceptibility measurements, and $H^-$ ions are confirmed by TPD and DRFTIR measurements. DFT calculations reveal that the interstitial cage sites play a pivotal role to stabilize anionic electrons or $H^-$ ions. Co-loaded $BaAl_2O_{4-x}H_y$ achieved significant activity (500 mmol $g_{Co}^{-1}$ $h^{-1}$) under mild conditions (340°C, 0.90 MPa) with a very low apparent activation energy (49.6 kJ $mol^{-1}$), which is in complete contrast to the catalytic performance of $Co/BaAl_2O_4$ (0.7 mmol $g_{Co}^{-1}$ $h^{-1}$, 100 kJ $mol^{-1}$). Isotope $N_2$ exchange reaction experiments reveal that the energy barrier of $N_2$ cleavage is largely lowered due to the strong electron donation. Furthermore, the lattice $H^-$ ions further boost ammonia synthesis by accelerating the N−H bond formation. These properties make this catalyst even comparable to the latest Ru catalysts at 300°C. Most importantly, even after air exposure, the activity of $Co/BaAl_2O_{4-x}H_y$ could be recovered by simple annealing in $H_2/N_2$ flow. This is because the three-dimensional $AlO_4$-based network in the stuffed tridymite structure has strong chemical stability and protects anionic electrons and $H^-$ ions from the oxidation. Such robustness and reusability are distinct advantages over the reported hydride-based Co catalysts for ammonia synthesis.

**Keywords:** plasma sputtering, metal oxides, oxidation of ethanol

**Introduction.** The alternative deposition method based on sputtering of metal nozzle (hollow cathode) with a flowing gas has attracted much attention. Inside the nozzle, a very intense discharge is ignited and the working gas (usually argon) flowing into a vacuum chamber forms the so-called plasma jet [1]. We decided to study a Co-Cu-Mn oxide system from the point of view of various conditions of plasma jet sputtering on stainless steel meshes and reveal their influence on the properties and activity in the total oxidation of ethanol as a model compound of VOCs.

**Experimental/methodology.** The Co, Cu, and Mn were deposited on stainless steel meshes (circular meshes with an outer diameter of 25 mm) by sputtering a) from three hollow cathodes in argon, b) from three hollow cathodes in argon and oxygen, and c) using hollow cathode prepared from calcined Co-Cu-Mn hydroxycarbonate pellets. After deposition, all samples were calcined for 4 h at 500 °C in air. The properties and catalytic activity were compared with those of Co, Ni-Co, and Ni-Cu oxide catalysts prepared on meshes using hollow cathode (or radio frequency magnetron) sputtering. The catalytic performance (on a per gram oxides basis) was compared with that of a pelletized commercial Co-Mn-Al catalyst (Astin 2-100).

**Results and discussion.** The experimental data of ethanol oxidation showed that the Co catalyst prepared by RF magnetron sputtering with argon as the working gas on stainless steel meshes was the least active of all catalysts. The use of a hollow Co cathode and the presence of oxygen in the working gas increased the performance significantly (almost 5 times). The activity of the binary catalytic components, Ni-Co [4] and Ni-Cu [5] oxides with a molar ratio of Ni:X (X=Co or Cu) of 1:1 obtained with hollow cathodes made of corresponding NiCo and NiCu alloys in Ar and oxygen environment did not cause an increase in the oxidation activity of the catalysts. The Co-Cu-Mn catalyst sputtered from three hollow cathodes using Ar as working gas showed comparable activity to the Co catalyst prepared in $Ar+O_2$ environment. The presence of oxygen in the working gas during simultaneous plasma jet sputtering of Co, Cu, and Mn was again reflected in the increased activity of the catalyst. Due to the different deposition rates of Co, Cu and Mn, we investigated the possibility of using as a hollow cathode a calcined Co-Cu-Mn hydroxycarbonate of defined composition with a molar ratio of Co:Cu:Mn of 3:1:1. Even in an $Ar+O_2$ environment, the activity of the catalyst obtained in this way was the lowest among the Co-Cu-Mn oxide catalysts studied (which could probably be due to the higher Cu content at the expense of Co). A significant advantage of thin-film catalysts supported on stainless steel meshes is (i) the very low amount of the expensive active phase required for catalyst preparation and (ii) low pressure drop across the catalyst bed. Due to the effect of internal diffusion during the catalytic reaction, the sputtered catalysts were up to 26 times more active than commercial pelletized Co-Mn-Al catalyst, although the amount of metal oxides in catalyst bed was 563 times lower.

# Mesoporous Pt–$MnO_x$–$Al_2O_3$ catalyst for dehydrogenation of perhydro benzyltoluene: Highly dispersed Pt–$MnO_x$ clusters for activity boosting

Yeongin Jo, Young-Woong Suh*
*Department of Chemical Engineering, Hanyang University, Seoul 04763 (Republic of Korea)*

**Keywords:** LOHC, dehydrogenation, catalyst, surface mobility

**Introduction.** To overcome thermodynamic hurdles in the dehydrogenation reaction, which is considered as the bottleneck of LOHC technology, we recently proposed a mesoporous Pt–$Al_2O_3$ catalyst synthesized by SDP (solvent-deficient precipitation) method [1]. Remarkably, this catalyst showed a much higher ratio of Pt single atoms and clusters compared to conventional catalysts. Herein, this consequence has been investigated in the respect of support properties and then is extended to the preparation of a new mesoporous Pt–$MnO_x$–$Al_2O_3$ catalyst (mPtMnA) to surpass the mesoporous 1 wt.% Pt–$Al_2O_3$ catalyst composed of Pt single atoms exhibiting rather low activity in the dehydrogenation of perhydro benzyltoluene ($H_{12}$-BT). To maximize the interaction between Pt and $MnO_x$, we optimized the construction process from Pt atoms to Pt–$MnO_x$ clusters by tuning the mobility of Pt single atoms on the surface of $Al_2O_3$.

**Experimental/methodology.** The applied SDP method is a one-pot synthesis to use the active metal source of $(NH_3)_4Pt(NO_3)_2$ and add $Mn(NO_3)_2{\cdot}6H_2O$ as Mn source. After grinding, the gel-phase precursor was subjected to the following heat treatment: calcination at 600 °C for 5 h with a ramping rate of 2 °C $min^{-1}$ and $H_2$ reduction at 500 °C for 3 h with different ramping rates. The prepared catalysts are denoted as mPt*x*MnA. The content of Pt is fixed at 1 wt.%, and *x* is the molar ratio of Mn to Pt.

**Results and discussion.** Compared with other synthesis methods, the synthesized mPtMnA exhibited the higher activities, possibly because of strong interaction between Pt and $MnO_x$. In particular, the dehydrogenation performance was greatly improved at the Mn/Pt mole ratio of 0.33 (Fig. 1a). To strengthen Pt–$MnO_x$ interaction, the ramping rate in $H_2$ reduction was controlled, thereby, highly dispersed Pt–$MnO_x$ composite cluster could be created, affording superior dehydrogenation performance (Fig. 1b). The SDP-derived pure $Al_2O_3$ was reported to have defect sites similar to those of boehmite [2], which can explain the high dispersion of Pt in the mPtA. Thus, it active Pt atoms are believed to have surface mobility due to unstable $Al_2O_3$ sites. The uniqueness of mPtA likely originates from the defective structure of $Al_2O_3$, which is also effective in the mPtMnA catalyst. From the HAADF-STEM images and CO-DRIFTS results, we can conclude that highly dispersed Pt–$MnO_x$ clusters with a size of 1.3 nm are formed from Pt single atoms anchored in the unstable sites at high ramping rates.

**Keywords:** renewable fuels, hydrodenitrogenation, $MoS_2$, incipient wetness impregnation

**Introduction.** Catalytic hydrodenitrogenation (HDN) is widely used for removing nitrogen-containing impurities from petroleum [1, 2]. The most commonly used HDN catalysts are $MoS_2$ supported on alumina and promoted by Ni [1, 2]. Alternative renewable feedstocks contain significantly higher amounts of nitrogen [3], which means replacing fossil feedstocks requires the development of new, highly active catalysts for the HDN process [2]. In this work, we present an initial study on the preparation of alumina-supported $MoS_2$-catalysts incorporating Ni, Na, Cr, Pt or Ru as promoters. The goal was to investigate and compare the effect these promoters have on the structure of the $MoS_2$ phase.

**Experimental/methodology.** Oxidic catalyst precursors were prepared using incipient wetness co-impregnation followed by calcination at 500 °C for 120 min under a 100 ml/min flow of air. Prior to impregnation, the γ-$Al_2O_3$ support had been calcined at 500 °C for 300 min . Ammonium heptamolybdate hexahydrate (AHM), nickel(II) nitrate tetrahydrate, sodium nitrate, chromium(III) nitrate, platinum(IV) nitrate and ruthenium nitrosyl nitrate were used as precursors. Citric acid was used as an additive, since previous work had shown it prevented the formation of crystalline $MoO_3$, thus improving the dispersions and metal loadings of the obtained catalyst precursors. The oxidic catalyst precursors were transformed into sulfide catalysts by sulfidation for 120 min at 400 °C in 10 vol% $H_2S/H_2$ in a batch reactor. In addition to the promoted catalysts, an unpromoted reference catalyst was also prepared with the same method.

Both oxidic catalyst precursors and sulfided catalysts were characterized. Powder X-ray diffraction (XRD), X-ray fluorescence (XRF), inductively coupled optical emission spectroscopy (ICP-OES), $N_2$ physisorption and Raman spectroscopy were used in order understand the physicochemical properties of the calcined catalyst precursors. Sulfided catalysts were analyzed using XRD, ICP-OES, X-ray photoelectron spectroscopy (XPS) and transmission electron microscopy (TEM) combined with energy-dispersive X-ray spectroscopy (EDS).

**Results and discussion.** Co-impregnation followed by calcination was found to give oxidic catalyst precursors in which the Mo and Ni, Na, Cr and Pt species were well dispersed on the support. However, crystalline $RuO_2$ was formed on the $RuMo/Al_2O_3$ oxidic precursor, implying that Ru dispersion was poor.

Sulfidation of the catalyst precursors was found to give the expected $MoS_2$ phase, but the nature of the promoter species after sulfidation varied. XPS showed evidence for the formation of the mixed NiMoS phase, which is generally accepted to be highly active for HDN. In contrast, it was deemed likely that Na remained oxidic after sulfidation. The other promoter metals Cr, Ru and Pt were reduced during sulfidation, which was deemed undesireable, since reduced metals are likely poisoned by $H_2S$ and therefore unlikely to significantly improve the HDN activity.

Even though no evidence was found for the formation of a mixed promoter-$MoS_2$ phase with any of the tested promoters except Ni, analysis of TEM images showed that the height of the $MoS_2$ stacks was lower for all the promoted catalysts, compared to the unpromoted reference catalyst. Thus, it was concluded that the promoters had an effect on the morphology of the $MoS_2$ phase and that less reducing sulfidation conditions should be tested in future work, in order to convert Cr, Pt and Ru into sulfidic phases.

# Selective Hydrogenation of Acetylene in Excess of Ethylene over Pd nanoclusters in 3D graphene-like carbon catalysts

D. Kaucký[1,*], J. Morávková[1], R. Pilař[1], G. Sádovská[1], S.S. Faal-Rastegar[1], A. Vondrová[1], P. Sazama[1]

**Keywords:** Acetylene, Ethylene, Selective Hydrogenation, Palladium, Charcoal, nano-structured Carbon.

**Introduction.** Selective hydrogenation of acetylene in an excess of ethylene over Pd catalysts is important for the purification of ethylene for polymerization processes. This study analyses the effects of the Pd clusters morphology and the Pd clusters-supports electronic interaction on the selectivity to the individual products (Figure 1). We investigated the possibilities of using Pd clusters deposited on a 3D graphene-like organized structure of zeolite-templated carbon to modify the electronic properties of the Pd clusters and exploit the well-accessible surface of the 3D graphene-like material for the preparation of hydrogenation catalysts.

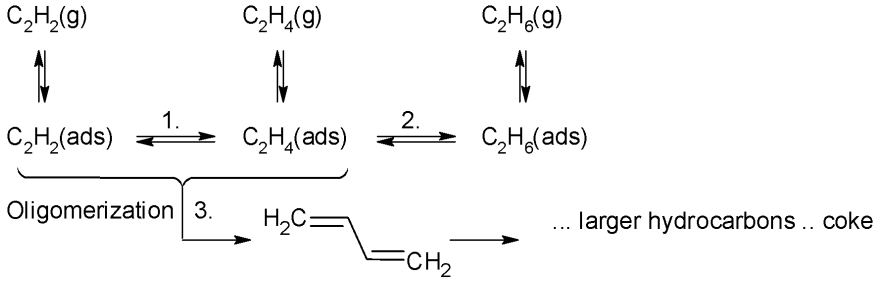

*Figure 1. The reaction scheme: acetylene hydrogenated to ethylene, and/or over-hydrogenated to ethane, while unsaturated reactants could condensate to higher products.*

**Experimental/methodology.** The well-defined and regular 3D channels system of the faujasite zeolite was replicated into the zeolite templated carbon material with well-defined dimensions and spatial connectivity of the micropores by nanocasting. In the process of zeolite nanocasting, carbon atoms were generated along the walls of the regular zeolite micropores. The faujasite zeolite of the molecular Si/Al ratios 6 in the $H^+$ form was used as a hard template. Carbonization of the zeolite was performed using chemical vapour deposition with propylene as a carbon precursor. The subsequent selective removal of the structural lattice of the zeolite provided an ordered 3D microporous graphene-like Y-carbon material [1]. Pd/Y-carbon, Pd-alumina and Pd-silica catalysts were prepared by an impregnation method.

**Results and discussion.** The catalytic studies demonstrate that the electronic interactions of the Pd clusters with the graphene layer and the well-accessible surface of the 3D organized structure of Pd/Y-carbon provide significantly higher activity compared to traditional Pd catalysts while maintaining high selectivity for the preferential hydrogenation of the triple bond in acetylene. The approach enabled an adaption of the electronic properties and the dispersity of active Pd clusters to increase the reaction rates and to tailor the catalyst selectivity.

**Keywords:** formic acid, dehydration, $TiO_2$/graphite catalysts

**Introduction.** Mechanochemical methods have emerged as simple and effective synthesis routes for producing catalytic materials [1]. This synthetic strategy, typically based on reactive extrusion or ball milling, provides materials with unusual properties based on a large variety of ingredients: metals, metal oxides (including mixed oxides) or hybrid composites (involving zeolites, MOFs, COFs, etc.). When regarding carbonaceous materials as support of metal nanoparticles some examples have been described [2], but no studies with graphite or carbon materials have been reported for their interaction with metal oxides.

In the present communication, we describe the possible formation of new acid sites at the surface of $TiO_2$ when it is mechanically treated with a high surface area graphite. Furthermore, these catalytic materials have been evaluated in the formic acid (FA) dehydration reaction [3].

**Experimental/methodology.** Three composite materials, $TiO_2$-graphite, with weight percent of 25/75, 50/50 and 75/25 were prepared by a procedure consisting of a mechanical mixture of both solids, previously ground in an agate mortar, using ultrasounds under ethanol as inert solvent (4 cycles of 20 min.). The starting materials are both commercially available: $TiO_2$ (Degussa, $S_{BET}$= 46 $m^2/g$) and high surface area graphite (HSAG from Timca, $S_{BET}$= 300 $m^2/g$). Before FA reaction studies the samples were treated at 300 °C under $N_2$ gas. Catalytic tests were performed in a continuous flow reactor with a reactant feed of $5.4x10^{-3}$ mol FA/min. All materials were characterised by Thermogravimetric Analysis, $CO_2$-TPD, $NH_3$-TPD, XRD and XPS.

**Results and discussion.** Catalytic measurements (Figure 1.A) show an improvement of specific catalytic activity to produce carbon monoxide for all mixture catalysts compared with the bare $TiO_2$. It should be notice that these samples do not suffer significant deactivation, even at higher reaction temperatures (250 °C). XRD does not display signals of anatase to rutile transformations in the $TiO_2$ structures. $NH_3$-TPD (Figure 1.B) reveals that in the mixture materials, prepared by mechanochemical interaction between $TiO_2$ and HSAG, an extra amount of acidic surface sites is generated. If it is assumed that dehydration of FA to CO and $H_2O$ occurs over acidic centers, these new acidic sites can explain the improved catalytic activities of the mixture materials. Finally, in the XPS analysis of the $Ti_{2p}$ peaks a significant shift of binding energies is observed when comparing pure $TiO_2$ and mixture $TiO_2$-graphite composites. This could be interpreted as a transfer of electrons at the interface of both components [4], but further measurements are required to confirm this hypothesis.

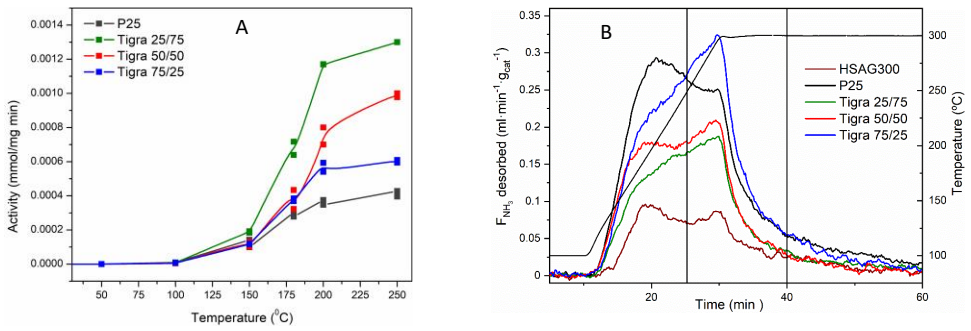

**Figure 1**. Comparative catalytic activities at different reaction temperatures for FA dehydration (A) and $NH_3$-TPDs (B).

**Keywords:** $NH_3$-SCR, NOx, Cu-zeolite, Supercritical fluids.

**Introduction.** Investigation of effects of synthesis method on catalyst performance is of high importance for the development of high performance diesel engine aftertreatment catalysts. Cu-zeolites, especially Cu-SSZ13 has been a center of attention as catalyst for Selective Catalytic Reduction of NOx. These catalysts are conventionally synthesized via aqueous ion exchange (AIE). Our group recently introduced the supercritical ion exchange (SCIE) route for Cu-zeolite synthesis and showed a certain degree of site speciation and auto-reduction differences among Cu sites formed by SCIE and AIE towards direct conversion of methane to methanol [1,2]. In this study, we extended the SCIE method to synthesize Cu-SSZ13 (CuS), Cu-ZSM5 (CuZ) and Cu-MOR (CuM) $NH_3$-SCR catalysts for the first time in literature and analyzed their performance.

**Experimental/methodology.** CuS (Si/Al:15), CuZ (Si/Al:23) and CuM (Si/Al:10) catalysts were synthesized via SCIE in supercritical $CO_2$ medium using copper(II)trifluoroacetylacetonate ($Cu(tfa)_2$). SCIE isotherms were measured at 40-80 °C and 28 MPa. CuM was also prepared via AIE using copper(II) acetate. Catalysts were characterized using XRD, FTIR, UV-Vis and XPS. Active species (ZCuOH or $Z_2Cu$ [3]) were characterized via $H_2$-TPR, $NO_2$-TPD and $NH_3$-TPD. Performance analysis of catalysts were carried out in a bench-top reactor. Steady state $NH_3$ oxidation, NO oxidation and Standard SCR reactions were performed between 150 to 500°C at 100k $h^{-1}$. Intrinsic kinetic parameters (activation energy (Ea) and pre-exponential factor) of SCIE-CuS and CuZ for Standard $NH_3$-SCR of NO were obtained by running the reactor at differential conditions and assuming 1$^{st}$ order reaction. Feeds were 500 ppm NO and/or $NH_3$ or $NO_2$, 0-5% $H_2O$, 0-8%$O_2$ in $N_2$ balance.

**Results and discussion.** SCIE isotherms showed that Cu loading could easily be tuned by adjusting equilibrium Cu concentration and temperature during synthesis. After SCIE, FTIR band at 1301 $cm^{-1}$ associated with v(C=C)+v(C-H) stretching vibrations in the $Cu(tfa)_2$ was observed of all CuM, CuZ, and CuS (Fig. 1a) with blue shifts of 4, 2, and 5 $cm^{-1}$, respectively, suggesting that some of the formed trifluoroacetylacetone, a product of the SCIE reaction [1], chemically bonded to the zeolite enabling site selective Cu exchange. In addition, $H_2$-TPR (Fig. 1b), $NO_2$-TPD and $NH_3$-TPD profiles showed that the structure and number of Cu species strongly depend on the SCIE conditions. To illustrate this, low temperature (150-200 °C) Standard SCR intrinsic kinetic parameters were measured and $Z_2Cu$ site dominated CuS had a lower pre-exponential factor ($6.6*10^8$ $m^3/g_{cat}/s$) and lower Ea (64 kJ/mol) than ZCuOH dominated CuZ ($3.5*10^{11}$ $m^3/g_{cat}/s$ and 87 kJ/mol, respectively). This was also in line with very low $NH_3$ oxidation and NO oxidation performance of CuS and very high activity of CuZ towards these aforementioned reactions. With the purpose of comparing synthesis methods, Standard SCR activities of SCIE-CuM and AIE-CuM catalysts were measured. SCIE catalyst showed higher deNOx performance than AIE-CuM catalyst at both lower (<250 °C) and high temperature (>400 °C) with lower $N_2O$ production at high temperatures (Fig. 1c). These results underline the significant potential of SCIE technique for the synthesis of $NH_3$-SCR catalysts for NOx abatement.

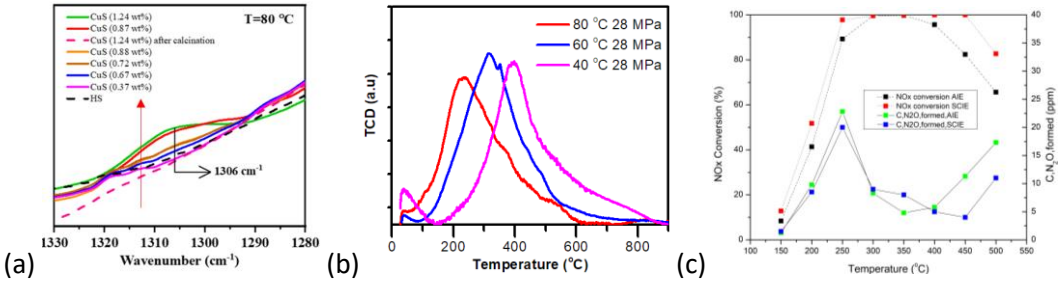

**Figure 1** (a) FTIR spect.ra of various CuS before and after SCIE (b) $H_2$-TPR profiles of CuS (0.67 wt%) prepared via SCIE at different synthesis conditions (c) Standard SCR NO conversion differences of CuM prepared via SCIE and AIE (2 wt%).

# Catalysts and reactors under dynamic conditions for energy storage and conversion

# Utilizing the redox cycability of modified spinel precursors for reactivation of Ni-based $CO_2$ methanation catalysts

Dennis Weber[1], Tanja Franken[1*]

[1] *Friedrich-Alexander-Universität Erlangen-Nürnberg, Institute of Chemical Reaction Engineering, Group of Catalytic and Electrocatalytic Systems and Processes, 91058 Erlangen, Germany*

**Keywords:** Catalysis, $CO_2$ methanation, spinels, mixed metal oxides

**Introduction.** Nickel is widely used as catalytic active metal for the $CO_2$ methanation due to its high selectivity and low cost. For $Ni/Al_2O_3$ catalysts, sintering of the nickel particles on the surface leads to a decrease in catalytic activity with increasing time-on-stream, especially under dynamic $H_2$ dropout conditions.[1,2] Therefore, a catalyst is needed in which the nickel particles are both finely dispersed and stable. Spinels offers atomically distributed Ni, but their high stability makes its activation challenging. However, we demonstrate that spinel phases can be tailored to allow low temperature activation, creating finely dispered and highly active Ni sites, that are redox cycable to reverse potential deactivation.

**Experimental/methodology.** $Ni_{0.9}Mn_xAl_{2-x}O_4$ ($0 \leq x \leq 2$) catalysts were prepared by coprecipitation of the corresponding nitrates with one molar sodium hydroxide at a constant pH of 9 and concurrent calcination at 800°C. Catalytic experiments were performed in a fixed-bed reactor at ambient pressure.

**Results and discussion.** The Mn-tailored spinels have good low temperature reducibility and show higher activity and stability compared to supported catalyst. The methane yields achieved with the optimized spinel composition are on average about 45% higher than with the supported catalysts. No deactivation was observed for these spinel catalyst in both static and $H_2$ dropout experiments with a time-on-stream of over 100 h.[3] In addition, the redox reversibility of the spinel phase enables to reintegrate and redisperse the catalytically active nickel particles, reversing potential deactivation. This so-called concept of "Dynamic Responsive Methanation Catalysts" (cf. Figure 1A) is, with regard to the use of renewable energies for hydrogen production and the associated hydrogen dropouts, a possibility to utilize these dynamic operating conditions for reactivation of the catalyst. The spinel catalyst shows high redox cycability, with activity and selectivity remaining nearly constant after 5 consecutive cycles of active site formation by reduction and active site reintegration by oxidation into the hosting spinel structure (c.f. figure 1 B & C).

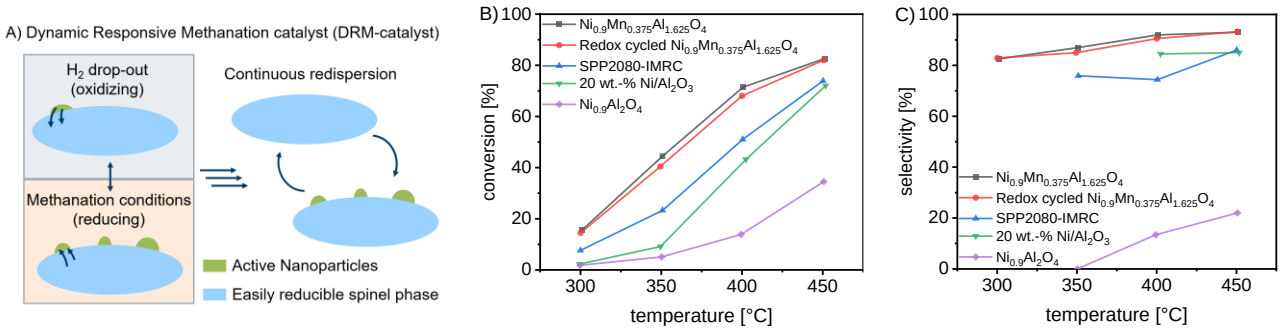

**Figure 1: Performance of activated Ni based catalyst precursor in the methanation of $CO_2$ to methane. # Stability of Fe-based Fischer-Tropsch Catalysts at dynamic reaction conditions captured by in-situ magnetometry

Q. Chang[1,2], R. Stegman[1], N. Fischer[1], H. Kotzé[1], D. de Oliveira[1], C. Zhang[2], J. Xu[2], X. Wen[2], Y, Yang[2], Y.W. Li[2], H. Niemantsverdriet[3], K.-J. Weststrate[3], Michael Claeys[1,*]

**Introduction.** The Fischer-Tropsch process can play a crucial role in converting carbonaceous feedstock into sustainable fuels and chemicals. It is operated in large scale plants using cobalt and iron-based catalysts. Iron-based catalysts are particularly suitable for the Fischer-Tropsch synthesis using biomass-derived syngas due to its high water–gas shift activity, flexible operating conditions, and its low cost[1]. During its use the catalysts will be exposed to a range of reaction environments, which include dynamically changing conditions when feedstocks from renewable sources are employed. Although controversy regarding the active phase in iron-based catalysts still exists, it is generally accepted that iron carbides are the active phase; while magnetite is inactive[2]. Water, one of the main products formed in Fischer-Tropsch synthesis, is thought to have a significant influence on phase composition and catalyst stability[3]. Studies have shown that the presence of water results in the oxidation of the iron carbide phase to magnetite[3], which results in catalyst deactivation[2].

**Experimental/methodology.** In this work the oxidation threshold of relatively pure unpromoted and K-promoted Hägg carbide catalysts as well their response to dynamic changes of the reaction environment/water partial pressure has been determined using *in situ* magnetometry[4]. The reaction has been conducted at 275°C, the reaction temperature used for medium temperature Fischer-Tropsch synthesis. The oxidation of the carbide can be detected via an increase of magnetisation due to the formation magnetite and its reversibility via a corresponding decrease of magnetisation. Importantly, these observations can be done at fully relevant industrial reaction conditions.

**Results and discussion.** Oxidation thresholds could be determined as being in the range of 3-4 bar of water, and potassium promotion of the catalysts was found to suppress the onset of this oxidation. This process was largely reversible and limited to surface near regions in of the catalyst promoted with medium levels of potassium (see figure). The results obtained will be discussed in conjunction with catalyst performance data.

**Introduction:**

The key to achieve a substantial reduction of $CO_2$ emissions into the atmosphere to counteract the man-made climate change is the employment of renewable energy resources. A promising approach for renewable energy storage is "Power-to-Liquid" concept (cf. www.spp2080.org): green $H_2$ and $CO_2$ either from local sources or the atmosphere are transformed into chemicals and fuels, like methanol. Currently, methanol is mostly produced from a fossil syngas as feedstock (CO, $CO_2$ and $H_2$), using a $Cu/ZnO/Al_2O_3$ catalysts (CZA). Switching to pure $CO_2$ as carbon feedstock brings new challenges. $CO_2$-hydrogenation is thermodynamically less favored compared to CO hydrogenation and leads to higher water formation. Both $CO_2$ and water deactivate the classical CZA catalyst. Modification by Ni and Ga is very promising for novel methanol catalysts which may help overcome CZA limitations.[1,2] Operando X-ray absoprtion spectoscopy (XAS) is a powerful tool to unravel the structural dynamics of novel $CO_2$-hydrogenation catalysts.

**Experimental:**

Coprecipitated $Cu/Ga_2O_3$ (CG) and $Ni/Ga_2O_3$ (NG) with high metal loading > 50% were investigated *via operando* XAS experiments with the aim to study the catalyst structure during $CO_2$-hydrogenation to methanol. The experiments were carried out at 30 bar with a novel high pressure cell.[3]

**Results and discussion:**

Activity tests of CG and NG showed an increased methanol formation compared to the reference Zn-promoted Cu/MgO model catalyst.[4] Hereby, the CG catalyst shows 100% methanol selectivity and high production rates. To better understand the superior performance of this catalyst, *operando* XAS-studies were conducted, including a $H_2$-dropout experiment. During $H_2$-dropout a slight decrease in methanol formation due to deactivation was observed. A following $H_2$ treatment could not restore the initial activity of the reduced catalyst. The selectivity towards methanol, however, stayed at 100%. According to operando XANES, there are no changes in the oxidation state of the catalyst during reaction and $H_2$-dropout detectable. Moreover, XANES/EXAFS revealed that switching the reaction conditions did not cause changes in the electronic environment of the Cu species (Figure 1). Hence, the bulk structure of the Cu particles is stable towards oxidizing conditions. To further increase the surface sensitivity now catalysts with smaller copper particles, prepared by flame-spray pyrolysis, are used to investigate the catalyst response to dynamic changes of the gas composition. Promotional effects of Ga on Cu surface and Ni bulk affecting the methanol selectivity, e.g. the formation of intermetallic Ni-Ga,[1] will be discussed in our contribution.

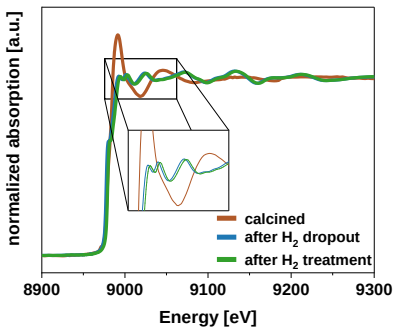

***Figure 1: XANES/EXAFS spectra of CG before reduction, after reaction followed by $H_2$-dropout and after the second reduction.***

# Separation and conversion of $CO_2$ to methanol over bifunctional catalysts under dynamic reaction conditions

Huidong Xu, Johannes A. Lercher and Andreas Jentys
*School of Natural Sciences and Catalysis Research Center, Technical University of Munich, Germany*

**Keywords:** $CO_2$ capture and hydrogenation, bifunctional catalysts, dynamic processes

**Introduction** $CO_2$ is the main component of greenhouse gases and its increasing concentration in the atmosphere is a critical environmental issue. Thus, novel integrated processes for the capture and conversion of $CO_2$ into chemicals and fuel components under dynamic reaction conditions are required to provide the necessary flexibility for fluctuating and non-stationary energy demands.
In this presentation, we present a combined sorbent and catalyst with dual functionality containing base and metal sites for $CO_2$ sorption and subsequent conversion to methanol.

**Experimental/methodology** The catalysts are based on ordered mesoporous polymers [1] acting as supports for amino groups ($CO_2$ adsorption sites) and for size-controlled Pt nanoparticles ($CO_2$ hydrogenation sites). The capacity for $CO_2$ sorption and the activity for the subsequent hydrogenation to methanol were measured using a fixed bed tubular reactor at 1 bar and temperatures between 70 and 120 °C, applying dynamic changes in the reactant feed to simulate the periodic operation of a $CO_2$ (pressure swing) absorber.

**Results and discussion** The reaction was carried out in a two step process. $CO_2$ was adsorbed at 70 °C until equilibrium was reached. After removing the physisorbed $CO_2$ by purging, the gas flow was switched to $H_2$ in He and the temperature was increased from 70 to 120°C during $CO_2$ hydrogenation. Although methanol formation was already observed at the $CO_2$ sorption temperature (70 °C), it was necessary to increase the temperature to 140 °C to completely remove all products from the catalyst (see Figure 1). A conversion of $CO_2$ to methanol of 25%, based on the irreversible $CO_2$ sorption capacity, was observed. Methanol and water were the only products formed, CO and $CH_4$ were not detected in any of the experiments.

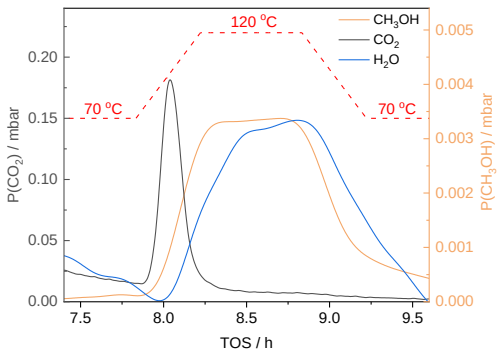

**Figure 1: Product formation during temperature increase for Pt-loaded sorbent/catalyst**

$CO_2$ sorption capacity and catalytic activity were influenced by the type of amine used (i. e., primary, secondary and bi-basic). The use of ordered mesoporous polymers increased the methanol yields compared to the $SiO_2$-based catalysts previously studied [2].

**Introduction.** Supported precious metals with atomic dispersion have proved promising for achieving maximum atom efficiency as well as improved activity and selectivity in catalyzing a growing number of thermo-, electro-, and photo- driven chemical reactions. We have recently reported the synthesis of thermally stable single atom catlaysts by atom trapping [1] and by confinement of single atoms using nanoglues [2]. Modificaiton of support surface by single atom trapping was found to form 2-D metal rafts, exhibiting enhanced reactivity [3]. We further found that these stablized single atoms can be readily activated by steam treatment [4] or thermal-shock treatment [5]. However, single atom catalysts are dynamic and undergo changes in their coordination, leading to altered reactivity patterns.

**Experimental/methodology.** Single atom catlaysts were synthesized using atom trapping [1]. A theory-guided approach along with spectroscopy and microscopy was used to identify the active sites in CO and methane oxidation.

**Results and discussion.** Dependence of turnover frequencies (TOFs) on CO partial pressure (pCO) from 0.5 to 4 kPa was studied on single atom 1 wt % $Pt_1/CeO_2$ catalyst prepared by atom trapping (Figure 1a). At 300 °C, CO partial pressure (pCO) was varied between 0.5 to 4 kPa while $O_2$ partial pressure ($pO_2$) was kept at 10 kPa. As shown in Figure 1b, under exactly the same pCO (1 kPa) and $pO_2$ (10 kPa), two stable working states (point-B vs. point-D) were observed with one order of magnitude difference in TOFs. With integrated kinetic studies, operando spectroscopies, and density functional theory calculations, we clarified the dynamic behaviors and reaction pathways under the lean CO oxidation condition. We found that different thermodynamically stable phases exist at critical CO and $O_2$ pressures, leading to varied adsorption configurations over isolated $Pt_1$ on $CeO_2$. Such dynamically responded boundaries dictate the reaction pathways involved and reactivity of single atom catalysts. We further discovered that a Langmuir-Hinshelwood mechanism via a carbonate-like intermediate prevails over single atoms on a reducible support, leading to a reduced reaction barrier by half compared to the typical Mars-van Krevelen mechanism and, thus, an increased turnover frequency by one order of magnitude.

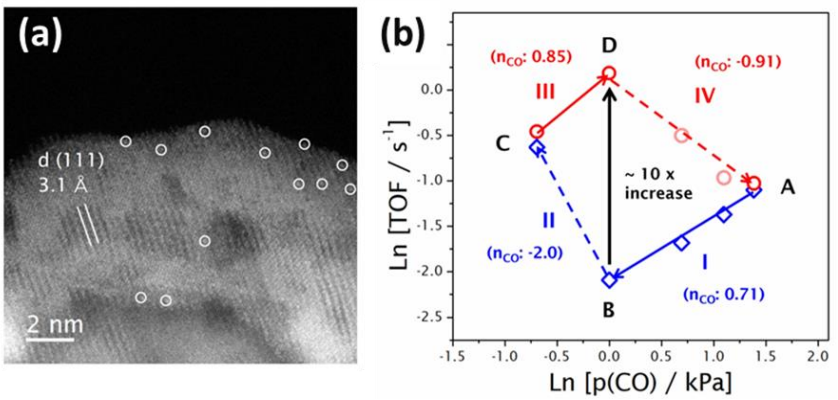

**Figure 1** (a) AC-STEM images of 1 wt % $Pt_1/CeO_2$ catalyst prepared by atom trapping showing the presence of atomically dispersed Pt on $CeO_2$ (111) step edges. (b) Dependence of CO oxidation rate on the partial pressure of CO on 1 wt % $Pt_1/CeO_2$. Conditions: 10 % $O_2$. 0.5-4 % CO. 300 °C.

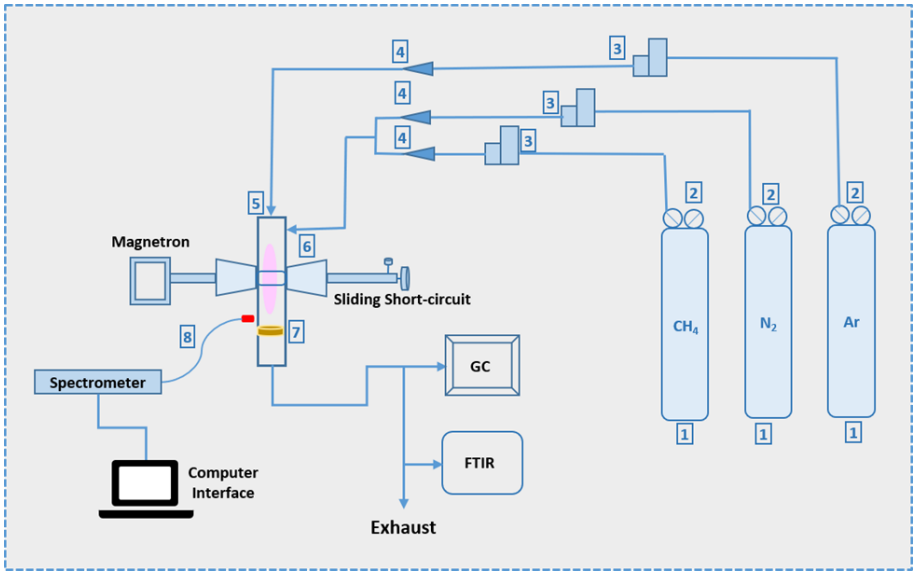
# Simultaneous $CH_4$ and $N_2$ Conversion under Microwave and Microwave Plasma Catalytic Processing



Sarojini Tiwari, Jianli Hu*
*Department of Chemcial & Biomedical Engineering, West Virginia University*
**john.hu@mail.wvu.edu*

**Introduction**

Chemical processing industry is substantially dependent on natural gas as a feedstock. In the process, it has become one of the major contributors of green-house gas emission. Process intensification can substantially upgrade chemical industries to a carbon free and zero waste systems. The basic definition of an intensified chemical process has broadened from merely reducing the size of the processing plant to a holistic undertaking that can reduce waste and energy consumption with improved product yield. The direct conversion of Methane ($CH_4$), the major component in shale gas, to value-added chemicals can be qualified as an intensified process, if it is energy efficient, free of unwanted side products ($CO_2$), and leads to maximum conversion of $CH_4$ to useful products.

**Experimental/methodology**

Microwave catalytic reaction can activate $CH_4$ and $N_2$ simultaneously to produce $NH_3$ and $C_2$ products in a single step process, represented schematically in Figure below. The reactor system can be operated in two scenarios: microwave only and microwave plasma. The reactor system is equipped with optical emission spectrometer (OES) to measure surface plasma species and online MS and FTIR to quantify the products.

**Results and discussion**

Two highly stable molecules, $CH_4$ and $N_2$ were simultaneously activated in a single-stage microwave-heated catalytic reactor to form ammonia, ethane, ethylene, and acetylene at atmospheric pressure. Density functional calculations and micro-kinetics modelling were used to predict the reaction behavior at temperatures ranging from 573 K to 973 K and validated with experimental analysis. The influences of terrace (111) and step (211) sites on K promoted Ru crystals were established in product formation and catalyst coking. $NH_3$ formation occurs predominantly on the step (211) sites while $C_2$ product formation can occur on both the sites. It was found that the elementary reaction steps leading to $NH_3$ synthesis occurs due to the non-thermal effects of microwave irradiation while $C_2$ products formed simultaneously are due to the thermal effects only. A reaction mechanism is postulated on the catalyst coking and validated experimentally by in-situ regeneration using $H_2$ and $O_2$.

The main challenge in simultaneous conversion of methane and nitrogen to ethylene and ammonia under plasma conditions is the low selectivity. This is largely due to the difficulties in controlling the reactions among the intermediates. To address this challenge, this article explored an innovative strategy - post-plasma catalysis in a microwave-enhanced plasma (MWP). After placing the thermally heated $CeO_2$ catalyst in the post plasma region, the active nitrogen-based species generated a steady amount of ammonia (selectivity=9%). The selectivity of ethylene increased from 3% to 37%, the highest among the $C_2$ products. While under conventional thermal heating, in the absence of plasma, the catalyst over-hydrogenated the acetylene to ethane and no ammonia was produced from nitrogen.

# Elucidating the role of metallic Fe and $Fe_3O_4$ on the in-situ formation of steady-state phases responsible for efficient $CO_2$ hydrogenation to higher hydrocarbons

L. Kraußer, H. Lund and E. V. Kondratenko*

*Leibniz-Institut für Katalyse e.V., Albert-Einstein-Str. 29a, 18059 Rostock, Germany*
**Evgenii.Kondratenko@catalysis.de*

**Keywords:** $CO_2$ Hydrogenation, Fischer-Tropsch Synthesis, Iron Nanoparticles, Heterogeneous Catalysis

**Introduction.** The $CO_2$ Fischer Tropsch Synthesis ($CO_2$ FTS) requires a catalyst that is active for both the conversion of $CO_2$ to CO and subsequent CO hydrogenation to hydrocarbons with minimal $CH_4$ selectivity. In this regard, bulk or supported Fe-based catalysts are widely used but require activation through reductive pretreatment resulting in various Fe-containing phases, which are distributed inhomogeneously along the catalyst bed.[1] This way, it is challenging to control the steady-state catalyst phase composition which, however, affects the catalytic activity and product selectivity. Therefore, we present a facile and swift catalyst preparation method consisting of physical mixing Fe nanoparticles, $Fe_3O_4$ and promoters without any form of pretreatment to analyze reaction-induced phase changes and the resulting consequences on catalytic performance. This knowledge is necessary to enable purposeful preparation of catalysts with hindered $CH_4$ formation.

**Experimental.** $Fe_3O_4$, alkali metal promoters, e.g., $K_2CO_3$, $Na_2CO_3$, and metallic Fe (particle sizes: 30-40 nm ($Fe^a$), 90-100 nm ($Fe^b$) and 790 nm ($Fe^c$)) were obtained commercially. The materials were mixed physically using a mortar (molar ratio $Fe/Fe_3O_4$ = 0, 1, 2, 4, 8; K/Fe = 0.01) and tested directly for $CO_2$ hydrogenation at 300 °C and 15 bar without any pretreatment using a feed with a $H_2/CO_2$ ratio of 3.

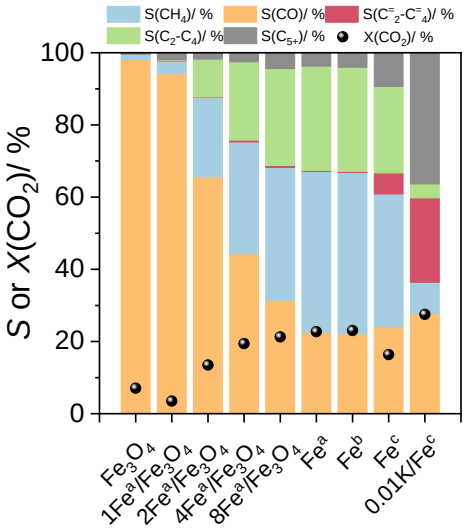


**Fig. 1: Catalytic properties for $CO_2$ hydrogenation. Conditions: 300°C, 15bar, $3H_2/CO_2/0.3N_2$, 6 mL/min; particle size $Fe^a$=30-40nm, $Fe^b$=90-100nm, $Fe^c$=790nm**

**Results and discussion.** The catalysts consisting of pure $\alpha$-Fe nanoparticles are not only more selective towards higher hydrocarbons ($C_{2+}$) than the $Fe_3O_4$-containing samples but also exhibit a significantly higher $CO_2$ conversion (Fig.1). In fact, both $CO_2$ conversion and $C_{2+}$ selectivity decrease drastically with increasing $Fe_3O_4$ content in the $Fe/Fe_3O_4$ mixtures. This indicates that $Fe_3O_4$ is not required in the initial catalyst composition to enable CO formation, which challenges conclusions from previous literature stating that $Fe_3O_4$ is the active phase catalyzing the conversion of $CO_2$ to CO under the applied conditions.[2] We put forward that Fe carbides ($Fe_xC_y$) formed in situ from $\alpha$-Fe catalyze this reaction instead. By physically mixing $K_2CO_3$ with $\alpha$-Fe nanoparticles (0.01K/$Fe^c$), $CH_4$ formation can be suppressed significantly (9% selectivity at 28% $CO_2$ conversion) likely due to electronic promoter effects on the hydrogenation ability of $Fe_xC_y$.[1] The selectivity to higher hydrocarbons ($C_{2+}$) and lower olefins ($C_2^=$-$C_4^=$) increases to 64 % and 23 %, respectively. These results are comparable to those reported on state-of-the-art Fe-based catalysts which, however, require time- and cost-intensive pretreatment.[3] Operando XRD studies are in progress to elucidate the mechanism and kinetics of reaction-induced $\alpha$-Fe conversion into steady-state phases including their spatial distribution. Steady-state isotopic transient kinetic analysis will provide the lifetime and concentration of active species yielding CO and $CH_4$.

**Introduction:** In this work, the concept of a catalytic plate reactor (CPR) is followed as a combination of a plate heat exchanger and a chemical reactor. The CPR consists of metal plates that are coated with a catalytically active layer on one side and heated from the backside. The liquid feed is continuously flowing through the slit between the plates. The high thermal conductivity of the metal plates and the direct contact to the catalytic surface avoid temperature gradients, enabling fast heat-up and cool-down cycles.[2] Therefore, a CPR is suitable for quick start-stop cycles, as required, e.g. for dynamic operation scenarios. Furthermore, CPRs have a low pressure drop, faciliating a fast gas transport. A major challenge in the realization of CPRs is the production of mechanically stable and active coatings. We have devised a method that is based on spray-coating a sol-gel composite ceramic dispersion to address this issue. Our catalytically activated plates are tested for the endothermic dehydrogenation of the hydrogen storage molecule perhydro-benzyltoluene (H12-BT) as an example reaction to emphasise the benefits of the CPR-concept. This study covers large parts of the development chain of a CPR, starting with the evolution and analysis of catalyst coatings, testing their dynamic performance in a small-scale continuous set-up, and finally scaling up to a CPR of technical size.

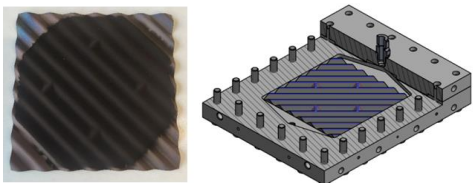

**Figure 1: Embossed metal plate after coating (a); CAD-Drawing of the used CPR**

**Experimental:** For the catalytic activated plates, a planar metal plate is spray-coated with a self-developed sol-gel-composite dispersion, which forms a porous metal oxide support layer, when calcined. By a Design of Experiments (DoE) approach the mechanical stability and coating load were greatly enhanced. Simultaneous a good sprayability of the dispersion was maintained. With the novel recipe, the prepared plates can reach a coating thickness of up to 500 µm without crack formation. After a successful coating and calcination, the catalyst precursor platinum sulphite acid is impregnated onto the support layer and subsequently reduced under hydrogen.

**Results and discussion:** In addition to planar substrates, three-dimensional embossed plates that improve hydrodynamics (see Figure 1), can be coated, using our highly flexible spray coating process. These plates were tested in a new designed CPR at temperatures between 280 °C and 320 °C and elevated pressures of up to 3 bar. The results of the reaction condition optimization for this CPR-module are shown in Figure 2. At a temperature of 310 °C and a pressure of 1.5 bar, a high conversion of >50 %, suitable for technical application is reached. The catalyst showed no significant activity loss during 20 h of operation, making a further scale-up of this catalytic reactor concept highly attractive.

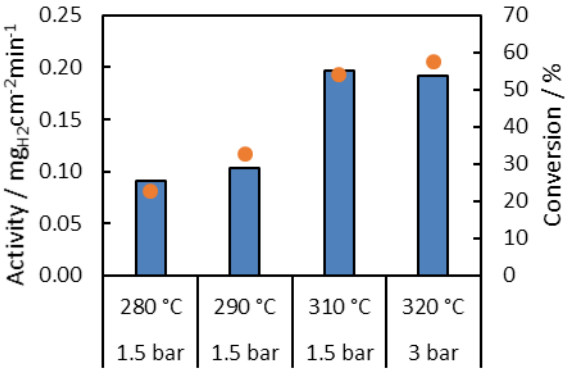

**Figure 2. Continuous dehydrogenation experiments in a CPR (feed = 1 $g_{H12\text{-}BT}$ $min^{-1}$; $m_{cat}$ = 6.93 g; catalyst = 3.63 wt.% Pt-S/$Al_2O_3$).**

# Sulfur tolerance of Na-Ru/$Al_2O_3$ dual function material during the cyclic $CO_2$ capture and catalytic methanation

S. Cimino[1*], E.M. Cepollaro[1], L. Lisi[1]

[1]*STEMS- CNR, Napoli, Italy*
[*]*stefano.cimino@cnr.it*

**Keywords:** $CO_2$ capture and utilization, Power to gas, Chemical looping, Sulfur poisoning

**Introduction**

Converting $CO_2$ captured from flue/process gases or even from air using green hydrogen made from renewable energy is a way to contribute to reaching the ambitious decarbonization goals set for 2050 and also a valuable solution to store excess electrical energy in fuels/chemicals solving the intrinsic variability of renewable sources [1]. The integrated $CO_2$ capture and methanation with Dual Function Materials (DFM) is emerging as a vibrant field of research for its potential to increase the efficiency and reduce the cost of current multistage CCU processes [2]. However, testing the S-tolerance and durability of DFMs during prolonged cyclic operation with feeds containing sulfur impurities is an area requiring detailed investigation before the integrated process is to be scaled up to applications [1]. In this work, we set out to investigate for the first time the effect of sulfur poisoning during the cyclic $CO_2$ capture and methanation performed over a Sodium-Ruthenium on γ-$Al_2O_3$ DFM, which is reported among the best performing formulations at mid-low temperatures [1-3].

**Experimental/methodology**

Ru and Na were dispersed sequentially inside 1mm $Al_2O_3$ spheres by impregnation with nitrate precursors. Their loadings in the final DFM were deliberately kept low (ca. 1 % and 2.8 % wt., respectively) to better highlight the possible sulfur-poisoning effects on both the sorption and catalytic functionalities during prolonged operation in a fixed bed reactor at 300 °C with alternate feed conditions [3]. In particular, we present the results obtained during several repeated cycles carried out with the simultaneous presence of $CO_2$, $H_2O$, $O_2$, and $SO_2$ (10–100 ppmv) in the process gas stream to assess the impact of sulfur poisoning on $CO_2$ adsorption and conversion, methane productivity and selectivity, as well as the fate of sulfur under relevant operating conditions. The main physicochemical properties of the fresh and sulfated DFM were correlated with the results from catalytic hydrogenation tests of either preadsorbed or gas phase $CO_2$ and in-situ DRIFT study. Eventually, we preliminarily investigated possible regeneration strategies for a heavily sulfated DFM.

**Results and discussion**

Cyclic operation with $SO_2$ (10–100 ppmv) and $O_2$ in the flue gas demonstrated a remarkable sulfur tolerance of the DFM in the integrated process under both dry and humid feed conditions. In particular, during the $CO_2$ capture step, the DFM completely removed $SO_2$ storing it as sodium sulfates, which are rather stable species at 300 °C and were only marginally converted to $H_2S$ during the subsequent catalytic methanation step, thus avoiding severe poisoning effects. However, the accumulation of S above ca 100 µmol/gDFM progressively reduced the $CO_2$ adsorption capacity of the DFM that tended to vanish when its strong basic Na-sites were finally saturated by sulfates. Careful analysis of transient methanation tests of gas phase and/or pre-adsorbed $CO_2$ coupled to the in-situ DRIFT results on the fresh and sulfated DFMs suggested the occurrence of a peculiar and favorable self-regeneration mechanism for the catalytic Ru sites, preserving them from any significant sulfur poisoning effect.

# Enhanced $Ca_2Fe_2O_5$ Composites for Chemical Looping Reforming of Methane

A. Strazzolini[1], M. Boaro[1*], C. de Leitenburg[1], A. Trovarelli[1]

[1]Dipartimento Politecnico, Università degli Studi di Udine, 33100 Udine, Italy.
[*]*marta.boaro@uniud.it*

**Keywords:** $H_2$ generation, chemical looping, oxygen carrier, steam methane reforming, calcium ferrite oxides, ceria-zirconia.

**Introduction.** Chemical Looping Reforming (CLR) of methane using an oxygen carrier (OC) mediator has recently gained the interest of the scientific community, since this multi-step process could afford higher efficiency of current syngas production technologies and overcomes some of their issues, such as $CO_2$ emissions from burners, high steam consumption and high energy demand for air separation [1]. $Ca_2Fe_2O_5$ has proven to be a valid alternative to single Fe-oxides as oxygen carrier, due to higher phase reversibility as well as a lower equilibrium $pO_2$ [2]. The aim of this work is to boost the activity and stability of $Ca_2Fe_2O_5$ in methane steam reforming-chemical looping cycles (MSR-CL) through the implementation of a catalyst-assisted process [3] based on Ni-promoted $Ca_2Fe_2O_5$-$Ce_{0.8}Zr_{0.2}O_2$ composites.

**Experimental/methodology.** $Ca_2Fe_2O_5$ (C2F) and $Ce_{0.8}Zr_{0.2}O_2$ (CZ) were prepared by coprecipitation route. Catalyst-assisted OCs were prepared by incipient wetness impregnation of $Ni(NO_3)_2$ aqueous solutions selectively into CZ (iCZ) or C2F (iC2F). A Ni doped C2F (dC2F) was also prepared via Pechini synthesis. The composites (iC2F-CZ, C2F-iCZ and dC2F-CZ) were prepared physically mixing the single carriers and keeping Ni/Fe molar ratio constant to 0.025. Materials were characterized by means of XRD, BET, TGA, SEM-EDS. Chemical looping tests (800 °C, GHSV≈20'000 $h^{-1}$, 0.2 g of sample) were performed in a microreactor facility equipped with a mass spectrometer. Fig 1. shows the feed conditions of a typical CL test cycle.

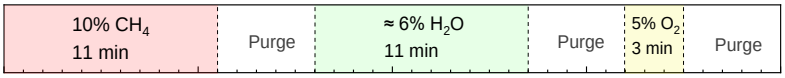

**Fig 1.** CL test cycle feed conditions (reactant concentrations and steps times).

**Results and discussion.** Preliminary results on composites materials without the addition of Ni agreed with literature reports [4]. CZ addition to C2F has beneficial impact on both steps of MSR-CL with the best performance obtained for the composite having a C2F:CZ mass ratio equal to 1. All catalyst-assisted samples reacted faster with $CH_4$ in comparison to unpromoted samples. The best results were achieved with the C2F- Ni impregnated CZ composite (C2F/iCZ), which shows a nearly tripled $CH_4$ conversion and hydrogen production by water splitting (Fig. 2), the highest CO selectivity and the lowest carbon deposition during reduction. The interplay between the two constituents of this composite was investigated by comparing different OC bed configurations, i.e. single bed composed by mixed C2F and iCZ vs. layered dual bed, made interposing a glass wool plug between the unmixed components. The mixed composite exhibited similar initial fuel conversion and the lowest tendency toward carbon formation, but its performances decreased significantly over cycles in comparison to what was found for the DB configurations. Based on spent samples observations (XRD, $H_2$-TGA), a different structural evolution of the C2F in the mixed bed configuration is hypothesized. Further characterization and tests are underway to unravel the mechanism behind the steady deactivation of the composite and to understand the key parameters that could, on the contrary, contribute to its optimization.

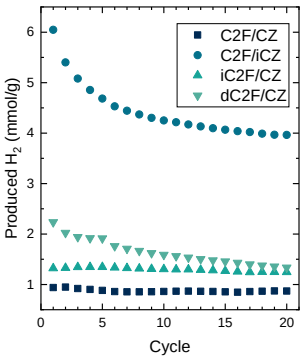

**Fig. 2.** Specific hydrogen production of catalyst-assisted composite OCs during steam oxidation step. Prior to the test, samples were subjected to five reduction/oxidation cycles at 850 °C, exposing them alternatively to 5% $H_2$ and 5% $O_2$.

**Keywords:** water electrolysis, oxygen evolution reaction, perovskite oxides, electrocatalyst, epitaxial model catalysts

**Introduction.** The bottleneck of electrochemical water splitting is the oxygen evolution reaction (OER). The high overpotential and limited stability at this half-reaction hinder the economical energy conversion. Active materials with a lower overpotential are less stable and stable materials require higher overpotentials to trigger the OER.[1] Epitaxy allows the combination of a stable but less active material with an active material with limited stability as well as a precise variation of the chemical composition of the catalyst and thus the active transition-metal oxygen bonds/hybrid electronic states.[2]

**Experimental/methodology.** The model catalysts were fabricated by pulsed laser deposition (PLD) to achieve well-defined model catalysts with defined thin film thicknesses. The surface morphology maintained similar while the chemical and structural composition of the catalysts were varied. The crystallinity and strain were investigated by x-ray diffraction (XRD) and reciprocal space mapping (RSM) before and after the OER. The measurement of the activity and stability of the superlattices were performed with cyclic voltammetry (CV) and chronopotentiometry (CP) in alkaline environment (0.1 M KOH) with a standard-three electrode setup.

**Results and discussion**. Based on the epitaxy approach we can correlate chemical composition, layer thickness, and electronic structure to OER activity and stability parameters. We find that the transient behavior of perovskite-type OER catalysts can be tuned by the chemical composition and detailed geometry of the epitaxial catalyst. As we find, a superlattice structure in which we layer a particularly stable material and an active oxide, leads to enhanced stability of the catalyst, while maintaining significant OER activity of the superlattice.

**Keywords:** hydrogen, formic acid, charge/discharge cycle

**Introduction.** The problems associated to the "greenhouse effect" have raised the social awareness towards $CO_2$ emissions minimization and orientation of the energy models to carbon dioxide free energy sources. Thus, nowadays the hydrogen is atracting all attention as green fuel, being the only warning associated to its transportation and storage. In this regard the use of liquid organic hydrogen carriers (LOHCs), such as formic acid (FA), presents a possible solution to this warning. Although containing only one hydrogen molecule per molecule and lower hydrogen density compared to the others LOHCs, the FA shows several important advantages; i.e. it can be synthesized directly from the lignocellulosic biomass or by hydrogenation of $CO_2$, being the later considered as an effective technology to deal with the $CO_2$ emissions control. The success of such a technology relies on the use of green hydrogen produced using renewable energy and one unique catalyst that could assure the charge ($CO_2$ hydrogenation to formic acid) and discharge (formic acid dehydrogenation) hydrogen cycles. That is why, this study dedicates to the preparation, characterization and activity of paladium based catalysts for the reaction of $CO_2$ hydrogenation to formic acid and its dehydrogenation to hydrogen gas.

**Results and discussion.** A series of Pd catalysts have been prepared and tested separately in both reactions. The variations of active phase nature and loading, support nature and reaction parameteres have been carried out in order to obtain an optimal performance in both reactions. Once the catalysts selected, the charge/discharge cycles are performed. One example is presented in Figure 1, using a 10%Pd/activated carbon (AC) catalyst.

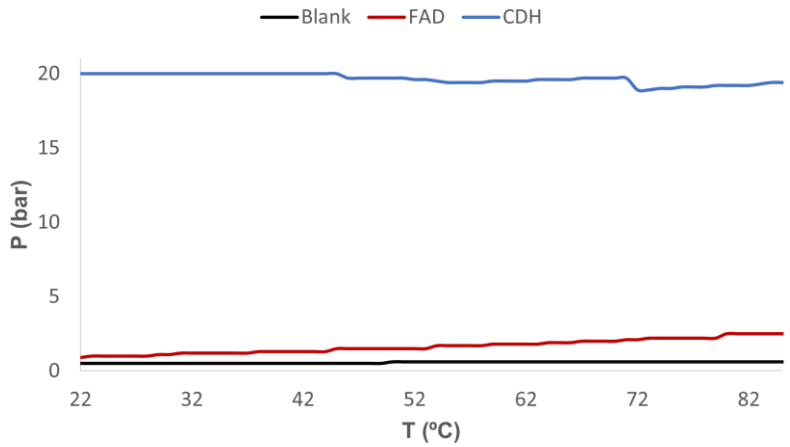

**Figure 1. Charge/discharge cycle over 10%Pd/AC catalyst.**

The first stage of the cycle, the dehydration of formic acid, is carried out at different temperatures and the formation of gas ($CO_2$ and $H_2$) increased continuously as a function of the reaction temperature. Once the cycle finished, the pressure is released and the $CO_2$+$H_2$ mixture is introduced in the reactor for the second cycle ($CO_2$ hydrogentation to FA) over the catalyst. The formic acid concentration, pH of the reaction suspension and pressure changes are monitored during the cycles and showed that the catalyst participates in both, charge and discharge reactions of hydrogen.

**Keywords:** Ruthenium nanoparticles, Methanation, Particle size effect, Supercritical water gasification, Catalyst stability

**Introduction.** Supercritical water gasification (SCWG) of wet biomass has drawn considerable attention in recent years as a clean and renewable synthetic natural gas production technology.[1] Ru has proved to be the most performant active phase for such reaction.[2] At nanoparticle surface, "hollow" ruthenium sites allowing high coordination of CO (*B5* sites) proved lower CO dissociation energy barriers.[3] A DFT study showed that 1.5 nm Ru NPs supported on graphite contained more of these sites than 1.0 nm Ru NPs.[4] These findings are in line with the high SCWG activity observed with Ru/C catalysts composed of small Ru NPs (1.2-1.4 nm)[5], indicating a structure sensitivity for this reaction. However, the geometry of a particle is known to greatly depend on the atmosphere it is exposed to, even at low partial pressures.[6] The effect of particle size on Ru activity in SCWG may therefore greatly differ from theory. Here, we will report the particle size effect in a model SCWG system, using Ru/CNF catalysts of different Ru NP sizes to gasify aqueous glycerol solutions to $CH_4$.

**Experimental/methodology.** A continuous fixed bed reactor was operated at 405–410 °C and 28.5 MPa using aqueous glycerol (6–20 wt%) at varying flows to control space flow velocity and maintain low conversion rates (kinetic regime).

**Results and discussion.** Ru/CNF catalysts of different Ru nanoparticle (NP) sizes (0.9-2.7 nm) were assessed for their performance in continuous supercritical water gasification (SCWG) of glycerol. A structure sensitivity of Ru was demonstrated, with high initial turnover frequencies (TOF) for Ru NPs smaller than 1.2 nm. Deactivation happens essentially through: 1) coking, which occurs more readily at low Ru surface densities and is limited to nanometric layers, and 2) sintering, which led to final NP sizes ranging from 2 to 3 nm independent of the catalyst loading (1 to 30 wt% Ru). A correlation between TOF and the density of surface Ru atoms was found, with an optimal surface density (0.4-0.7 $atom_{Ru,sfc}.nm^{-2}$) resulting in high initial and good steady-state TOFs, allowing longer lifetimes through the delay of coke formation. CNF as support enables high metal loadings, which could help in decreasing the costs of SCWG plants and hence make this technology even more attractive.

# Perovskite Oxides as Catalysts for Methanol Steam Reforming

T. Berger[1], J. Bock[2], F. Schrenk[1], H. Drexler[1], L. Lindenthal[1], C. Rameshan[1]

[1]*Chair of Physical Chemistry, Montanuniversität Leoben, Austria*
[2]*Institute of Materials Chemistry, Technical University of Vienna, Austria*

**Keywords:** catalysis, renewable energy, hydrogen storage,

**Introduction.** Methanol Steam Reforming (MSR) provides a promising solution for the storage and on-demand production of hydrogen for the utilization as an energy carrier in e.g.: Proton Exchange Membrane Fuel Cells (PEMFC). Due to the high reaction temperatures required and possible side reactions leading to the formation of carbon monoxide the use of suitable catalysts is of crucial importance. Even a proportion of 10 ppm carbon monoxide in the inlet gas can lead to a PEMFC performance loss of up to 80% [1]. A promising material for the reduction of the reaction temperature as well as high selectivity towards MSR are perovskite type oxides. These materials, with a general formula of $ABO_3$, display high resistance against agglomeration of nanoparticles socketed in the surface [2]. The composition of the catalyst can be specifically modified with suitable doping materials for the A- or B-site and can thus produce exsolved nanoparticles on its surface which fit the requirements necessary for MSR. [3]

**Experimental.** Different B-site doped (Cu, Ni, Co) perovskite type oxide catalysts in addition to the undoped basic structures of $Nd_{0.6}Ca_{0.4}FeO_3$ and $Pr_{0.6}Ca_{0.4}FeO_3$, were studied concerning their suitability for catalysing MSR. The onset temperature of the reaction of MSR as well as the selectivity of the individual catalysts against the production of carbon monoxide were of particular interest. As a result of the water saturated gas atmosphere a quantification of the reaction gases proved to be challenging. Therefore, a calibration strategy for a Mass Spectrometer (MS) was applied in combination with the development of a Python toolkit. This enabled us to quantify possible changes within the reaction atmosphere and compare the different investigated catalysts according to their catalytic activity. Additionally, operando XRD measurements at beamline P02.1. at DESY were conducted to investigate possible phase changes and deposition phenomena of carbon during the reaction.

**Results and discussion.** The experiments showed that each investigated material exhibited catalytic activity towards MSR regarding the yields of $H_2$ and $CO_2$ as well as a decrease in the reaction temperature. An increase in the catalytic activity could be tied to doping the B-site with the elements Ni, Co and Cu. Interestingly, the formation of CO at elevated temperatures could be observed in all catalysts examined, the degree depending on the basic structure and the doping material used. However, with catalysts doped with Cu high selectivity at lower temperatures for up to 370 °C could be observed towards the formation of $H_2$ and $CO_2$ instead of the unwanted side product CO, making them particularly interesting for further research in the on-demand production of hydrogen.

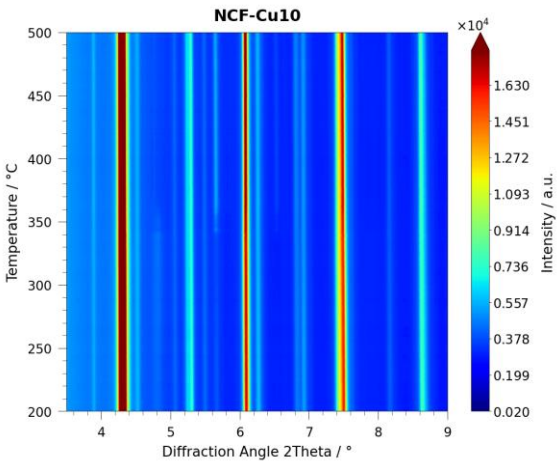

**Fig. 1: Illustration of the operando XRD measurement during reaction conditions conducted at Beamline P02.1 at DESY (Hamburg) for $Nd_{0.6}Ca_{0.4}Fe_{0.9}Cu_{0.1}O_3$.**

# DFT investigation of the dynamics of Cu/ZnO, Cu/GaxOy, Ni/ZnO and Ni/GaxOy Catalyst under operating conditions

Claude Coppex, Jelena Jelić, Felix Studt

*Karlsruher Institutit für Technologie, Karlsruhe, Deutschland*
*felix.studt@kit.edu*

**Keywords:** DFT, $CO_2$toMet, Methanol , Cu/ZnO, surface dynamics

**Introduction.**

To reduce our carbon footprint Germany has vowed to reduce the $CO_2$ emissions by 40% until 2020 and 80% by 2050. To achieve this the electricity production of renewable energy needs to be increased drastically, which brings challenges to the electricity grid due to their fluctuating production time and the chemical industry which relies heavily on fossil derived substrates. Power2X summarizes projects concerned with the storage of electric energy in chemical energy usually involving carbon species. A very promising way for long-term and mobile storage is the conversion to a valuable chemical like Methanol, which has excellent storage properties and also serves as a base chemical. A renewable route for the production of methanol is the hydrogenation of $CO_2$/CO over the Cu/ZnO/$Al_2O_3$ catalyst. The mechanism has been under debate since the investigation of the catalyst for the process ~100 years ago.[1]

**Experimental/methodology.**

With theoretical modelling we investigate the surface dynamics of the "inverse" metal oxide/transition metal catalysts (Cu/ZnO, Cu/GaxOy, Ni/ZnO and Ni/GaxOy) under $CO_2$ hydrogenation conditions. For each of the metal oxide/transition metal systems we constructed a Phase diagram (Fig. 4) based on calculated alloy structures and the chemical potential of the gas phase. The thermodynamic stability of each system for the given reduction potential of a reaction mixture is a function not only of the heat of formation of the alloy/intermetallic compound but also of the reducibility of the metal oxide.

**Results and discussion.**

As a starting point, we studied the formation of surface (Fig. 2) and bulk alloys/intermetallic compounds. In all cases, the formation of a surface alloy is more favorable than a bulk alloy (Fig. 3). We will present a summary of the phase diagrams of not only the stable surface facet (111) and (100) but also other surface facets with lower coordination like (110) and (211). Once the degree of alloying of the surface is reduced to a few structures (those corresponding to the operating conditions from the Phase diagram) we will investigate the influence of alloying on relevant intermediates in the $CO_2$ hydrogenation process.

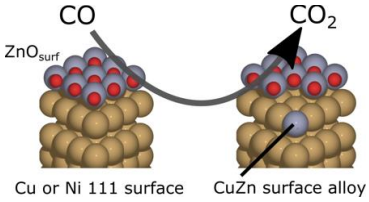

**Fig 1. Schematics of how the reducing atmosphere under reaction conditions will form the surface alloy.**

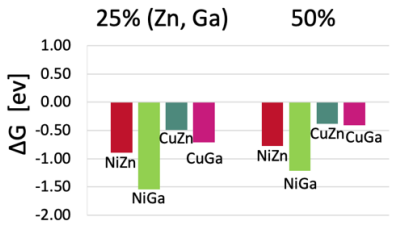

**Fig 2. The Formation energy of the surface alloy compared to the bulk alloy.**

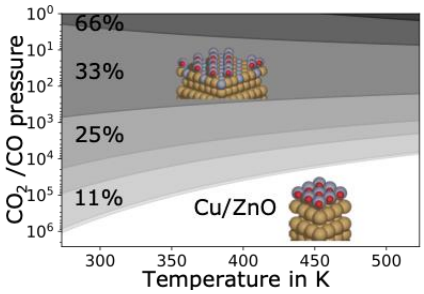

**Fig 3. The calculated Phase diagram of the Cu/ZnO system.**

# Chemical-looping application of Ni-Co/$MgAl_2O_4$ for syngas production by separate $CH_4$ decomposition and $CO_2$ activation

Yuchen Deng[1], Jong Wook Bae[1*]

[1]School of Chemical Engineering, Sungkyunkwan University (SKKU), Suwon, 16419, Republic of Korea

[*]E-mail: finejw@skku.edu

**Keywords:** Chemical looping; Ni-Co; mesoporous $MgAl_2O_4$; Methane decomposition; $CO_2$ activation.

**Introduction.** Global warming caused by emissions of greenhouse gases has become more deteriorating these decades, which leads to a growing importance of $CO_2$ conversion and utilization [1]. In 2015, Linde group revealed the pioneer pilot plants for a process named dry reforming of methane (DRM) which is able could transform two kinds of main greenhouse gases including $CH_4$ and $CO_2$ to syngas. Ni-based and Co-based catalysts are used in Linde Pilot Reformer (LPR). To promote the performance and longevity of these materials, the design of catalyst component and bulk structure is important, as well as investigation of the interactions between components [2]. Here, we proposed a new route to carry out the dry reforming of methane process by dividing the process into two parts including methane decomposition and reverse Boudourd of carbon dioxide. As methane decomposition into carbon and hydrogen occurred firstly followed by the coming of $CO_2$ feed gas which will react with the cardon on the surface of catalyst to carry out the reverse $CO_2$ boudourd reaction. In this way, deactivation caused by coke could be solved to some extent.

**Experimental/methodology.** The mesoporous $MgAl_2O_4$ and Ni-Co-Mg-$Al_2O_3$ materials were synthesized by evaporation induced self-assembly (EISA) method. The nickel and cobalt precursor were impregnated on the prepared supporter using the traditional dry impregnation method. All of the catalysts were calcined at 450 $^oC$ for 30 minutes with continue calcination at 800 $^oC$ for 2 h. A catalytic test on Ni-Co/$MgAl_2O_4$ catalysts was performed in a fixed-bed tubular reactor at atmospheric pressure with 0.1 g catalyst. Prior to the CL-CDR looping reaction, 10%$H_2$ balanced with $N_2$ was fed into the reactor at 800 $^oC$ for 2 h to reduce the catalyst. In the methane decomposition step, a flow of 30 cc/mim feed gas containing 5%$CH_4$/$N_2$ passed through for 30mins at 700 $^oC$. After using $N_2$ to purge the feed gas in the last step, 20%$CO_2$ balanced with $N_2$ flowed through the catalysts to carry out the reverse boudouard $CO_2$ reaction for 15 minutes at 700 $^oC$.

**Results and discussion.**

The activity of Ni -Co/$MgAl_2O_4$ maintained even after 20 cycles of CL-CDR process as shown in **Figure 1**. Spinel-type $MgAl_2O_4$ has positive effects on conversion on the catalyst surfaces, which affected the ratio of $H_2$ to CO and $H_2$ purity during methane decomposition step as well.

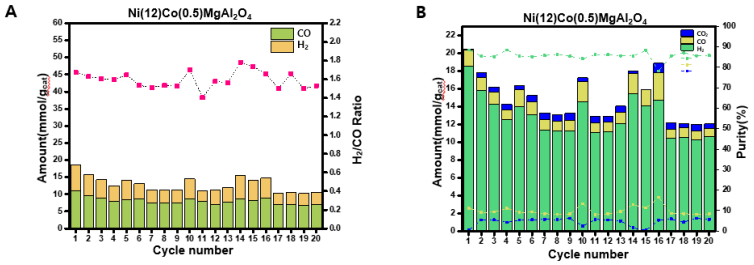

**Figure 1. (A) $H_2$ and CO yield within 20 cycles, (B) Purity of products formed by $CH_4$ decomposition.**

**Introduction.** In a chemical loop process, a solid oxygen carrier (SOC) is reduced and oxidized in successive steps: in the reducing step, the SOC lends oxygen to an electron acceptor; in the oxidizing step, the SOC is reoxidized by water steam, releasing hydrogen. This process is currently used in hydrogen storage cycles, in which hydrogen is used as a reducer and is released back by steam when required. The use of ethanol as a reducer allows to produce hydrogen from renewable biomass. Transition metal-doped iron oxides are effective SOC materials, as the reducing and oxidizing steps can be easily performed at the same temperature [1]. The nature of the transition metal heavily affects the pattern of reduction of ferrite by ethanol in the first step of the chemical loop [2,3].

**Experimental/methodology.** SOC materials have been prepared by precipitation in alkaline solution and calcination. They have been characterized by XRD, Raman and Mössbauer spectroscopy, $H_2$-TPR, $^{16}O$-$^{18}O$ exchange, N2 sorption. Redox cycles were carried out at 450°C in a flow reactor with alternate feed of ethanol and water vapor. Products of ethanol oxidation and SOC reoxidation were quantitatively analysed.

**Results and discussion.** In the reduction of copper ferrite, early formation of $Cu^0$ catalyzes ethanol reforming with the formation of CO and fast reduction of the spinel to iron carbides $FeC_x$ (Fig. 1). Manganese ferrite catalyzes ethanol oxydehydrogenation and is more slowly reduced to maganowustite (Mn,Fe)O. In the reoxidation step of the chemical loop, the deeper reduction of the Cu-bearing SOC allows a higher $H_2$ production but the oxidation of iron carbides develops COx, which affect the purity of the produced hydrogen, in a trade-off between conversion and selectivity.

**Keywords:** Pt/ceria, Short Puls Activation, OME.

**Introduction**

In previous work, we have shown that after activation by 5-10 s long reductive pulses, Pt/ceria catalysts can achieve very high CO oxidation activity at temperatures as low as 70°C [1]. However, under conventional Diesel exhaust ageing conditions (~800°C in lean exhaust), Pt/ceria catalysts deactivate through the formation of inactive Pt single atoms [2]. This deactivation requires a complicated 2-step activation procedure [1] that makes a practical application of these catalysts for Diesel exhaust after treatment difficult. Due to the lower ageing temperatures during operation with Oxymethylene Ether (OME) as an alternative Diesel fuel, Pt will not form single atoms, which greatly simplifies the application of the short pulse activation scheme. In this contribution, we demonstrate the application of short-pulse reductive activation of Pt/ceria catalysts for OME exhaust with a focus on CO abatement.

**Experimental/methodology**

Exhaust temperature profiles, mass flows, and raw emissions of a low-load cold-start driving cycle were measured on an engine bench and then reproduced on a dynamic lab test bench. A Pt/ceria catalyst was prepared by incipient wetness impregnation using commercial high-surface ceria (BET 140 $m^2/g$). The catalytic material was then coated on a cordierite monolith.

**Results and discussion**

To demonstrate the performance of Pt/ceria catalyst after short pulse activation, a sequence of drive cycles was measured on the dynamic test bench. In between the cycles, the catalyst was activated by a 10 s reductive pulse at 230°C, see Fig. 1 for the applied test sequence. The performance in the different cycles is compared with the performance of a commercial reference Diesel oxidation catalyst (DOC) in the same cycle. With the Pt/ceria catalyst, after each activation event nearly full CO conversion could be measured in the following drive cycle (Fig. 1: 2.DC, 5.DC and 9.DC). Without further activation, the activity slowly decreases from drive cycle to drive cycle but is restored with each new regeneration. After a deactivation step at 450°C mimicking full operation of the OME engine, the activation is completely lost but can be regained by a new activation pulse. [3].

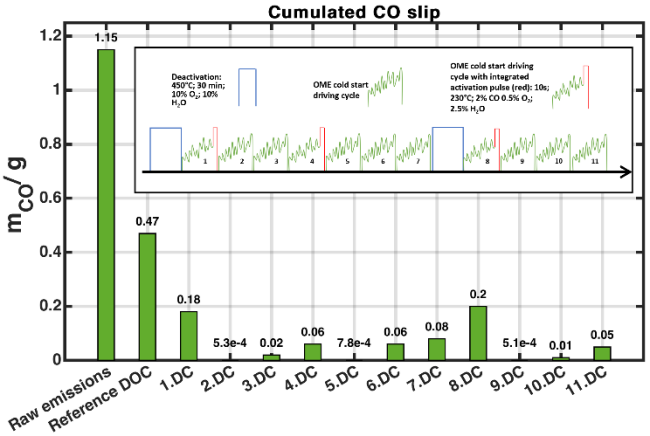

**Figure 1.** Comparison of the cumulated post-catalyst CO mass for the 30-minute OME cold-start driving cycle (DC) in the Pt/ceria test series: 1. DC - 11. DC. The cumulated mass of the raw emissions and the test with a reference DOC are provided for comparison.

**Introduction**

In order to limit the negative effect of climate change, the transition of the energy system from fossil to sustainable and climate neutral energy sources and energy carriers is a major challenge. However, since renewable energies (RE) such as wind and solar power are not equally available at all times and in all places, the storage and distribution of RE are of great importance. In this context, power-to-X technologies producing chemical energy carriers will be one piece of the puzzle. In particular, the methanation reaction is an important synthesis route, since it is already well investigated and can rather easily be implemented in the existing natural gas infrastrucutre. However, due to temporal fluctuations of the RE, a dynamic operation of the reaction is necessary when larger buffer tanks are to be avoided. This raises questions on the operation conditions, respectively on the effects of dynamic operation on potential deactivation of the catalyst applied. In the frame of the priority programm 2080 funded by the German Research Foundation, the methanation reaction is investigated under dynamic and deactivating conditions with focus on catalyst stability and deactivation phenomena.

**Experimental/methodology**

The $CO_2$ methanation reaction was investigated using an in-house developed reactor with multiple taps along the reaction coordinate (Fig. 1a), allowing for spatially and temporally resolved gas phase sampling in between dedicated reaction zones realized by implementing individual foils coated with the catalyst. The reactor further allows for optical access which will be used to gather data on adsorbed species on the catalyst's surface via DRIFTS, giving insights into the reaction mechanism on the catalyst's surface. From the extensive data obtained at different temperatures, feed gas composition (step changes), etc., information on catalyst stability under dynamic reaction conditions is deduced.

**Results and discussion**

Exemplarily, Fig. 1b shows the spatially resolved $CO_2$-conversion profile of the methanation reaction obtained at different reaction temperatures using an industrial methanation reference catalyst (IMRC). In the contribution, we will present and discuss spatial and temporal profiles of the methanation reaction under certain (dynamic) reaction conditions. Additionally, a modell for catalyst deactivation has been developed and will be compared with the data collected with the tap reactor.

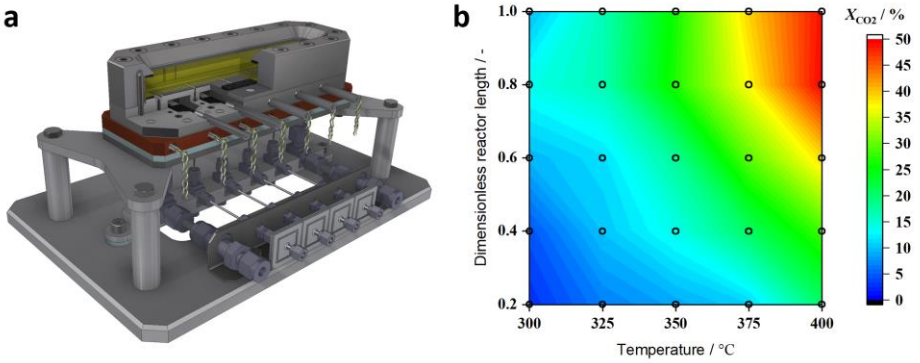

**Figure 1: (a) CAD drawing of the reactor used to gather temporally and spacially resolve operando data. (b) Spatially resolved CO2 conversion at different $T_R$ ($p_R$ = 5 bar, SV = 4 $ml_N\ min^{-1}\ mg_{cat}^{-1}$, $CO_2$:$H_2$ = 1:4 with 50 vol.% $N_2$). Heat map shows the interpolation of the 5x5 experimental points indicated by circles).**

**Introduction.** $CO_2$ hydrogenation to higher hydrocarbons via consecutive RWGS and Fischer-Tropsch synthesis is one promising approach to utilize $CO_2$ greenhouse gas into valuable chemicals and fuels. Iron based catalysts are well known to be widely used for this prosses. Using potassium as promoter is especially necessary to increase selectivity of $C_{2+}$ hydrocarbons and suppress methane formation. Even though iron-based catalysts have been studied for a long time, there are still open aspects regarding the mechanistic details. For this purpose, *operando* DRIFT spectroscopy studies under high pressure with MS analysis were performed on unpromoted and potassium promoted Fe/YZrO$_x$ catalysts.

**Experimental/methodology.**

Fe/YZrOx catalysts promoted by potassium was synthesized by incipient wetness impregnation method. The operando DRIFTS experiments were performed on a Nicolet iS10 spectrometer equipped with a high pressure/high temperature reaction DRIFTS cell (Harrick) connected to a gas supplying system and to an online mass spectrometer (OmniStar GSD320, Pfeiffer Vacuum). The catalysts were pretreated in $H_2$ ($H_2$/He, 1:1, 400°C, 120 min) followed by exposure to the reaction gas mixture ($CO_2$/$H_2$, 1/3, 15 bar, 300°C). In addition, the catalysts were studied by the sequential treatments in reaction gases: $CO_2$→He→$H_2$, $CO_2$→$H_2$ and $H_2$→$CO_2$ with 22% of $CO_2$ in He and 5% of $H_2$ in He.

**Results and discussion.** The DRIFT spectra of 1K-Fe/YZrOx recorded under different sequences of treatments are depicted in Fig.1. The surface of the catalyst after flushing in $CO_2$ is characterized by several carbonate and bicarbonate adsorbates with different structures[1]. After He treatment, a vanishing of ~~a~~ weakly adsorbed carbonates is observed. Further $H_2$ dosing leads to the transformation of surface carbonates only into $CH_4$ and $C_{2+}$ hydrocarbons. This could be an indication to a direct reaction route on the stable sites presented on the surface after treatment in He. Indeed, the direct addition of $H_2$ after $CO_2$ seems to lead to the formation of CO primarily from weakly adsorbed carbonates by RWGS reaction and further formation of methane from stronger adsorbed carbonates. Further studies are currently underway to validate this assumption.

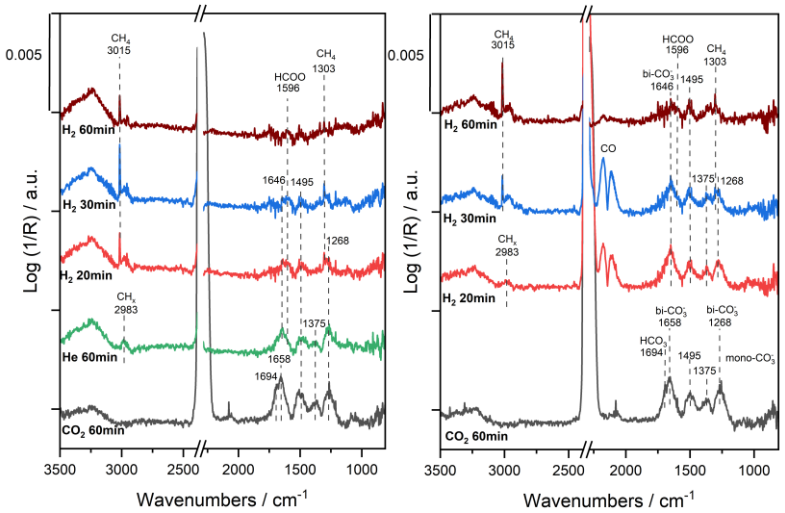

Figure 1. DRIFT spectra of 1K-Fe/YZrOx catalyst measured under sequential exposure to $CO_2$→He→$H_2$ (left) and to $CO_2$→$H_2$ (right) at 15 bar and 300°C.

# Effects of support acidity of noble and transition metal catalysts on the dehydrogenation of Methylcyclohexane

P. Fernandez[1], E. Farah[1], E. Kantarelis[1*]

[1]*KTH Royal Institute of Technology, Stockholm, Sweden*
[*]*ekan@kth.se*

**Keywords:** LOHC, hydrogen, dehydrogenation, surface acidity

**Introduction.** The current climate strategy urges to limit the use of fossil resources and increase the share of renewable energy and hence green $H_2$ is contemplated as a promising alternative. However, it exhibits a low volumetric energy density and thus its storage and delivery represent a major bottleneck. Chemical fixation of $H_2$ in liquid organic molecules-carriers (LOHC) undergoing cyclic hydrogenation-dehydrogenation reactions is a promising alternative. Nevertheless, existing catalysts are not fully optimized to allow the technology to reach its full potential[1]. The acidity of the support in the gas phase dehydrogenation of methylcyclohexane (MCH) has been identified as an important factor for affecting side reactions and more importantly the C-C scission[2]. In view of this, the present study extends to MCH dehydrogenation on a bimetallic -noble (Pt) and transition metal (Ni) catalysts supported on supports of different acidity. The effect of acidity on promoting the C-H scission selectivity is investigated together with anchoring as well as spillover phenomena with a focus on the long-term stability of the catalysts.

**Experimental/methodology.** The gas phase catalytic dehydrogenation of MCH is studied in a fixed bed reactor at a temperature range of 250 - 400 °C and atmospheric pressure (Fig1.). Conventional γ-$Al_2O_3$ was used as typical acidic support, while $MgAl_2O_4$ as non-acidic one and was synthesized according to the co-precipitation method. Pt and Ni were chosen as the noble and transition metals respectively. The MCH was co-fed to the reactor with $N_2$ at a 5:1 ratio. $H_2$ and other gaseous products were quantified using online GC-FID/TCD, while liquid samples were also analyzed offline to determine the selectivity towards toluene.

**Results and discussion.** $NH_3$ TPD experiments (Fig 2) indicate that γ-$Al_2O_3$ exhibits surface acidity as opposed to $MgAl_2O_4$ affecting metal dispersion and secondary reactions. Detailed experimental investigation is ongoing.

## Introduction

Ammonia ($NH_3$), an essential raw material for agricultural fertilizers and synthetic chemicals, has recently attracted attention owing to its applicability as a hydrogen carrier or fuel [1]. Industrial $NH_3$ synthesis is performed by the well-known Haber–Bosch process using Fe-based catalysts, which require harsh reaction conditions (20–30 MPa); thus, the development of both catalysts and reaction systems that allow the synthesis of $NH_3$ under mild conditions is desired to increase the use of $NH_3$. Although Ru supported on rare earth oxides (e.g., $Ru/Ce_{0.5}La_{0.4}Ti_{0.1}O_{1.8}$) [2] are promising catalysts for achieving this goal, Ru catalysts generally suffer from hydrogen poisoning, which inhibits the $NH_3$ synthesis at a high $H_2$ partial pressure in the reaction gas. The optimal H/N ratio of the reaction gas may depend on the reaction temperature owing to the effects of the hydrogen poisoning and the equilibrium concentration of $NH_3$. Thus, in a multi-bed $NH_3$ synthesis reactor that is typically adopted in industrial plants, controlling the H/N ratio for each catalyst bed at different temperatures can potentially improve the $NH_3$ productivity of the reaction system.

## Results and discussion

In this study, first, the H/N-ratio-dependence of the $NH_3$ synthesis activity of the developed Ru catalyst, $Ru(5\ wt\%)/Ce_{0.5}La_{0.4}Si_{0.1}O_{1.8}$, under isothermal conditions was investigated using a fixed-bed reactor. The H/N ratio at which the catalyst exhibited the highest activity shifted toward a lower value at a lower temperature, indicating that the suitable H/N ratio for achieving the optimal activity of the catalyst in $NH_3$ synthesis decreases with decreasing reaction temperature (Fig. 1a). Further, a prototype of a double-bed $NH_3$ reactor (Bed 1: high temperature, Bed 2: low temperature) was constructed to investigate the effect of the control of the H/N ratio for each catalyst bed (Fig. 1b). This control was achieved by the split supply of the feed gas to Bed 2. The $NH_3$ productivity increased as the H/N ratio of Bed 2 decreased with the split supply (Fig. 1c), suggesting that an appropriate control of the H/N ratio in Bed 2 against that of Bed 1 can improve the overall $NH_3$ productivity. Furthermore, the steady-state operation of the double-bed reactor with the recycling of the unreacted gas was also successfully achieved.

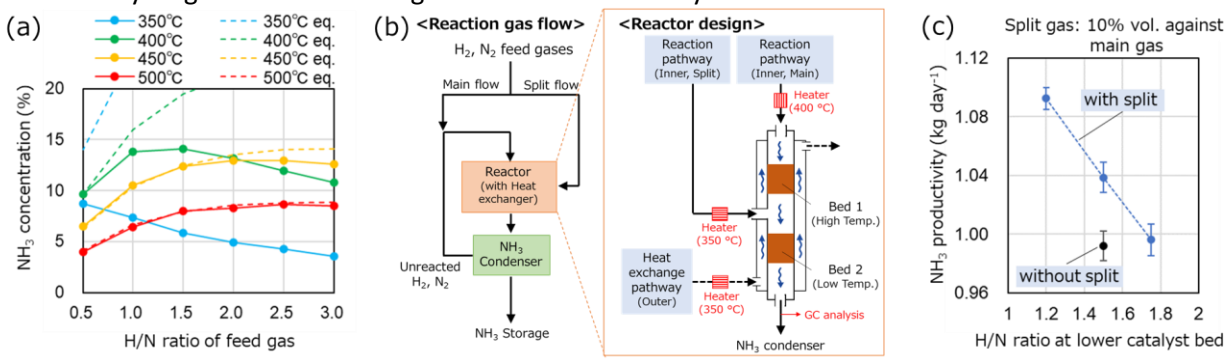

**Figure 1.** (a) H/N-ratio-dependence of $NH_3$ production on $Ru/Ce_{0.5}La_{0.4}Si_{0.1}O_{1.8}$ (catalyst, 1 mL; flow rate, 185 mL $min^{-1}$; pressure, 8 MPa). (b) Simplified gas flowsheet for a double-bed reactor. (c) Effect of the split supply of $H_2/N_2$ gas on $NH_3$ productivity (catalyst, 20 mL for each bed; reaction gas, H/N = 1.5 with a flow rate of 7.4 L $min^{-1}$; pressure, 8 MPa). The split supply gas of 0–100% $H_2/N_2$ (0.74 L $min^{-1}$) was introduced into Bed 2 to control the H/N ratio at 1.20–1.75.

**Introduction**

Power-to-liquid processes can be considered the key for renewable electricity-based liquid fuel generation. [1,2] For this purpose, $H_2$ generated *via* water electrolysis and $CO_2$ provided *via* "carbon capture" are converted together on a suitable catalysts [3] and hydrocarbons, various olefins and methanol can be synthesized via Fischer-Tropsch process (FTS)[2]. For catalyst improvement, *in-situ* and *operando* characterization of FTS catalysts is considered essential to derive structure-activity relationships. [4] In this respect, *operando* X-ray absorption spectroscopy (XAS) can be used to observe structural changes of active sites of heterogeneous catalysts at work. The study is of significant importance, mainly in view of growing demand for energy storage using $CO_2$ as feedstock and renewable electrical energy.[5] For this purposes, a dedicated *operando* reactor system has been recently developed at the CAT-ACT beamline at KIT Light Source [6] that allows an operation close to the industrially relevant FTS conditions [4].

**Results and discussion**

The high-pressure and high-temperature setup was developed in-house [5] and installed at the CAT-ACT beamline.[6] As a pilot study, commercially representative Co-Ni-Re/γ-$Al_2O_3$-FTS-catalysts were investigated at 250°C and 30 bar for more than 300h. The products were investigated by online μ-GC and offline GC-FID to trace the catalytic activity and selectivity. The study showed that considering the high stability of the catalysts, the main reason of catalyst deactivation is due to macroscopic effects such as pore blocking by reaction products and diffusion limitation. The formation of carbon species was confirmed from XAS analysis and investigated by complementary characterization methods, such as Raman spectroscopy, TPH, and TPO. It was found that the formation of atomic carbon, surface carbides, hydrocarbons, graphitic carbon deposits and hydrogen resistant carbon species, led to increased limitation of pore diffusion. Based on this obtained information, we aim to prepare a model FTS catalyst and further optimize it for improved activity and selectivity. For the synthesis of model catalysts, different methods like wet-impregnation, co-precipitation, flame spray pyrolysis etc. are used. Considering different atomic structures produced by different methods, the structure-activity relation is explored in detail, including the metal-support interaction and the role of promoters using *operando* spectroscopy. Part of the findings, will support new energy-related initiatives in Germany, like the Care-o-Sene project [7], a research collaborations focused on the production of sustainable aviation fuel.

# Additively manufactured reactor development for exothermic synthesis

Niko Heikkinen*, Christian Frilund, Niko Virkki, Pekka Simell, Matti Reinikainen, Antti Pasanen

*VTT Technical Research Centre of Finland, Espoo, Finland*

**Keywords:** Additive manufacturing, metallic 3D printing, Fischer-Tropsch synthesis

Current chemical industry is in a phase of transition from fossil raw materials to renewable feedstocks. In order to create feasible synthesis routes for varying renewable feedstocks, novel reactor solutions are required. We present the design and testing of a heat exchanger type reactor, suitable for many exothermic synthesis reactions, such as Fischer-Tropsch and methanol synthesis and methanation. Our approach was to prepare the reactor with metal additive manufacturing (AM) to gain simplification, and most importantly, improved design freedoms over the traditional manufacturing methods of these types of devices. The basic design was inspired by cross-flow heat exchangers, often used in microfluidics, having multiple distinct channels for both the hot fluid and cold fluid side. Cross-flow heat exchangers, can be manufactured by for example diffusion bonding, vacuum soldering and laser welding where etched metal plates are co-joined together to form the channel networks [1].

The laboratory scale unit was designed to meet the requirement for high pressure (up to 30 bar) and moderate temperatures (up to 400 °C). It features a cylindrical channel geometry where the 1.5 mm i.d. catalyst (i.e. gas) filled channels have a 5 mm centre-to-centre distance from each other with a total of 20 catalyst channels of 75 mm height (72 mm actively cooled height). The reactor body features flange surfaces at both ends of the gas channels. This, combined with the straightforward catalyst channel geometry, allows for easy full access to the catalyst channels for convenient particulate catalyst filling and removal. The reactor body also featured integrated pockets for cartridge heaters.

The continuous Fischer-Tropsch experiments were performed at a temperature of 209 – 229 °C, pressure of 20 bar and a $H_2$/CO ratio of 2. The reactor was packed with a catalyst bed of 3.34 gram and reduced at 400 °C with $H_2$ (100 $cm_3$ STP $min^{-1}$ $gcat^{-1}$) for 16 h. In total, five different reaction conditions (from A to E) were tested during the ~390 h time-on-stream. Table 1 presents the reaction setpoint temperature, gas flows, results for CO conversion and selectivity. Especially interesting value is the CH4 selectivity. In a presence of local hotspots in the catalyst bed, typically the CH4 selectivity will be increased. In parallel to the 3D printed reactor development, the same Co-Pt-Si/γ-$Al_2O_3$ catalyst was tested in a traditional tubular reactor without active reaction heat removal. In these experiments, the CH4 selectivity ranged between 16 - 18 m-% at a CO conversion level of ~15 %.

*Table 1, A reaction condition summary for each reaction setpoint. Pressure was fixed to 20 $bar_a$ in all steps.*

| Reaction setpoint | Temperature [°C] | Total inlet gas flow [nL $h^{-1}$] | Gas hourly space velocity [nL $g_{cat}^{-1}$ $h^{-1}$] | CO conversion [%] | Wax ASF-α [-] | $CH_4$ selectivity [m-%] | $C_{5+}$ selectivity [m-%] | O/P ratio ($C_2$-$C_4$) [-] |
|---|---|---|---|---|---|---|---|---|
| A | 209 | 18 | 5.4 | 16 | - | - | - | - |
| B | 209 | 12 | 3.6 | 25 | - | - | - | - |

[3]*Hydrogenious LOHC Technology GmbH, 91058 Erlangen (Germany).*

**Keywords:** LOHC, hydrogen, energy storage, operando, XRD, XAS, catalysis, reactor, single crystal.

**Introduction.** Liquid organic hydrogen carriers (LOHC) represent a promising alternative for the storage and transportation of hydrogen [1,2], enabling high $H_2$ storage densities in a liquid at ambient conditions [3]. In order to make this truly cyclic, a high catalyst stability at the dehydrogenation reaction is necessary.

**Experimental/methodology.** We are studying the dehydrogenation reaction of liquid benzyltoluene at its interphase with solid Pt catalysts. For this, we use high energy X-Ray diffraction (HEXRD) and X-Ray absorption spectroscopy (XAS) to study the reaction in operando under realistic conditions (300 °C, 1-5 bar). These measurements provide atomic-scale insights on the degradation processes of the catalyst during the reaction. We perform these measurements at the ID31 and BM23 beamlines of the European Synchrotron Radiation Facility (ESRF).

**Results and discussion.** In this presentation we will report on the design of a suitable semi-industrial reactor for the operando HEXRD studies, adapted for both model and commercial catalysts. We also describe strategies to optimize the catalyst and diffraction geometry to avoid background scattering and stability problems that arise when studying HEXRD on such commercial scale systems, and discuss about the representativeness of model catalysts for these studies.

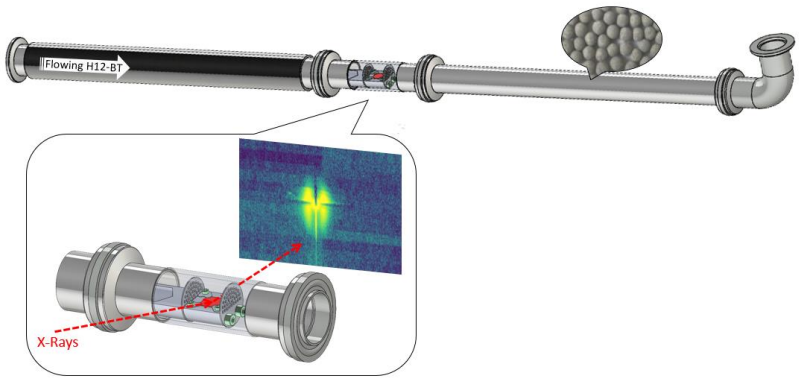

**Image 1. Semi-industrial reactor for LOHC dehydrogenation suitable for operando HEXRD studies.**

Furthermore, we will present the first results from operando HEXRD measurements at ID31, where we can follow the changes of the nanoparticles and their lattice parameter along the reaction.
We will also present the design of a model cell adapted to study the reaction at small scale with XAS on commercial catalysts, and show the first results acquired with this technique, that shed light onto the changing chemistry of the catalyst.

**Key words:** Reactor design, Multiscale modeling, Mass transfer, Rotating fixed bed, Reaction kinetics, RWGS

Converting $CO_2$ into fuels and chemicals is an important step in mitigating the negative environmental impacts of $CO_2$ emissions. Direct use of $CO_2$ is still in its infancy, and syngas, mostly from coal gasification, remains the main source of CO and hydrogen for the chemical industry. Direct production of methanol and dimethyl ether from $CO_2$ is difficult due to low yields and unfavorable thermodynamic conditions. The catalytic reverse water-gas shift reaction (RWGS) offers a promising solution for the conversion of $CO_2$ into fuels. Metal-based catalysts have been developed to improve the efficiency, CO selectivity, and stability of the reaction, with recent advances in catalyst design and a deeper understanding of the reaction mechanism leading to improved catalysts. However, catalyst stability at high temperatures needs further improvement, and the active sites of the reaction remain controversial. Two main mechanisms for the RWGS reaction have been proposed in the literature: the redox mechanism and the formate mechanism.

The XMTE (external mass transfer eliminator) reactor, specifically designed to perform experiments without mass transfer limitations, is highlighted as a key component of the proposed process. This allows accurate determination of microkinetic mechanisms and reaction kinetics, which is critical for developing a microkinetic model and determining kinetic parameters. The reactor design is also discussed as a major improvement over conventional CSTR reactors, as it mitigates the weaknesses of these systems and allows for optimal operation.

In addition to the development of the process and reactor design, the work presented includes the exploration of the RWGS reaction at ambient pressure with the proposed HiFUEL W230 catalyst as a starting point for further research on more complex conversions such as oxidative methane coupling. The results should provide insight into the potential for increasing syngas to fuel production and efficiency, as well as the economics of the process. Overall, XMTE highlights the potential of the proposed process and reactor design to address the global chemical to fuel shortage and improve production efficiency.

**Keywords:** $NH_3$ decomposition, Hydrogen production, Ru/Al@$Al_2O_3$, Core-shell

**Introduction.** Because of climate change resulted form $CO_2$ emissions, the transition from a carbon economy society to a hydrogen economy one is drawing attention. $NH_3$ is a promising hydrogen carrier for its high gravimetric (17.8 wt.% $H_2$) and volumetric (121 kg/$m^3$ in the liquid form) $H_2$ density. Hydrogen production through $NH_3$ decomposition reaction occurs at high temperature (> 450 °C) and requires a lot of energy. Therefore, it is required to develop a catalyst for efficiently producing hydrogen at low temperatures. A broad range of metals have been tested for $NH_3$ decomposition, such as Ru, Ni, Rh, Co, Fe, Pt, and Pd. Among them, Ru has been the most active and stable metal. In addition to active metals, the importance of the catalyst support in the supported catalyst can be emphasized because the support stabilizes the active sites not to be deactivated through sintering and agglomeration. The surface area, mechanical and thermal properties of a support are additional factors that have a significant impact on catalyst performance. Especially, the thermal conductivity of the catalyst support can affect the catalytic performance for the highly exothermic and endothermic reaction. In the Al@$Al_2O_3$ core-shell, the Al core is desirable to guarantee the facilitated heat flux and the $Al_2O_3$ layer is essential to stabilize the Ru metal against sintering and agglomeration under reaction conditions.

In this study, we prepared various Ru/Al@$Al_2O_3$ catalysts with different Al contents by changing the reaction time during wet impregnation method. Then, we applied them to $NH_3$ decomposition reaction and found that the $NH_3$ decomposition activity was dependent on the Al content in the Ru/Al@$Al_2O_3$ catalysts.

**Experimental/methodology.** The activity of the $NH_3$ decomposition reaction was evaluated in a packed-bed reactor at atmospheric pressure. In general, catalyst powder of 100 mg was loaded in the middle of a quartz reactor (O.D. = 9.525 mm, I.D. = 7.745 mm) and retained by quartz wool. Before the activity test, the prepared catalyst sample was first reduced with pure $H_2$ gas at a flow rate of 30 mL/min at 350 °C, if not specified, for 1 h, followed by cooling to 25 °C. $H_2$ gas was then switched with He gas to purge the residual hydrogen at a flow rate of 30 mL/min for 30 min. Then, the feed gas, which was composed of 25 mol% $NH_3$, 70 mol% He, and 5 mol% $CH_4$, was fed into the reactor at a total flow rate of 100 mL/min. $CH_4$ was used as an internal standard. The catalytic activity for $NH_3$ decomposition was monitored by increasing the temperature from 300 to 600 °C under atmospheric pressure. The reactants and products were separated using a Porapak Q column and analyzed using a thermal conductivity detector (TCD) in a gas chromatograph.

**Results and discussion.** Catalytic activity for $NH_3$ decomposition was evaluated for Ru/Al@$Al_2O_3$ catalysts. $NH_3$ conversions as a function of the reaction temperature over different catalysts are shown in Fig. 1. The $NH_3$ conversion at 400 °C decreased in the following order: Ru/Al@$Al_2O_3$(0h) > Ru/Al@$Al_2O_3$(1h) > Ru/Al@$Al_2O_3$(2h) > Ru/Al@$Al_2O_3$(4h) > Ru/Al@$Al_2O_3$(6h). This implied that the catalytic activity was dependent on the Al content in the Al@$Al_2O_3$.

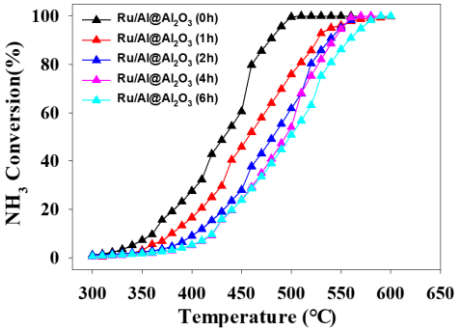

**Figure 1 $NH_3$ decomposition for $NH_3$ decomposition over Ru catalysts. Reaction conditions: feed composition (25 mol% $NH_3$, 70 mol% He, and 5 mol% $CH_4$), WHSV = 60,000 mL/$g_{cat}$/h.**

# Pair Distribution Function for local restructuring phenomena in γ-$Al_2O_3$ supports and active catalyst particles

F. Manzoni[1*], S. Schlicher[2], M. Bauer[2], M. Zobel[1]

[1] *Institute of Crystallography, RWTH Aachen University, Aachen, Germany;*

[*]*manzoni@ifk.rwth-aachen.de*

**Introduction.**
Supported catalysts feature a complex interplay of local disorder and defect structures: small metal clusters, phase transformations of active species, nanoparticle-support interactions creating additional interfacial phases, as well as defective aluminum oxide supports. To adress this plethora of structural motifs, we employ total scattering. While X-ray absorption spectroscopy can element-specifically analyse few coordination shells and short-range order, Pair Distribution Function (PDF) analysis of high-energy X-ray scattering data can access disorder and structure on lengthscales from ~ 1 Å to several tenths of nanometers.

**Experimental/methodology.**
The PDF is a histogram of all interatomic distances in the sample, from which we can evaluate cluster and nanoparticle sizes and structures, local and possibly thermal disorder, as well as support restructuring. In order to achieve ultimate insight into the supported species or the support only, difference-PDFs (d-PDF) are calculated. For this, the total scattering of an unloaded supported is subtracted from the catalyst, both measured at reaction conditions, typically in transmission mode in a glass capillary. We have pushed laboratory PDF to achieve such insight on ex-situ samples [1,2], complementing sub(second) resolution for operando studies at synchrotron sources.

**Results and discussion.**
Here, we show how to access both the structure of active species (Fig. 1a) and the $Al_2O_3$ support (Fig. 1b). The d-PDF refinement in Fig. 1a highlights the sensitivity of the PDF technique to identify the co-existence of $Fe_2O_3$ clusters of only 1 nm diameter next to larger γ-$Fe_2O_3$ nanoparticles on an $Al_2O_3$ support - impossible to detect in common X-ray diffraction data, but well in line with XAS results for the cluster species. [2] The defective short-range order of the $Al_2O_3$ support of this study as well as the one of common $CO_2$ methanation catalysts such as Ni@γ-$Al_2O_3$ can further be characterized via PDF analysis. Despite a recently improved structural model for γ-$Al_2O_3$ by Paglia et al.[3], based on an improved tetragonal structure with defective oxygen sublattice, this model is insufficient to accurately describe the short-range order < 10 Å, see Fig. 1b. We address these deficiencies, which become particularly important when small changes of nanoparticle-support interactions of Ni@$Al_2O_3$ methanation catalysts are followed operando to derive structure-activity relationships for in-situ PDF measurements at P02.1 beamline, PETRA III.

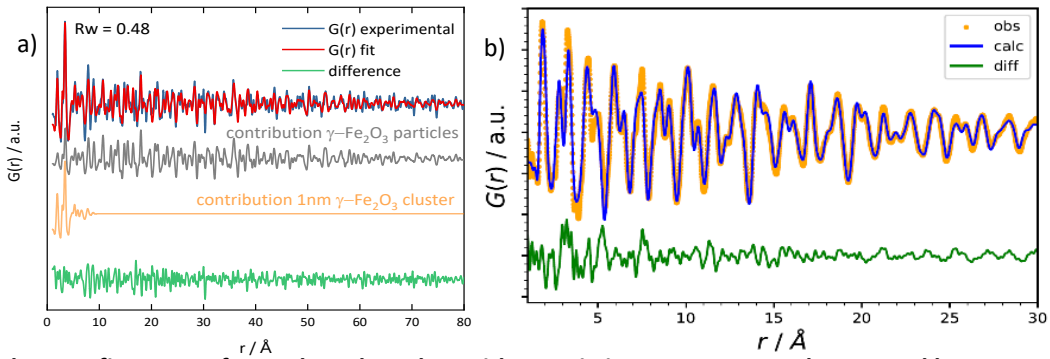

**Fig1: a) d-PDF refinement of an Fe based catalyst with co-existing γ-$Fe_2O_3$ 1 nm clusters and larger particles. b) Local restructuring in γ-$Al_2O_3$**

**Introduction.** The minimization of the energy supply to conduct chemical transformations is one of the fundamental ideologies of process intensification and it is of crucial importance in the journey towards a greener chemical industry. For exothermic processes, packed bed reactors with periodic flow reversal, i.e., reactors in which the feed is switched between the two reactor ends, can be an elegant solution to the problem. Indeed, the heat generated from the chemical reaction is stored in the reactor and it can be used to heat up the cold feed, thus enhancing the reaction rate. After several flow reversals, an oscillatory steady state is attained. Autothermal operations are achieved by carefully calibrating the cycle duration and feed temperature, which can be kept much lower than in conventional packed beds [1]. To date, the main industrial applications of reverse flow reactors are the catalytic oxidation of sulfur dioxide and the combustion of volatile organic compounds (VOCs) [2]. In the present work, a comprehensive model for a reverse flow reactor was developed and implemented. Axial dispersion effects were considered for both the mass and the energy balances to simulate non-ideality for the fluid phase. The chemical reaction was assumed to occur in the solid phase and, therefore, intraparticle diffusion of the reactants in the catalyst was taken into account. The influence of the cycle duration, feed temperature as well as the main kinetic and heat/mass transfer parameters was checked via a parametric investigation.
**Experimental/methodology.** A system of Partial Differential Equations (PDEs) appeared in the definition of the problem, which was numerically solved by the method of lines. The method replaces the spatial derivatives with a central difference approximation. To simulate the alternance of the feed and outlet positions, dedicated oscillating functions were employed.
**Results and discussion.** A reference simulation is displayed in Figure 1.

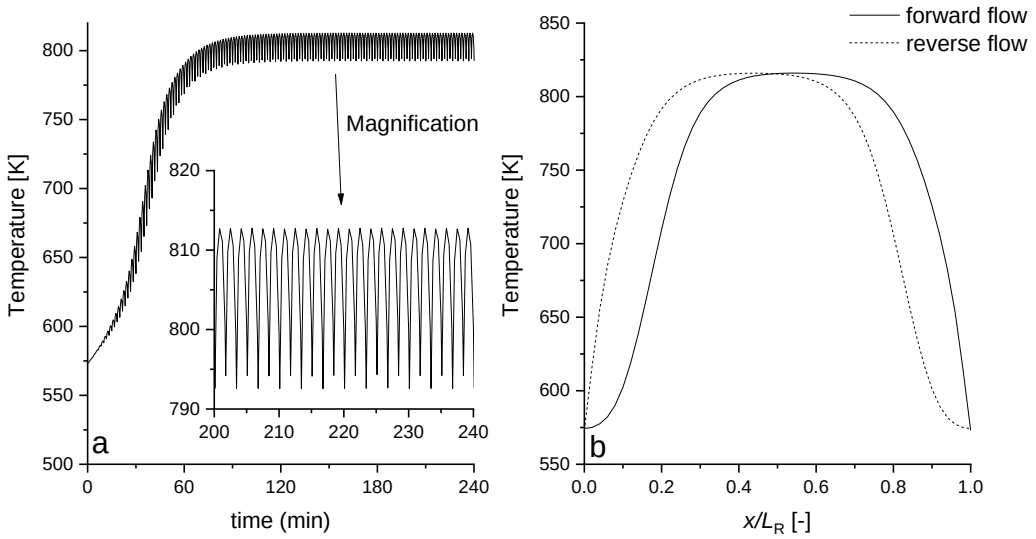

**Figure 1. a) Temperature profile vs time at the reactor center. b) Temperature profile vs the dimensionless axial coordinate.**

As revealed, an oscillatory steady state is attained (Fig. 1a) and a quasi-isothermal temperature profile appeared in the catalytic bed, thus improving the thermal efficiency of the catalytic process. The heat wave goes forth and back in the catalytic bed, producing two symmetric states (Fig.1b). In general, the model was very flexible even predicting even harsh operating conditions.

# Exploring the Benefits of Sorption Enhanced Reforming for Sustainable Hydrogen Production from Biorefinery Side Streams

A. Mostafa[1], I. Rapone[2], A. Bosetti[2], M. C. Romano[1], A. Beretta[1] and G. Groppi[1*]

**Keywords:** Mathematical modelling, $CO_2$ capture, Sustainable hydrogen, Adiabatic reactor.

**Introduction.** Aiming to reach carbon neutrality by 2050, urgent measures to mitigate $CO_2$ emissions are needed. The supply of sustainable hydrogen streams is a key issue, increasing the interest in using waste streams and the by-products of the biorefinery as a source of low-C hydrogen [1]. However, such side streams could contain significant amounts of hydrogen; for thermodynamic reasons, this has a severe impact on the reforming process by limiting the fuel conversion. Sorption Enhanced Reforming (SER) is a promising option for achieving high yields of almost pure hydrogen from such complex streams as the continuous $CO_2$ removal shifts the equilibrium of the hydrocarbons steam reforming (SR) and the water gas shift (WGS) reactions towards the production of $H_2$. In this work, we address the effect of the $H_2$ content in feed of an adiabatic SER reactor using a 1D dynamic heterogeneous reactor model.

**Methodology.** A model of an adiabatic fixed bed reactor was developed on the gProms® platform consisting of mass and energy balances of two well mixed solid phases (sorbent and catalyst) and of the gas flow phase. Ni based reforming catalyst and CaO as a regenerable $CO_2$ sorbent are assumed for this study, and the kinetics of the process are obtained from literature. The modelling of the individual phases highlights the role of each on the thermal behavior of the bed and the global performance of the reactor.

**Results and discussion.** SER combines SR, WGS, and $CO_2$ sorption reactions in a single reactor. The latter is a gas solid reaction that proceeds until saturation of active sorbent, making the process dynamic in the fixed bed configuration. The overall performance of the process was evaluated based on key performance indices (KPIs) calculated as integrals from the start of feeding to the breakthrough time at varying inlet $H_2$ feed content. As shown in Figure 1, presenting the effect of the $H_2$ content in the feed on the KPIs, the increased content of hydrogen in the feed hinders the integral $CH_4$ conversion, reducing the net $H_2$ productivity and the efficiency of $CO_2$ capturing. For a $CH_4$ stream fed to the SER reactor working at an initial solid temperature of 700°C and inlet gas temperature of 600°C, a pressure of 10 bar, with space velocity of 365 $Nm^3/m^3_{rec}h$ (3646 $Nm^3/m^3_{cat}h$), the $CH_4$ conversion dropped from 90% to 82% passing from a feed of pure $CH_4$ to a stream containing 40% mol $H_2$, and the carbon capture ratio (CCR) decreased from 86% to 80%. Nevertheless, to achieve the same result (82% conversion and high purity produced $H_2$ from a 40% $H_2$-diluted stream), a conventional externally heated steam reforming should be run at about 765°C and combined with downstream WGS reactors, $H_2$ purification and $CO_2$ capturing unit.

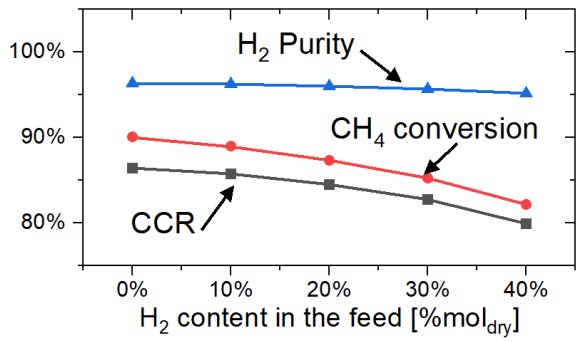

**Figure 1. Effect of $H_2$ presence in the feed on the KPIs of the SER process.**

Extending the analysis to include C2+ hydrocarbons, higher fuel conversion and CCR values are found with a conversion of 88% and CCR of 83% calculated for a stream of 10% $C_3H_8$, 50% $CH_4$, 40% $H_2$ fed to the SER reactor at the same working conditions. This conversion value could be achieved running a conventional externally heated steam reforming at about 780°C to fully convert the higher hydrocarbons and limit the extensive methanation.

# $CO_2$ methanation: Effect of $H_2$ load fluctuation on the performance of a monolithic reactor.

Douglas E. Pérez Vilela[1], Ximena García C.[2*]

[1] *Department of Chemical Engineering, University of Concepcion, Faculty of Engineering (Chile)*
[*] *xgarcia@udec.cl*

**Introduction.** The monolithic honeycomb reactor has proven to be an attractive technological proposal to be used in CO2 methanation since it presents a lower resistance to mass/heat transport and a negligible pressure drop in contrast to the fixed-bed adiabatic reactor [1]. On the other hand, the reactor must respond quickly and adequately to the disturbance of the $H_2$ load, being this type of reactor an excellent option for this [1]. As a contribution, the effect of the fluctuation of the $H_2$ load on the performance of this equipment in $CO_2$ methanation was studied, using an axial symmetric, heterogeneous, and non-stationary 2D mathematical model on a full scale.

**Methodology.** First, a base case was considered, where $NiAl(O)_X$ was selected as the catalyst with the kinetics of Koschany et al., 2016. A step-type reduction of 20 % of the $H_2$ load was chosen. The effect of the type of catalyst and the consideration of the Reverse Water Gas Shift (RWGS) on the performance of the monolithic reactor before the perturbation of the $H_2$ load were also studied. A 0.5 wt. % Ru/γ-$Al_2O_3$ catalyst with the kinetics of Falbo et al., 2018 (Case 1) and a 5 wt. % $Ni_{0.4}Co_{0.6}/SiO_2$ catalyst prepared by our research group [2] (Case 2) were used, where the RWGS is considered as an additional reaction for this.

**Results and discussion.** In Figure 1.a. the recovery time to the new steady state ($t_{rec,EE}$) is shorter for case 1 compared to the base case and case 2. Additionally, the maximum temperature of the reactor ($T_{max}$) is lower and remains practically constant throughout the dynamic operation of the equipment, especially for case 2. It can also be seen that the location of the hot spot in the dimensionless axial coordinate (z/L) is farther from the reactor inlet for case 1 (in case 2 no hotspot was observed (z/L = 1) during dynamic operation of the reactor). These trends are consistent with what has been mentioned for Ru in the literature (higher dynamic/thermal stability compared to Ni [1]). In Figure 1. b, the highest $CO_2$ ($XCO_2$) conversion at the reactor outlet (z/L = 1) is obtained for the base case, because of a higher reaction rate than other cases. For case 2, the trends observed above are generated by the combination of Ni with Co and the use of other support. It is also important to mention that the yield towards methane was 21 % for case 2, implying that the RWGS prevailed for the operating conditions proposed in this study. This has the effect of reducing the temperature increase caused by the heat of reaction released in the methanation of $CO_2$, thus observing an additional effect that helps improve thermal/dynamic stability compared to other cases. In conclusion, there is an important effect of the fluctuation of the $H_2$ load on $CO_2$ methanation performance when changing the catalyst and considering the RWGS reaction. These factors are important to improve the stability of the dynamic operation of this reactor in an industrial application.

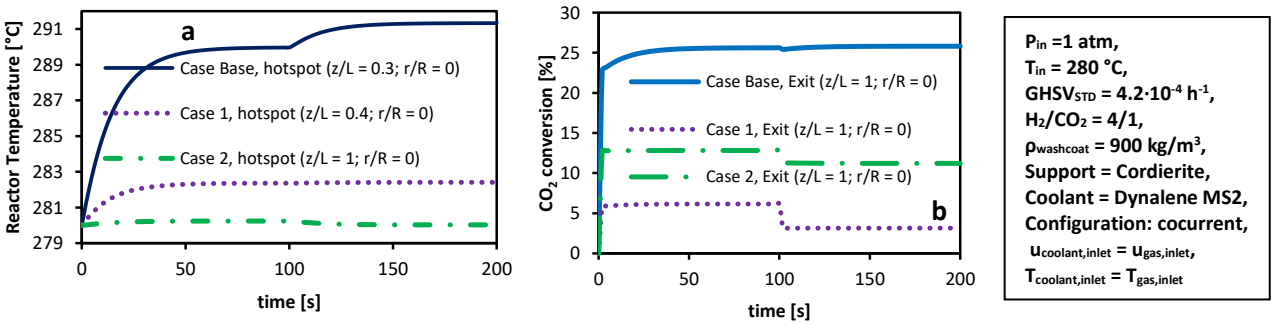

**Figure 1. Temperature (a) and conversion (b) profile in the centerline of the reactor (r/R = 0) as a function of time. The dimensions and physical properties of the reactor of ref. [3]**

**Keywords:** Hydrogen, energy carrier, formic acid, catalysis, heterogeneous catalyst, solid molecular catalyst (SMC), single-site catalyst, ruthenium, covalent organic framework (COF)

**Introduction.**
A sustainable future of the chemical industry and our society necessitates an efficient utilization of resources. Limiting the use of precious metals such as ruthenium, palladium or platinum during chemical reactions and adopting novel carbon feed streams such as $CO_2$ over fossil fuel based resources are key factors to achieve this. One promising strategy for the storage of hydrogen generated by water electrolysis unifying these two concepts is the utilization of solid molecular catalysts (SMCs) for the decomposition of formic acid (FA) to and synthesis of formic acid from $CO_2$ and $H_2$. SMCs offer a fusion of the high activity of homogeneous catalysts and the straightforward handling and recycling of heterogeneous catalysts.[1, 2]

**Experimental.**
Based on a procedure previously reported by Wang et al., a new versatile subclass of BINAP containing SMCs for the formic acid decomposition reaction was developed utilizing a Pd catalyzed Suzuki crosscoupling polymerization reaction of brominated BINAP oxide and a aromatic boronic ester (Fig. 1).[3, 4]

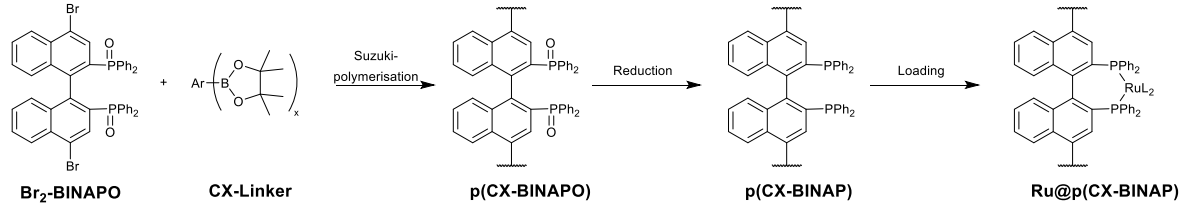

**Fig. 1 Synthesis of $RuL_2$@p(CX-BINAP) catalysts via $Pd(PPh_3)_4$ catalysed Suzuki cross-coupling reaction, reduction via transfer oxygenation with $PPh_3$ and $HSiCl_3$ and loading via wet impregnation in MeOH.**
After the phosphine oxide moieties in the polymeric material were reduced by a transfer oxygenation utilizing $PPh_3$ and $HSiCl_3$ and wet impregnation of the obtained supporting material using noble metal salts, the catalytically active materials were obtained. Subsequently, the SMCs were investigated for their activity in the decomposition of aqueous formic acid to $H_2$ and $CO_2$ in batch and continuous reactions.

**Results and discussion.**
A series of SMCs containing BINAP moieties with tuneable surface areas exhibiting turnover frequencies (TOFs) of up to 134 000 $h^{-1}$, turnover numbers (TONs) of up to 921 000 and selectivities of up to 99.97 % in the decomposition of formic acid were obtained after wet impregnation with different ruthenium salts. We propose the active catalyst species in pristine samples to be Ru single sites as confirmed by HR-TEM and XPS measurements of pristine catalyst samples.

**Introduction:**

One approach to mitigate $CO_2$ emissions is the Power-to-Liquid (PtL) concept which converts green $H_2$ and $CO_2$ to liquid fuels/chemicals, such as methanol.[1] The hydrogenation of $CO_2$ to methanol, compared to conventional methanol synthesis from syngas (CO and $H_2$), is thermodynamically unfavored and the higher water content in the product stream leads to faster catalyst deactivation.[2] The modification of the widely applied methanol catalyst Cu/ZnO/$Al_2O_3$[1] with $ZrO_2$, instead of $Al_2O_3$ prompts a higher tolerance against water-induced deactivation.[3] Flame spray pyrolysis (FSP) is a fast and reproducible catalyst synthesis method which allows tuning of particle size, crystallinity and morphology by varying parameters, *i.e.* precursor feed rate, solvent, concentration, etc.[4] We used FSP to generate Cu/ZnO/$ZrO_2$ catalysts with different particle sizes to study their influence on activity in $CO_2$-methanol synthesis.

**Experimental/methodology:**

By varying the feed rate (2 – 12 mL/min) of precursors (Cu acetate monohydrate, Zn acetate dihydrate, Zr oxide 2- ethylhexanoate dissolved in MeOH/EHA 1:1) a series of Cu/ZnO/$ZrO_2$ catalysts was synthesized *via* FSP. The catalysts were thouroughly characterized by XRD, ICP-OES, BET, STEM-EDX and $H_2$-TPR. Prior to the reaction the catalysts were reduced in 10% $H_2$ in $N_2$ at 275 °C. $CO_2$ methanol synthesis conditions (3:1 $H_2$:$CO_2$ in $N_2$) were applied at 235 °C and different pressure ranging from 1-40 bar.

**Results and discussion:**

Applying a lower feed rate leads to a smaller flame. Hence, the particles have a shorter residence time in the flame preventing larger particle formation and crystallization.[5] X-ray diffraction patterns show an increase in crystallinity and crystallite size with increasing feed rate, as previously reported for other systems[6], which could also be confirmed with STEM-EDX. The catalytic performance in $CO_2$-methanol synthesis is shown in Figure 1 for three catalysts. The catalyst synthesized with 2 mL/min feed rate shows the highest selectivity towards methanol but the lowest $CO_2$ conversion. The opposite trend was observed for the catalysts prepared at 5 and 8 mL/min which show higher activity accompanied with a loss in selectivity. Since the particles become larger with a higher feed rate, this may indicate that the reaction is structure-sensitive and dependent on the particle size. Our work acts as basis to obtain a more fundamental understanding of this attractive catalyst system.

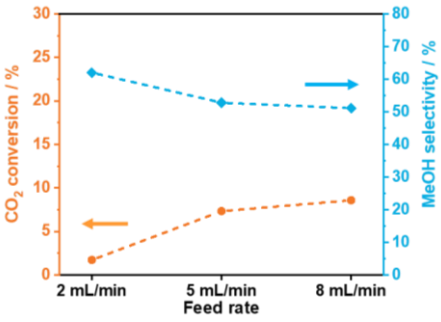

**Figure 1: $CO_2$ conversion (orange) and methanol selectivity (blue) of catalysts prepared with different feed rates (reaction conditions: 20 bar, 235 °C, 85% $H_2$:$CO_2$ = 3:1 in $N_2$, WHSV = 36 L/$g_{cat}$·h).**

**Keywords:** Dimethoxymethane, H2-efficient, Hβ zeolite, structure-activity relationship

**Introduction.** Dimethoxymethane (DMM), the shortest of the homologous oxymethylene ethers ($OME_x$) with the general structure $H_3C\text{-}O\text{-}(CH_2O)_x\text{-}CH_3$, is a promising diesel additive since it has the potential to decrease harmful soot emissions during combustion, thus eliminating the typical soot $NO_x$ tradeoff. Besides, intensive research is being made to sustainably produce DMM from $CO_2$ and renewable $H_2$ feedstocks. Yet, its current production relies on an oxidative pathway where the stoichiometrically produced $H_2$ is directly oxidized and $H_2O$ is formed as by-product. Our group thus recently presented a novel DMM synthesis strategy *via* the gas-phase nonoxidative dehydrogenation of methanol, where $H_2$ is produced as by-product instead of $H_2O$.[1-4] The potentially closed $H_2$ circulation significantly improves the overall energy efficiency of the process, making this approach highly attractive.

**Experimental/methodology.** For selective DMM synthesis *via* dehydrogenation of methanol, a bifunctional catalyst with both acidic and dehydrogenative sites is required. Our group previously designed a Cu/Hβ-zeolite catalyst, where a high $SiO_2/Al_2O_3$ ratio (520) is achieved by dealumination of the zeolite, and on which afterwards 1 wt.% Cu is loaded by incipient wetness impregnation.[1] Combining these results with literature research,[5] Ag was introduced as dehydrogenative metal instead of Cu on the optimized Hβ support. Ag/Hβ was then tested as catalyst in the non-oxidative dehydrogenation of methanol to DMM in a fixed-bed continuous flow gas-phase reactor setup and parameters such as Ag loading, catalyst pre-treatment, and reaction temperature were optimized. Furthermore, stability tests and various characterization techniques, *e.g.*, XRD, ICP-OES, $H_2$-TPR, FTIR spectroscopy, and $N_2$-physisorption, were performed, to shed light on possible structure-activity relationships.

**Results and discussion.** The current Cu/Hβ catalyst shows high DMM selectivity (81.5%) with a methanol conversion of 3.7% after 1500 min time on stream (TOS) at 200 °C.[1] However, a long induction time of 800 min, low stability, and low conversion when compared to the calculated equilibrium conversion (7.6%) are the existing challenges upon using the Cu/Hβ catalyst. When using the optimized Ag/Hβ, improved catalyst stability as well as a shorter induction time (600 min) could be achieved, while maintaining high DMM selectivity (73.1%) with a methanol conversion of 2.1% after 1500 min at 240 °C.[2] Interestingly, no formaldehyde is formed when increasing the reaction temperature to 280 °C when using Ag/Hβ as a catalyst, suggesting a well kinetic matching between the dehydrogenative and acidic functionalities of Ag/Hβ. $H_2$-TPR and XRD results show that both $Ag_2O$ and metallic $Ag^0$ species are present on the catalyst. These results leave room for deeper investigations on possible structure-activity relationships, such as PDF and *in situ* FTIR analysis.

**Keywords:** micromixer synthesis, MicroJet Reactor (MJR), Confined Impinging-Jet MicroReactor (CIJMR), continuous-flow synthesis, mixed metal oxides, precious metall nanoparticles, platinum nanoparticles, platinum nickel nanoparticles, core/shell nanoparticles, fuel cell catalysts

**Introduction.** In this contribution we report on an actual development in the field of fabrication and new application of micro-structured devices in chemistry enabling (multiphase) mixing, reactions and heat transfer which are otherwise not possible with standard devices. In the field of material syntheses micro-structured devices allow a strict control over process parameters offering the possibility to design materials with tunable properties such as particle size distribution, shape, composition and surface properties. In turn, the mentioned features contribute remarkably to the performance of catalytic materials [1].

**Experimental/methodology.** We implemented a new design of a CIJMR in form of a cross mixing device analogous to the Synthesechemie (Dr. Penth) or Ehrfeld MicroJet Mixer (MJM) described by Dittert *et al*. [2]. The newly constructed MJR is completely dead volume free and allows the continuous preparation of nano-scale metal and metal chalcogenide particles by precipitation reactions from appropriate precursor solutions. Due to the short mixing times in the µs to ms range crystallite nucleation and crystal growth are well separated from another and enable concentration limited particle growth and thus nano-particle (NP) syntheses. To generate a deeper understanding of the processes within the MJR modelling was performed by the CFD program ANSYS Fluent including also chemical reactions. Our CFD modeling investigations were based on RANS, LES and DES approaches. It can also be broadened to syntheses in supercritical media as well as high-throughput approaches generating gradient libraries for high-throughput parameter screening.

**Results and discussion.** We started our research on the MJM with the syntheses of alternative support materials for fuel cell application to replace the standard carbon instable at typical operating conditions of PEMFC. Additionally, we applied this reactor concept by preparation of nano-scale sulfides, selenides and tellurides for photovoltaic and other applications. We widened our expertise on precious metal NP in form of single element, mixed metal (alloys/intermetallic phases) or core-shell NP by investigating the system Pt – Ni. As intended, the particle syntheses in the size range between 5 - 10 nm was successful. We also extended the reactor system and currently use a second microreactor in series of the first reactor for the syntheses of either Ni@Pt or PtNi@Pt - NP. These particles are in the focus for applications as fuel cell electrocatalysts. The stabilization of these particles was mostly achieved by chemical agents utilizing alkali metal hydroxides (Co4Cat process) [3].

All in all, we will present a significant contribution for the development of new approaches for a more effective synthesis and screening of new functional materials for industrially relevant applications.

**Keywords:** Dry reforming of methane, Ni/$ZrO_2$+$Al_2O_3$, Sr promoter

**Introduction.** Chemical conversion of global warming gases of $CH_4$ and $CO_2$ via dry reforming of methane (DRM) is an urgent need of this era. DRM is an endothermic reaction that cheap Ni-based catalytic active metal has opted for. A combination of $ZrO_2$ and $Al_2O_3$ support was used due to their better dispersion and thermal stability [1, 2] . The DRM reaction is: $CH_4 + CO_2 = 2H_2 + 2CO \quad \Delta H^0_{298\,K} = +247.31 \frac{kJ}{mol}$

The strontium (Sr) addition to Ni-based catalysts increases the dispersion of Ni and improves the resistance to carbon deposition [3]. The use of Sr promoter over novel $ZrO_2$+$Al_2O_3$ supported Ni catalyst can be expected to be highly efficient towards DRM. Herein, we have synthesized 5Ni+3Sr/ $ZrO_2$+$Al_2O_3$ catalyst and characterized and employed it for DRM.

**Experimental/methodology.** The catalyst is prepared by impregnation of the required amounts of Ni $(NO_3)_2.6H_2O$ by 5.0 wt.% loading of Ni, Sr $(NO_3)_2$ promoter over 10wt%$Zr_2O_3$+90wt%$Al_2O_3$ support. The dried, calcined and powdered catalyst is packed in a fixed bed. The catalyst is pretreated under $H_2$ stream at 700°C for 60 min and then switched to gas feed (3:3:1 for $CH_4$, $CO_2$, and $N_2$ gases) at 800°C with a space velocity of 42,000 ml/gcat $h^{-1}$. The outlet gas from the reactor is analyzed by GC. $CH_4$ and $CO_2$ conversions were calculated:

$$CH_4 \text{ Conversion } (\%) = \frac{CH_{4,in} - CH_{4,out}}{CH_{4,in}} \times 100 \,;\; CO_2 \text{ Conversion } (\%) = \frac{CO_{2,in} - CO_{2,out}}{CO_{2,in}} \times 100$$

**Results and discussion.** XRD result shows the presence of cubic $ZrO_2$ phase. All the catalysts have type IV isotherm. DRM reaction generated 78% $CH_4$ and 82% $CO_2$ conversions up to 430-minute time on stream at 800°C. The incorporation of Sr enhanced the basicity and moderates the NiO interaction with support. The weight loss over 5Ni+3Sr/ $ZrO_2$+$Al_2O_3$ catalyst is also minimal. All total, 3wt% Sr incorporation into 5wt%Ni/$ZrO_2$+$Al_2O_3$ catalyst brings as high as 90% $CH_4$ conversion and $CO_2$ conversion.

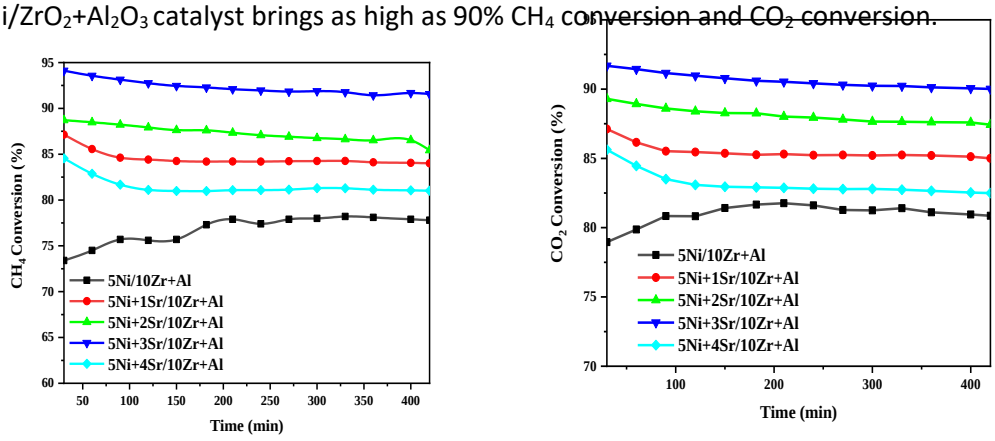

**Figure $CH_4$ and $CO_2$ convesions vs Time on stream**

**Introduction.** In order to facilitate widespread use of polymer electrolyte membrane fuel cells (PEMFCs), development of more affordable systems is needed, which involves replacement of the traditional Pt/C electrocatalysts with more corrosion resistant and cheaper ones. In our previous studies this concept was realized by synthesizing anode Pt electrocatalysts with different Pt content supported on a conductive and corrosion resistant composite consisting of oxophilic metal M (M: W, Mo)-doped $TiO_2$ and various carbonaceous materials [1-2]. In such a unique material system, the corrosion resistance and nanoparticle-stabilizing ability of $TiO_2$, the good co-catalytic properties of doping metals as well as the large surface area and high conductivity of active carbon are brought together. The transition metal dopant facilitates the oxidation of CO at much lower potentials than on pure Pt, which is important when hydrogen from steam reforming is considered as fuel. Moreover, the Sn dopant is believed to promote the oxygen reduction reaction (ORR), thus Sn-doped $TiO_2$-carbon composites can also be used at the cathode side. The aim of the present work is the study of $Ti_{(1-x)}Sn_xO_2$-C (x: 0.1-0.3) composite supported Pt electrocatalysts.
**Experimental/methodology.** The synthesis of novel $Ti_{(1-x)}Sn_xO_2$-C (x: 0.1-0.3, C: Black Pearls 2000 (BP), CABOT)) composite supports with mass ratio of the $Ti_{(1-x)}Sn_xO_2$/C= 75:25 and 25/75 was performed by multistep sol-gel synthesis followed by high-temperature treatment (HTT) in Ar. Raman spectroscopy, XRD, XPS, SEM/EDX and TEM were used to characterize the bulk and surface microstructure. Electrocatalytic performance of the 20 wt.% Pt catalysts was studied by cyclic and $CO_{ads}$-stripping voltammetry measurements combined with long-term stability test; catalytic activity of the catalyst samples was also tested in the ORR and hydrogen oxidation reaction (HOR) by rotating disc electrode technique [2].
**Results and discussion.** The electrocatalysts prepared according to an adapted method developed for Mo-containing composites [2] consisted of rutile crystallites and metallic Sn in a small amount (1-2%), had an inhomogeneous microstructure and exhibited unusually low electrochemical surface area (ECSA) (~30 $m^2/g_{Pt}$). To avoid these shortcomings, the synthesis of the Sn-containing composite was modified by simultaneous introduction of the precursors of Sn and Ti at the beginning of the synthesis, before the addition of carbon and the aging step. We demonstrated that the composites and Pt electrocatalysts obtained using this preparation route were free of segregated $Sn^0$ or $SnO_2$ phases, possessed a more homogeneous/uniform mixed oxide distribution, and the ECSA values were comparable to those obtained on Mo-based composites of similar composition (~60-80 $m^2/g_{Pt}$). In order to clarify the possibility of using these catalysts as anode or cathode in PEMFCs, their electrocatalytic characteristics were investigated in the ORR and the HOR. A sharper increase in the HOR current observed on Sn-containing catalysts compared to Pt/C indicated the efficiency of this catalytic system. It has been demonstrated that the behavior of electrocatalysts mainly depended on the synthesis route used in the preparation of the composite support materials and was not influenced by the Ti/Sn ratio.

The electrochemical $CO_2$ reduction reaction ($CO_2$RR) offers the opportunity to convert CO2 into fuels and chemical feedstocks, while mitigating anthropogenic CO2 emissions and storing renewable energy. Multi-carbon ($C_{2+}$) compounds (e.g., ethylene, ethanol, propanol) are among the most attractive $CO_2$RR products owing to their commercial value and high energy densities. However, optimizing the selectivity of $CO_2$RR electrocatalysts towards one particular product remains a crucial challenge that is not trivial to .address because multiple intermediates are involved in the $CO_2$ to $C_{2+}$ conversion pathway
In these context, unambiguous relationships between the activity, selectivity and stability of the catalyst .with its structure and composition becomes crucial to make concrete progress in this field
In this talk, I will showcase a few examples which highlight how shape-controlled nanocrystals can contribute to address the selectivity challenge in $CO_2$RR. First of all, I will discuss how size control of Cu nanocubes and Cu octahedra has revealed the importance of facet-ratio to maximize the selectivity towards ethylene and methane, respectively. Second, I will present our recent computational-experimental efforts towards using well-defined NCs, in the framework of a tandem scheme based on the coupling of Cu nanocrystals with CO-generating Ag, to elucidate selectivity rules at the hydrocarbons/alcohols branching nodes in the $CO_2$RR pathway and increase ethanol production. Finally, I will discuss a few examples .adressing catalyst stability during CO2RR, a topic which is still underexplored

# Toward Enhancement of Activity of Low-Pt-Content-Electrocatalysts for Oxygen Reduction

Pawel J. Kulesza*, Iwona A. Rutkowska, Aldona Kostuch, Sylwia Zoladek

Faculty of Chemistry, University of Warsaw, Pasteura 1, PL-02-093 Warsaw, Poland

The proton-exchange membrane fuel cell (PEMFC) technology is one of the most promising approaches for energy conversion in automotive applications. The progress in this subject is greatly hindered by the high cost and scarcity of the state-of-the-art platinum-based materials which are regarded as the most effective cathode catalysts. Therefore, most of the current research studies have been devoted to the optimization of active centers and maximization of their utilization, which should allow the lowering of the cathode Pt loadings without loss of performance and durability. Unfortunately, the problem of electrochemical stability and the danger of generation of higher quantities of the undesirable hydrogen peroxide intermediate may become even more serious in the case of systems utilizing lower amounts of the Pt catalyst.

Among important strategies is the hybridization, activation, and stabilization of carbon-supported Pt catalysts by functionalization through admixing with certain nanostructured and typically substoichiometric metal oxides. Special attention is paid to application of the bi- or multi-metallic Pt-based alloys in their various forms and structures. Among other important issues are such features as porosity, hydrophilicity, and degree of graphitization of carbon components, in addition to the existence of metal–support interactions, high electrochemical active surface area, electronic structure of interfacial Pt, and the feasibility of adsorptive or activating interactions with oxygen molecules. Hybrid supports, which utilize metal oxides (e.g., $CeO_2$, $WO_3$, or $ZrO_2$) have been demonstrated to stabilize Pt and carbon nanostructures and diminish their corrosion while exhibiting high activity toward the four-electron (most efficient) reduction of oxygen.

The rotating ring-disk electrode (RRDE) methodology, are typically applied to diagnose mechanisms and dynamics of ORR. A tempting alternative for recording the electrochemical responses is to integrate the current and to report charge passed as a function of time. Chronocoulometry offers important advantages including good signal-to-noise ratio because the act of integration smooths random noise on the current transients. Furthermore, by integrating the responses, it is possible to separate surface phenomena (e.g. interfacial oxidation of carbon or platinum) more readily from bulk electrochemical responses (ORR).

# Tailoring of Fe single-atoms on hollow carbon spheres for the oxygen reduction reaction

[5] *Instituto de Ciencia y Tecnología del Carbono, INCAR-CSIC, Francisco Pintado Fe 26, 33011 Oviedo, Spain*

**Keywords:** oxygen reduction, Fe electrocatalysts, single-atom catalyst, hollow carbon spheres

**Introduction.** Single-atom catalysts (SACs) have emerged as one of the most promising alternatives to noble metal-based catalysts for highly efficient oxygen reduction reaction (ORR)[1]. A broad range of non-platinum group metal electrocatalysts has been developed, among which Fe−N−C nanostructures have been considered one of the most promising candidates. Most strategies for the synthesis of SACs need delicate procedures. Therefore, developing strategies to tailor atomically better dispersed Fe sites in N-doped carbon supports is highly desirable. Herein, we reported the design of hollow carbon spheres with highly stable Fe centres and enhanced catalytic activity in ORR.

**Experimental/methodology.** Carbon spheres (CSs) were synthesized by sol-gel polycondensation through Stöber's method, followed by thermal annealing and silica etching, according to a previously reported procedure [2]. The hollow CSs were then doped with nitrogen and Fe by adapting a procedure reported elsewhere [3]. The effect of metal loading was studied by varying the proportion of metal precursor during the synthesis. In addition, the role of each precursor during the synthesis of the optimized electrocatalyst was elucidated by preparing additional materials in the absence of specific precursors. All samples were physicochemically characterized using suitable techniques, including high-resolution transmission electron microscopy (HRTEM) and scanning transmission electron microscopy-high angle annular dark field imaging (STEM-HAADF) in combination with energy-dispersive X-ray spectroscopy (EDX). The catalytic performance of the samples in ORR was assessed by electrochemical measurements using a three-electrode cell configuration in alkaline media.

**Results and discussion.** The performance of the Fe-N-doped hollow CSs in ORR seems to be governed by the quality of Fe species rather than the overall Fe load. Nitrogen seems to modulate the charge density nearby the active sites and limit the agglomeration of the metal precursor during the synthesis. Glucose enhances the metal-heteroatom coordination and subsequent dispersion of active sites on the carbon surface. The activity of the best-performing metal-free CSs ($CS_7$Fe-N) in ORR is still far from that obtained with the commercial noble metal-containing Pt/C. Nevertheless, it is thus noteworthy that $CS_7$Fe-N revealed superior stability (97%) than Pt/C (92%) in the same conditions. Therefore, the methodology herein reported opens a window of possibility for the development of highly stable ORR electrocatalysts based on single-atom Fe-N hollow CSs.

**Keywords:** hydrogen production, mesoporous carbon, nanoparticles, surface modification, plasma oxidation, oxygen functional groups

**Introduction.** The effective use of the active phase is the main goal of optimisation of the supported catalysts. Carbon supports do not interact strongly with the metallic or metal oxide phases; thus, oxidative treatment is often used to enhance the number of anchoring sites for deposited particles. Oxidation treatments can deteriorate the textural properties or electrical conductivity of carbons, especially those exhibiting a well-developed porosity and a specific surface area. Cobalt spinel, $Co_3O_4$, is an active phase for multiple thermal (e.g. $N_2O$ decomposition) and electrochemical (e.g. oxygen evolution reaction) catalytic processes, and its dispersion controls the overall effectiveness of the catalyst [1,2]. In this study, we set out to investigate whether the oxidation pretreatment of mesoporous carbon allows the depositing of a higher loading and a more dispersed cobalt active phase.

**Experimental/methodology.** We used graphitic ordered mesoporous carbon obtained by a hard-template method from KIT-6 silica as active phase support. To obtain different quantities and speciation of oxygen functional groups, we used a low-temperature oxygen plasma. By varying the generator power, pressure in the plasma chamber, and treatment time, we obtained a broad range of plasma oxidative capabilities. The oxidised carbons were then subjected to equilibrium adsorption of $Co^{2+}$ ions from a pH 5 buffer solution. After filtering, the cobalt oxide phase was deposited by washing the filtrate with KOH. The main methods used to characterise the studied materials were X-ray photoelectron spectroscopy for surface oxygen content and speciation, along with transmission electron microscopy for the determination of the quality of the deposited cobalt oxide phase. Catalytic performance was evaluated in the oxygen evolution reaction in a three-electrode setup in chronoamperometric mode.

**Results and discussion.** We have found that the oxidative pretreatment of mesoporous carbon influences the speciation of the deposited cobalt oxide phase. Moreover, the activity of the electrocatalysts in the oxygen evolution is positively correlated with the relative content of COO-type groups and negatively correlated with the C=O-type groups on the carbon support. Additionally, the high relative content of COO-type groups on the carbon support is correlated with the presence of well-dispersed $Co_3O_4$ nanoparticles. The results obtained indicate that to achieve a better dispersed and more catalytically active material, it is more important to control the speciation of oxygen functional groups rather than to maximise their total concentration. The results obtained with the model systems were used to develop highly active oxygen evolution electrocatalysts with an active $Co_3O_4$ phase supported on mesoporous carbon.

# In situ XAS investigation of carbon-supported single-site catalysts for water oxidation

Wenchao Wan,[1] Liqun Kang,[1] Zongkun Chen,[1] Serena DeBeer,[1] Robert Schloegl,[1] Saskia Heumann[1*]

[1]*Max Planck Institute for Chemical Energy Conversion, 45470 Mülheim an der Ruhr, Germany*

**Keywords:** carbon material, in situ X-ray absorption spectroscopy, single-atom catalysis, water oxidation

**Introduction.** Atomically dispersed single metal atoms on highly conductive carbon support have emerged as a new catalyst class for electrocatalysis. Metal species in the form of single-site catalysts (SSC) well coordinated with non-metal atoms on the carbon support, such as N and C, which contains both the features of molecular and heterogeneous catalysis, provide an ideal platform for mechanistic study.[1-3] However, study on the structural evolution of this type of catalyst to acquire the real active species has barely reported. Herein, a novel and convenient coordination strategy was reported to construct a series of SSCs containing the most widely studied transition metals (Fe, Co, Ni) in the form of a single element (Fe/Co/Ni) and dual elements CoFe and NiFe. The atomic feature of the as-prepared SSCs was systematically characterized by a series of techniques, such as high-angle annular dark-field scanning transmission electron microscopy (HAADF-STEM) and X-ray absorption spectroscopy (XAS). The oxygen evolution reaction (OER) performances of SSC show that two metal elements (CoFe and NiFe) are superior to these of SSC with a single metal element. In situ XAS together with the post-HAADF-STEM measurements clearly show that the newly formed new active species containing the M-O-M moieties during the OER is the real active sites.

**Experimental/methodology.** The catalysts were synthesized through a coordination strategy combined with a pyrolysis process. In particular, a molecular containing phenol groups was used as the ligand to coordinate Fe, Co, and Fe ions in water, and further mixed with C/N containing complex. The mixture was subjected to a pyrolysis process in an inert atmosphere to obtain the final catalysts.

**Results and discussion.** The atomistic dispersion of the metal elements on carbon was directly observed through HAADF-STEM as shown in **Figure 1a**. The metal content ranges around 3-5 wt.% determined by EDX. The local structure of the metal centers was identified by XAS and other spectroscopic techniques. All these results indicate the atomic dispersion of the metal species on carbon, and the metal atoms are well coordinated by the non-metal N/O atoms. In situ XAS measurements together with post-HAADF-STEM measurements demonstrate that the structural restructure occurred to all the SSCs during the OER which promotes the formation of hydroxides or oxides containing the typical M-O-M (M=Fe, Co, and Ni) moieties **Figure 1b-d**. In addition, the coordination and the oxidation of the metal centers also vary under different potentials. Our research offered strong experimental evidence in the structural reconstruction of the carbon-supported single-site catalysts for the OER, which may reflect the fact that carbon-supported SSC act as a pre-catalyst instead of the real active phase for the OER.

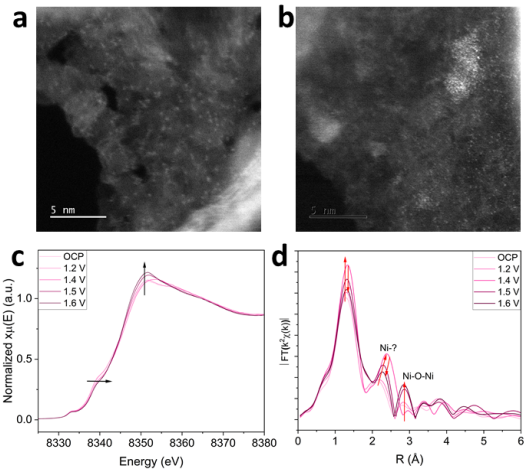

**Figure 1.** HAADF-STEM images of the Ni SSC (a) before and (b) after the OER. (c-d) In situ XAS spectra of Ni SSC under the OER.

# Electrocatalysts for Alkaline Oxygen Reduction and Evolution Reactions

S. Wierzbicki[1,2], T. Darvishzad[1], J. Gryboś[1], P. Stelmachowski[1], Z. Sojka[1], K. Kruczała[1*]

[1]Faculty of Chemistry, Jagiellonian University in Krakow, Gronostajowa 2, 30-387 Krakow, Poland.
[2]Doctoral School of Exact and Natural Sciences, Jagiellonian University in Krakow, Gronostajowa 2, 30-387 Krakow, Poland.
*kruczala@chemia.uj.edu.pl*

**Introduction.** The growing global demand for energy combined with the need to protect the natural environment, makes the development of an alternative to fossil fuels, clean energy sources a crucial issue. Hydrogen has been considered one of the most promising chemicals for energy storage, which can be converted back into heat and electrical energy. The most efficient way to generate electricity from hydrogen is the fuel cell (FC) technology. In the recent decade, a significant amount of research has focused on the development of anion-exchange membranes (AEMs) and oxygen reduction and evolution reaction (ORR and OER) catalysts to be used in AEMFCs [1-4].

**Experimental/methodology.** Multi-walled carbon nanotubes (MWCNTs) doped with nitrogen and sulfur atoms and with deposited manganese–cobalt spinel catalysts were studied to reveal the role of active centers in the ORR and OER in alkaline media. Commercial MWCNTs were oxidized by boiling in concentrated nitric acid and then doped with N and S heteroatoms using thiourea precursor. Manganese-cobalt spinels supported on the MWCNTs were synthesized by a microwave-assisted solvothermal route. The catalysts were comprehensively characterized by transmission electron microscopy (TEM), X-ray diffraction (XRD), Raman spectroscopy (RS), and X-ray fluorescence spectroscopy (XRF).

**Results and discussion.** The spinel active phase consists of well-dispersed nanocrystals with sizes in the range of 5-8 nm. The electrocatalytic activities in ORR and OER were examined in alkaline media by rotating ring-disc electrode (RRDE) and rotating disc electrode (RDE) techniques, respectively. It was found that N- and S-doped MWCNT catalysts exhibit high activity in ORR with $E_{onset} \approx 0.890$V, and a number of electrons exchanged $n \approx 3.83$, which remained essentially the same, within experimental error, upon spinel deposition (**Figure 1a**). The addition of the spinel phase does not improve the electrocatalytic properties. The advantage of the dispersed spinel active phase was observed in OER, the activity of these samples was comparable to that of the $RuO_2$ benchmark catalyst (**Figure 1b**). The calculated bifunctional potential gap values, $\Delta E = 0.78$ V, confirm the high activity of the developed catalysts. In the case of ORR, the observed reactivity was accounted for by the incorporation of nitrogen and sulfur to the MWCNTs, whereas for OER the locus of the active centers is moved towards the manganese-cobalt spinel nanocrystals dispersed on the MWCNTs matrix. Functionalization of the latter with N and S atoms is then catalytically redundant.

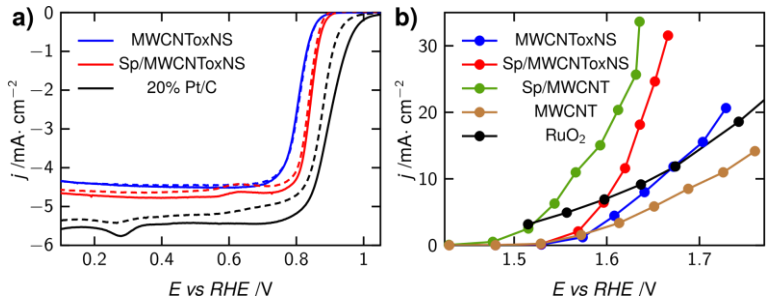

**Figure 1.** LSV profiles recorded during ORR (**a**), and OER I-V curves **(b)** at 1600 RPM in $O_2$ and Ar-flushed 0.1 M KOH solution, respectively.

# Activity and durability of hierarchical Fe-doped $Ni(OH)_2$/Ni catalysts for alkaline oxygen evolution reaction: In situ XANES studies

Sang-Yeon Lee[1], Yong-Kul Lee[1*]

[1]*Department of Chemical Engineering, Dankook University, 152 Jukjeonro, Yongin 16890, South Korea*

**Keywords:** NiFe-LDH, alkaline oxygen evolution reaction, XANES

Nature of activation and degradation of NiFe layered double hydroxide (NiFe-LDH) and hierarchical Fe-doped Ni(OH)2/Ni has been explored using in situ X-ray absorption near edge structure (XANES) spectroscopy coupled with cyclic voltammetry (CV) in a potential range of 0–0.9 V (vs. Hg/HgO). A series of NiFe-LDH samples have been prepared by electrodeposition with varying Ni/Fe molar ratios from 99:1–16:84. Fe has been doped on Ni(OH)2 and anodized Ni as Fe-Ni(OH)2 and Fe-ANi, respectively. The case of conventional NiFe-LDH, obtained by the co-electrodeposition, presents lower overpotential in OER than Ni(OH)2, but still shows 15% degradation during 100 CV cycles. The in situ XANES analysis confirmed that γ-NiOOH was still isolated during CV cycles, as seen in Ni(OH)2. In contrast, Fe-doped Ni(OH)2 obtained by adding 20 ppm of Fe to the electrolytes (Fe-Ni(OH)2) led to a lower overpotential and showed high activity and stability during 100 CV cycles. To realize a better conductivity environment, anodic oxidation of Ni was applied at 3 V to obtain Ni(OH)2 on the surface of the Ni phase (ANi). It shows even better activity and stability than NiFe-LDH. The Ni phase of Fe-ANi is maintained as Ni2+ regardless of potential changes. Fe-ANi also shows a lower white line intensity and a higher pre-edge intensity in the Fe K-edge XANES, which proves the adsorption of Fe on the surface of Ni. Overall, these findings provide important insight that a highly active and durable OER catalyst can be obtained by anodic pretreatments of Ni foam followed by Fe-dopping.

# CuCr Catalysts For Ammonia Electro-Oxidation: A Study On Activity And Selectivity

**Annie Cleetus[1*], Hanan Teller[1], Alex Schechter[1]**

[1] *Department of Chemical Sciences, Ariel University, Israel*

**e-mail: annieclEetus2@gmail.com*

**Keywords:Ammonia oxidation, electro-catalyst, bimetallic catalyst, non-noble catalyst**

**Introduction.**

Ammonia is considered as one of the most efficient hydrogen carrier, as it contains 17% of $H_2$ by weight. Being carbon free at the end use, energy generation from ammonia ($NH_3$) has become a matter of interest in the past years. In the efficient conversion of ammonia to electricity in fuel cell technologies, such as portable power sources, a major challenge is the identification of a suitable catalyst that can selectively oxidize $NH_3$ to $N_2$ at low over potentials, and ambient pressure and temperature, at high rates. In this work, low cost bimetallic carbon supported CuCr catalysts which were found to be more active than elemental Cu and Cr were prepared and tested for activity and selectivity towards AOR.

**Experimental/methodology.**

A simple sodium borohydride reduction method was used for the synthesis of the catalyst. The formation of alloy was confirmed through PXRD. AFM and HR-SEM was used for further characterization of the nano-particles. Electrochemical measurements were performed using a potentiostat to study activity and stability. Online mass spectroscopy and UV-Visible spectroscopy was used to identify the byproducts of the process.

**Results and discussion.**

The CuCr activity was found to increase with Cu content, however it was higher than pure Cu, which reveals a synergistic effect between Cu and Cr in the oxidation of $NH_3$, due to electronic interactions between Cr and Cu [1]. Cyclic voltammetry on stable catalysts with 90% Cu in 0.1 M KOH and 0.1 M $NH_3$ revealed a peak current density of 22 mA/mg at a scan rate of 20 mV/s compared with 0.04 mA/mg for Cr and 6.9 mA/mg for Cu under the same conditions (Fig 1.). PXRD measurements have revealed the presence of oxides and hydroxides of Cu and oxides of Cr along with the metallic phases on the electrode surface that contributes to the activity of the catalyst. Mass spectrometry measurements have identified $N_2$ as the major product of oxidation along with trace amounts of $N_2O$ and $N_2H_4$. Subsequent LSV coupled with chronamperometry at 1.1 V (vs RHE) in 0.1 M KOH and 0.1 M $NH_3$ for 1hr has shown an increase in peak current density for the initial 3hrs followed by a decrease suggesting the saturation of the active sites in the first 3 hrs of oxidation. Pre-oxidation in KOH was found to improve the activity and stability of the catalyst over time. Dissolution of Cu and Cr ($CrO_4^{2-}$) into the solution has also been identified through ICP and UV-Vis spectroscopy. 90% Cu catalyst of CuCr in similar conditions show higher peak current density compared to commercial Pt catalyst (14.8 mA/mg) thus corroborating the potential of CuCr based catalysts for ammonia oxidation in fuel cells in the future.

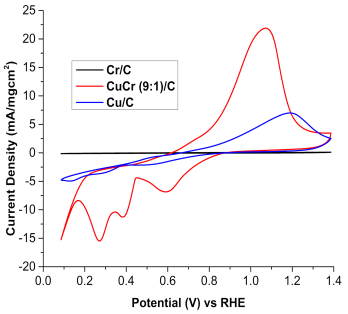

Figure 1: Variation of current density Vs potential of the catalysts in 0.1M KOH and 0.1M $NH_4OH$ solution at a scan rate of 20mV/s.

**Introduction.** Carbon materials are desirable for electrocatalysis, owing to their superior conductivity, stability, and structural tunability. Platinum and platinum alloys supported on carbon blacks (CBs) are benchmark catalysts for Proton Exchange Membrane Fuel Cells (PEMFCs). Platinum confinement in the pore system of mesoporous carbon prepared by hard-templating was shown to suppress catalyst degradation in PEMFCs.[1] Despite the precise control over the morphology, the template removal and low yield restrict industrial application. As a remedy, we establish an easy synthesis of carbon gels through sol-gel polymerization of resorcinol (R) and formaldehyde (F), ultimately resulting in graphitic mesoporous carbons.
**Experimental/methodology.** The general reaction consists in mixing R and F in the presence of a basic catalyst. Then, the solution is heated for a certain time to obtain crosslinked gels.[2] By incorporation of specific metal salts, we synthesize mesoporous and highly graphitic carbon spheres (GRF-Sphere) in a simple way without employing any hydrothermal steps, solvent exchanges, supercritical drying, or post-activation techniques.
**Results and discussion.** The conventional carbonized RF spheres are not suitable for PEMFCs, as they are commonly non-graphitic and microporous (Fig. 1.). However, modification of the synthesis route allowed the production of mesoporous, highly graphitic carbon spheres (GRF-Sphere), thanks to the porogenic and graphitization effect of $Fe(acac)_2$. Pt nanoparticles with an average size of 3 nm were deposited in the pores of GRF-spheres by incipient wetness impregnation and subsequent annealing. The catalyst Pt/GRF was highly active for the ORR, i.e., with a specific acitivity > 0.45 mA $cm^{-2}_{Pt}$. The stabilization of the active phase by pore confinement was demonstrated with an accelerated stress test in the typical operating range of a PEMFC (Fig. 1). Pt/GRF retained a significantly higher share of active surface area compared to a common Pt/Vulcan catalyst. When the concentrations of R and F were increased 25-fold, a graphitic, mesoporous gel (GRF gel) was obtained at a volume yield of 70 g $L^{-1}$, underlining the potential of this process for industrial application.

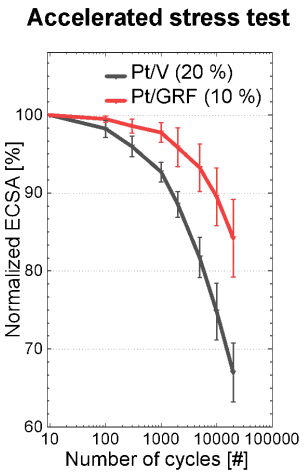

**Fig. 1. Properties of conventional RF, vs. RF graphitized with $Fe(acac)_2$. The specific activity (SA), mass activity (MA), electrochemically active surface area (ECSA) of Pt/GRF and stability results in comparison to Pt/Vulcan are shown.**

**Keywords:** hydrogen evolving reaction, iron complex, electrocatalysis

Non-noble metal-based systems are intensely studied in the electrocatalytic hydrogen evolution reaction (HER) as cost-efficient substitutes for platinum. In this study, we report the catalytic behavior of four Fe(II) complexes containing the bidentate ligands 2-(2′-pyridyl)benzoxazole ($\mathbf{L^{O}}$), 2-(2′-pyridyl)benzthiazole ($\mathbf{L^{S}}$), 2-(2′-pyridyl)benzimidazole ($\mathbf{L^{NH}}$) and 2-2′-bipyridyl ($\mathbf{L^{py}}$) in the electrocatalytic HER. In the ligand series, a heterocyclic donor group by the 2-pyridyl function is systematically changed. This small structural feature is expected to define the predominant equilibrium species in solution and affect the stabilization of the reduced complex forms. Indeed, earlier studies suggested that catalytic oxidations by Fe(II) pre-catalysts containing the $\mathbf{L^{O/S/NH}}$ ligand series exhibited activity and stability of the corresponding oxidized species depending on the systematically varied, non-coordinating heteroatom [1,2].
The complexes were isolated and analyzed as solids by known procedures [1]. Electrochemistry was performed in a 3-electrode cell, using a glassy carbon working electrode, under argon. Hydrogen production during controlled potential electrolysis in an H-cell was quantified by GC. Solution equilibria were analyzed by UV-vis spectroscopy, or electrochemistry upon titration of the complex with the ligand, or trifluoroacetic acid.
We found that the differences in the reduction potentials of the compounds in acetonitrile correlate with the basicity of the ligands. The addition of trifluoroacetic acid as proton source suggested that the Fe(II) $\mathbf{L^{S/O/NH}}$ complexes act as homogeneous catalysts in the HER. Kinetic studies and controlled potential electrolysis were used to explore the structure-activity relationships. The catalytic activity could be associated with the $\mathrm{Fe}(\mathbf{L^{S/O/NH}})_2^{2+}$ structural moiety. In contrast, the complex with $\mathbf{L^{py}}$ was inactive in catalysis, due to the persistence of the low spin $[\mathrm{Fe}(\mathbf{L^{py}})_3]^{2+}$ species in the reaction mixture. As shown by our findings, the differences in the redox behavior of the compounds correlate with the basicity of the ligands that in turn depend on the non-coordinating O/S/NH function.

**Introduction.** Since the pioneer work of Jaramillo et al. in 2007[1], $MoS_2$ has been considered promising to replace platinum (Pt) for the Hydrogen Evolution Reaction (HER) electrocatalysis. If the activity of $MoS_2$ has been linked with the total edge site concentration for both hydrotreatment reactions and HER reaction, no evidence has been given yet that well-performing $MoS_2$ catalysts for hydrotreatment reactions could lead to improved HER catalysts as well. In this study, we compare the thiophene hydrodesulfurization (HDS) and HER activities of a series of $MoS_2$ catalysts prepared with or without citric acid (CA) and with or without cobalt (Co) or Pt single atoms as promoter.

**Experimental/methodology.** Three series of mono- bi- and trimetallic ($MoS_2$/C, Co-$MoS_2$/C and Pt1%-$CoMoS_2$/C) catalysts with different amounts of CA were prepared by an incipient wetness impregnation method[2]. The thiophene HDS tests were carried out within a differential glass reactor at 623 K. Electrochemical measurements were carried out using a bi-potentiostat (Autolab PGSTAT302N) with a catalyst loading of 300 $\mu g_{powder}$ $cm^{-2}$.

**Results and discussion.** The comparison between the activity in thiophene HDS and HER on $MoS_2$ catalysts (Figure 1) reveals that for both reactions the addition of CA is beneficial on the three composition series up to an atomic ratio of CA/metal of 2. This positive effect could be linked to a decrease in slab length as revealed by High Angle Annular Dark Field Scanning Transmission Electron Microscopy. The introduction of Co or (Co+Pt) further increases the activity towards both reactions, the best catalyst being Pt1%-$CoMoS_2$/C prepared with the atomic ratio of CA/metal of 2. This parallel in activity ranking is in agreement with active sites being the same for both reactions, providing rational guidelines on how to improve the HER activity.

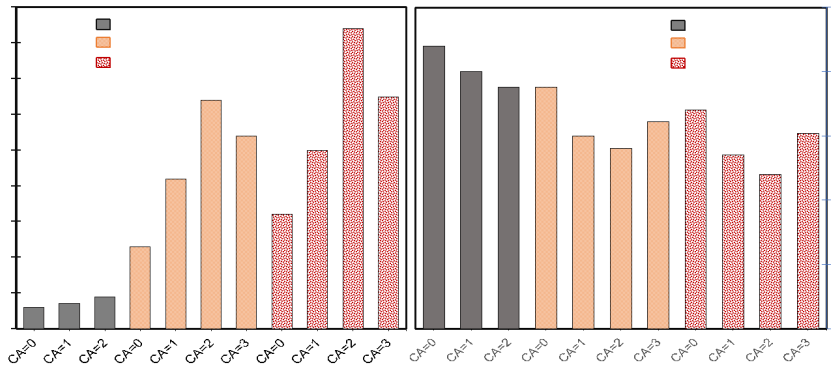

**Figure 1. Effect of promotion and citric acid addition in $MoS_2$/C activity for HDS and HER reactions.**

Finally, the dissolution of Mo, Co, and Pt elements during HER was monitored *in situ* using an eletrochemical flow cell connected to an inductively coupled mass spectrometer for the best-tested catalyst. Mo dissolves, particularly in the first cycles in agreement with the leaching of partially sulfided Mo entities[2]. Thus, improving the Mo sulfidation degree should lead to more stable catalysts.

# Electrosynthesis of ammonia with high selectivity and high rates via engineering of the solid-electrolyte interphase

Shaofeng Li*, Jens K. Nørskov*, Ib Chorkendorff*

*Department of Physics, Technical University of Denmark, Kongens Lyngby, Denmark*

**Keywords:** ammonia, electrosynthesis, SEI, high selectivity, high rates

**Introduction.** Ammonia ($NH_3$) is one of the most abundantly produced chemicals, with an annual production exceeding 182 million tonnes.[1] Currently, the only known reliable method of electrochemical $NH_3$ synthesis at ambient temperature is lithium-mediated nitrogen reduction (LiNR).[2] Although the accurate mechanisms are still not entirely understood, it is broadly believed that this LiNR process relies on the metallic lithium reduced from $Li^+$ to dissociate $N_2$ followed by a sequence of electron and proton transfers to form $NH_3$ with suitable proton donors.[2] Our recent work has demonstrated 78% FE at a current density of -0.004 A $cm_{geo}^{-2}$ achieved by adding 0.6 to 0.8 mol% oxygen to the 20 bar $N_2$ atmosphere, which is attributed to the modification of the solid-electrolyte interphase (SEI) layer formed between the active (lithium) surface and the electrolyte during operation.[3] To overcome the gap of low current density, we also proposed increasing the current density (e.g., -0.1 A $cm_{geo}^{-2}$) by the use of high surface area copper electrodes.[4] The challenge still remains to achieve high FE and a commercially relevant current density (i.e., around -1.0 A $cm_{geo}^{-2}$) in a single system.

**Experimental/methodology.** The electrochemical measurements were conducted with Bio-Logic SP-200. The produced $NH_3$ was quantified by colorimetric indophenol method. X-ray photoelectron spectroscopy (XPS) was conducted on a ThermoScientific Thetaprobe instruments with an Al Kα x-ray source and base pressure below $9.0\times10^{-10}$ mbar. X-ray diffraction (XRD) patterns were recorded on a Malvern Panalytical Empyrean X-ray diffractometer ($K\alpha_1$ = 1.540598 Å). Our calculations are based on density functional theory (DFT) within the generalized Kohn-Sham scheme, using in the Vienna Ab initio Simulation Package (VASP).

**Results and discussion.** In this work[5], we systematically address this challenge by modifying the SEI layer and improving the accessible surface area (per geometric surface area) simultaneously. We concentrate on determining the dynamic changes of the SEI under different experimental conditions and understanding how the SEI layer improves the performance of the LiNR process by tuning the ionic conductivity. We study several electrolytes, and suggest that a fluorine-based electrolyte is the best. In combination with a highly porous Cu electrode, we demonstrate 95 ± 3% faradaic efficienct (FE) at a current density of -0.1 A $cm_{geo}^{-2}$ under 20 bar $N_2$. In addition, we show a FE of 71 ± 3% is achievable at a current density of -1.0 A $cm_{geo}^{-2}$, delivering an $NH_3$ production rate of 2.5 ± 0.1 μmol $s^{-1}$ $cm_{geo}^{-2}$ (Figure 1B). The new results are attributed to the uniform lithium fluoride (LiF)-enriched SEI layer that facilitates even lithium deposition and suppresses the uncontrolled electrolyte degradation. The different SEI layers were characterized with XPS and XRD, where we confirmed the presence of lithium fluoride. Moreover, we also found that the produced $NH_3$ does not only exist in the electrolyte, but also in the gas phase and in the deposited layer with SEI, and the $NH_3$ concentration distribution in different phases is highly related to the lithium salt used.

**Keywords:** molten proton conductor, fuel cell, methanol reformer, hydrogen, copper catalyst

**Introduction.** A high-temperature proton exchange membrane fuel cell (HT-PEMFC) based on PBI doped with phosphoric acid (PA) can be functional between 120–200°C [1,2]. A traditional methanol reforming copper-based catalyst operates between 200 and 300°C. To address the mismatch of the operating temperatures between the fuel cell and the methanol reformer, the simplest and most efficient approach would be to develop a new type of fuel cell capable of working at above 200 °C. We have proposed the concept of internal reforming methanol fuel cell (IRMFC), where the methanol reformer is incorporated into the anode compartment of a HT-PEMFC. This system could effectively operate at 200–210 °C [1]. We have recently prepared a molten proton conductor electrolyte membrane (PBI membrane doped into molten $CsH_5(PO_4)_2$), with promising performance at 160–220 °C [2]. In the present work, we report on the performance of last generation IRMFC modules (reformers, single cells and stacks).

**Experimental/methodology.** IRMFC modules were designed, constructed, assembled and tested based on: (i) Combustion synthesized CuZn-based methanol refroming catalysts (mainly CuZnGaAlOx (CZGA) and commercial HiFUEL R120 catalyst (CuZnAlOx) as reference material) supported on the GDL of a carbon paper (catalyst loading = 100 mg/cm$^2$). (ii) $CsH_5(PO_4)_2$-doped polybenzimidazole (PBI) molten proton electrolyte membrane sandwiched between two gas diffusion electrodes (GDEs; Pt loading= 0.5 mg/cm$^2$) and MEAs active area of 10-27 cm$^2$; (iii) Au-coated Al plates (1 mm thickness; double serpentine flowfields). The integrated cells (1 cell and 4 cell modules) were tested at 160-220$^o$C under various $H_2$/He and $H_2O$/MeOH feedstreams. An electronic load was employed for the collection of polarization curves were collected via an electronic load, while inlet/outled gas streams were monitored with a GC/MS system.

**Results and discussion.** This study demonstrated the functionality and the promising prospects of last generation of IRMFCs, where a molten proton conductor fuel cell (MPCFC) was integrated with a methanol steam reformer, and efficiently operated on hydrogen or reformate feed streams at 220 °C. Either the single cell or the cells of the stack, showed a stable electrochemical behavior, since a hydrogen-rich stream (>99.9% methanol conversions; <0.5% CO selectivity) was provided by the methanol reformer, resulting in a mean cell voltage of 0.7 V at 200 mA/cm$^2$ (220 °C), keeping an OCV >1 V, similarly with the corresponding runs under simulated hydrogen streams. All the modules were tested over a period of 1 month including startup/shutdown cycles. Humidifcation of the anode feedstream was favorable in order to avoid dehydration of the electrolyte, while observed degradation was also attributed to the proton conductor loss in CL (EIS and CV analysis), a behavior that has been improved with last generation membranes [3].

**E-mail corresponding author: b.ligt@tue.nl*

**Keywords**: $CO_2$ electroreduction, copper oxide, ethylene, ethanol

Despite its promising performance for $C_{2+}$ product formation in electrochemical reduction of $CO_2$ ($CO_2RR$), Cu-based catalysts exhibit a relatively poor selectivity towards important chemical intermediates such as ethylene and ethanol. Up to 16 different products can typically be formed during $CO_2RR$.[1] Cu is the only element that can form C-C bonds at an appreciable rate.[2] Therefore, it is critical to better understand the active sites of Cu-based electrocatalysts, as it can lead to better catalyst design with improved selectivity towards desired products. A common approach is to investigate the reactivity of well-defined surface terminations of Cu, which can be achied by employing shape-controlled (nano)particles.[3] Here, we expanded on such studies by evaluating the impact of Au on well-defined $Cu_2O$ surfaces for the electrochemical reduction of $CO_2$. This promoter metal was chosen, because it can reduce $CO_2$ to CO, which is widely accepted as the key intermediate for C-C coupling.[2,4]

In this study, $Cu_2O$ nanocubes that predominantly expose the (100) facet were synthesized with a ligand-free method. The (100) facet is more active in the production of ethylene at the expense of unwanted methane formation, which takes place predominantly at the (111) facet.[3] The surface of the nanocubes was decorated with Au nanoparticles, as can be seen from the TEM images in **Figure 1**. The electrocatalytic tests were done in a range of potentials in neutral electrolyte (0.1 M $KHCO_3$). With Au as promotor, we found that more CO is formed, which can facilitate the formation of $C_{2+}$ products. The nanostructured catalysts were (electrochemically) characterized prior to and after $CO_2RR$, leading to valuable insights in the differences in activity and morphology.

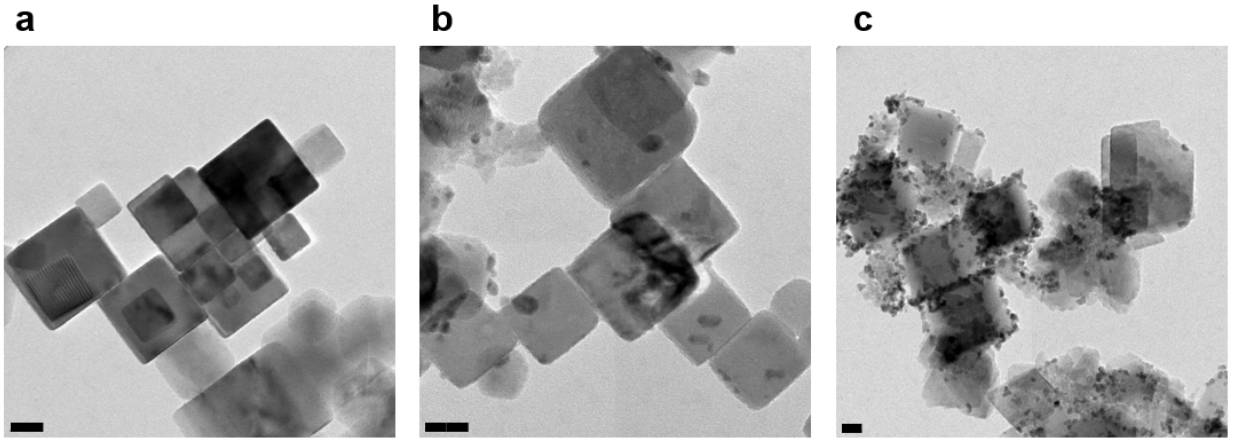

**Figure 1.** TEM images of **a**, $Cu_2O$, **b**, 1Au/$Cu_2O$ and **c**, 5Au/$Cu_2O$. The scalebars correspond to 20 nm.

**Keywords:** $CO_2$ electroreduction, nickel catalysts, long-chain products.

**Introduction.** Despite an intense catalyst search lasting for more than three decades, to date, only copper-based catalysts have been known to generate multicarbon products in $CO_2$ electroreduction at appreciable rates and are mostly limited to ethylene and $C_2$-$C_3$ oxygenates.[1]

**Experimental.** Catalyst evaluation was performed on gas diffusion electrodes. Structural properties under reaction were assessed by X-ray absorption near edge spectroscopy (XANES) and extended X-ray absorption fine structure (EXAFS). CO adsorption strength was evaluated by CO stripping. Mechanistic aspects were studied by reduction of selected compounds and density functional theory (DFT) simulations.

**Results and discussion.** We disclose herein that catalysts derived from inorganic nickel oxygenates (INOs), herein exemplified for the best performer phosphate-derived nickel (PD-Ni), can generate 29 products including up to $C_6$ hydrocarbons and $C_4$ oxygenates with relevant Faradaic efficiencies (FE).[2] Sustained operation yielded ca. 12% FE for $C_{2+}$ products (**Fig. 1a**). The distribution of the predominant hydrocarbons closely fitted the Anderson-Schulz-Flory (ASF) distribution (**Fig. 1b**). The unique feature of these materials is the presence of stable, polarized $Ni^{\delta+}$ sites observed by operando XANES (**Fig. 1c**) and associated to Ni-O bonds via operando EXAFS, which can bind CO moderately as revealed by CO stripping analysis (**Fig. 1d**). Mechanistic studies on PD-Ni suggest that $Ni^{\delta+}$ sites favor a path reminiscent of the Fischer-Tropsch process where COOH + $CH_x$ coupling is followed by $CH_x$ insertions. Advanced product quantification enabled us to identify performance trends arising from variation of key operation parameters (*e.g.*, electrolyte pH). Our results unlock the latent reactivity of polarized nickel to give access to a broader pool of valuable products.

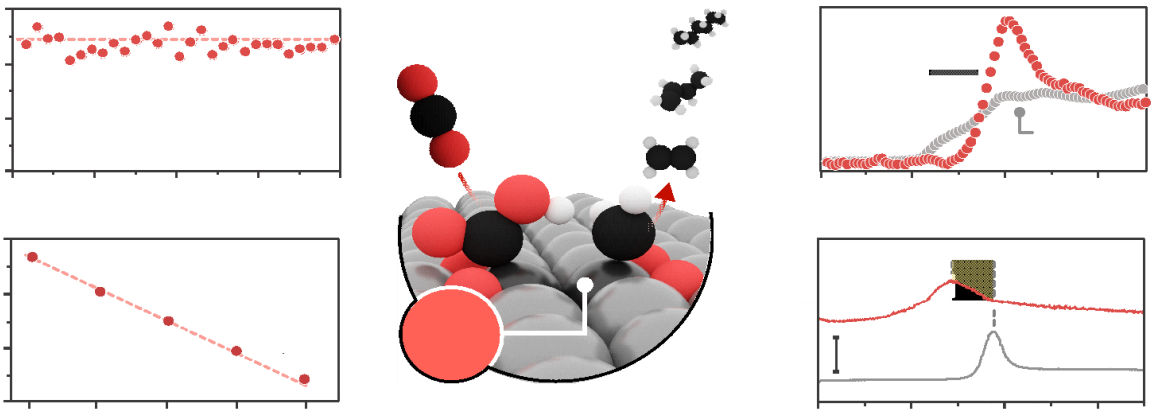

**Figure 1. (a) FE for $C_2$-$C_6$ products. (b) Fitting of the hydrocarbon distribution to the ASF model. (c) Observation of polarized Ni sites in PD-Ni by operando XANES. (d) Milder CO adsorption strength on PD-Ni by CO stripping analysis.**

**Introduction.** Polymer electrolyte membrane fuel cells (PEMFC) convert chemical energy into electricity in an efficient and environmentally friendly way. Electrocatalysts are the primary elements of PEMFCs. The most commonly used commercial PEMFCs electrocatalyst, the carbon supported platinum (Pt/C), is known to suffer from electrocorrosion and is not resistant to CO poisoning. In our previous studies conducted in a three-electrode electrochemical cell, higher stability and CO tolerance was demonstrated for mixed oxide - carbon $Ti_{(1-x)}Mo_xO_2$-C (C= Black Pearls 2000 (BP), Vulcan XC-72) composite supported Pt electrocatalysts compared to commercial Pt/C [1]. Due to their conductivity, stability, and high specific surface area (SSA), novel carbonaceous materials such as carbon nanotubes, graphene, graphene nanoplatelets (GNP) offer new solutions for above catalysts in both hydrogen oxidation and oxygen reduction reactions. Present work aimed the study of composite supported catalysts from graphene derivatives.

**Experimental/methodology.** 75 wt. % $Ti_{0.8}Mo_{0.2}O_2$-25 wt. % C type of composites were synthetized by multistep sol-gel method followed by high temperature heat treatment in Ar (HTT, 600°C, 8 h) [1]. Graphite oxide (GO), GNP and their mixture were used as starting carbonaceous materials. For comparison, BP based samples were also prepared. The effect of a solvothermal treatment step before the HTT was also studied. The composites were characterized by Raman spectroscopy, XRD, SEM, TEM and XPS. Pt nanoparticles (20 wt. %) were loaded on the composite supports by ethylene glycol-$NaBH_4$-assisted reduction [1]. Metal content was measured by ICP; SSA was obtained by $N_2$ physisorption. The electrical conductivity (σ) was estimated by use of impedance spectroscopy. Electrochemical performance was evaluated by polarization curves, cyclic voltammetry, and rotating disc electrode measurements.

**Results and discussion.** The new type of electrocatalysts contained the mixed oxide in rutile phase; no separate Mo-oxides were observed (Fig. 1A). In all samples, Pt existed in a highly dispersed form with an average particle size of 3-4 nm. Electrochemical surface area (ECSA) was calculated from cyclic voltammograms, and the long-term stability of the samples was expressed as $ECSA_N/ECSA_1$ values (N: number of cycles). Stability of our electrocatalysts was higher than that of commercial Pt/C (Fig. 1B).

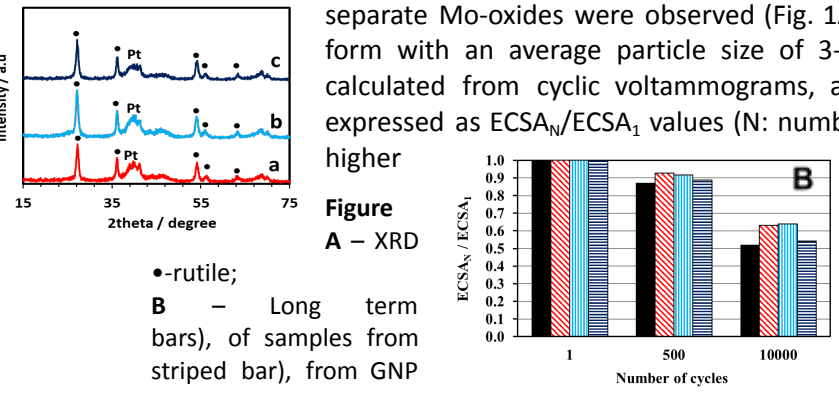

**Figure 1**. Characterization of the electrocatalysts. **A** – XRD patterns of samples from BP (a), GO (b), GNP (c), •-rutile; **B** – Long term electrochemical stability of reference Pt/C (solid bars), of samples from BP (diagonally striped bar), from GO (vertically striped bar), from GNP (horizontally striped bar)

The electrocatalytic properties of Pt catalysts supported by the novel composites will be correlated with their structural features in the lecture.

# Influence of the upper potential limit on the stability of PtRu catalysts for reformate PEMFCs during potential cycling-based anode ASTs

V.Berova[1], K. Hengge[1], T. Burger[1], C. Scheu[2], T. Jurzinsky[1*]

**Keywords:** accelerated stress test, platinum, ruthenium, stability, CO tolerance

## Introduction

Pt Ru catalysts are well-established anode catalysts for reformate operated proton-exchange membrane fuel cells (PEMFCs). The addition of Ru as a co-catalyst mitigates the CO poisoning of Pt sites due to its promoting effect towards CO-oxidation [1]. However, Ru is more susceptible to dissolution and thus less stable than Pt [2]. Therefore, major efforts must be taken to improve the durability of PtRu catalysts to enable long PEMFC lifetimes. Potential cycling-based accelerated stress tests are commonly employed to investigate the stability of electrocatalysts with little time and costs.
In this study, the effect of the potential on the degradation of a PtRu catalyst is investigated. For this purpose, several AST protocols based on square cycling the anode potential for 30000 cycles with varying upper potential limit were developed and tested on cells with the same material composition.

## Experimental

The ASTs were used to test a carbon-supported PtRu catalyst in a membrane electrode assembly (MEA) setup. The PtRu anodes were manufactured in-house with a patented technique [3], while for membranes, cathode catalysts, and GDLs commercially available products were applied. Before, during, and after the AST, electrochemical characterization was conducted via cyclic voltammetry, CO-stripping, and recording U-I curves. After the AST, post-mortem analyses were performed by means of transmission electron microscopy, X-ray diffraction, and cross-sectional scanning electron microscopy coupled with energy dispersive X-ray spectroscopy to analyze the prominent degradation mechanisms occurring for the different testing conditions.

## Results and discussion.

The upper potential limit showed strong influences on the degradation of the anode and consequently on the MEA. At potentials below 0.2 $V_{RHE}$ no significant Ru dissolution could be observed. With increasing the potential from 0.65 to 0.8 $V_{RHE}$, the severity of Ru dissolution increased resulting in a reduced CO-tolerance. At the same time, the consequent Ru crossover from anode to cathode, poisoning the cathode rose with increasing upper potential limit. By further raising the potential, additionally severe Pt dissolution occurred, which ultimately led to a drastically lowered electrochemical active surface area (ECSA) on the anode and thus overall cell performance.
Future work will address the correlation of these ASTs to long-term testing at constant potential.

**Keywords:** glucose detection, electrochemical oxygen filter

**Introduction.** Glucose detection is essential in industries including food production, viticulture, pharmaceuticals, and diagnostic medicine, such as the treatment of diabetes. Further, demand for fast, reliable, sensitive, and selective glucose sensors continues to grow. For example, by 2030, more than 5.4% of the global population, 366 million people, are expected to be affected by diabetes[1]. Enzymatic methods currently dominate, although growth in demand and scientific advancements have prompted the development and improvement of non-enzymatic detection methods[2]. Compared to enzymatic methods, non-enzymatic sensors are simpler to produce and implement and show potential to be more selective towards glucose. Previous research has shown many potentially viable methods of non-enzymatic glucose sensors[2,3], including Ni-based catalysts. However, these glucose sensors only work in highly alkaline environments which is not conducive to in situ measurements. Therefore, a novel glucose sensor is proposed which implements an electrochemical pH tuner in a four-electrode electrochemical setup. The purpose of the additional electrode is to reduce water into $OH^-$ species, increasing the pH locally, only around the Ni catalyst, providing a sufficiently alkaline environment for precise measurements.

**Experimental/methodology.** Electrode preparation was performed using a three-step electrochemical synthesis process in a three-electrode setup. Electrodeposition of a Ni-porous catalyst from a $NiCl_2$ precursor was first optimized on glassy carbon,[3] and then applied to a gold microelectrode. Hydrogen bubble formation during Ni deposition was exploited to create the porous Ni nanostructure. $NiCl_2$ concentration, deposition time and deposition current were optimized for the greatest glucose sensitivity using cyclic voltammetry and chronoamperometry. The glucose detection measurements were done in alkaline solutions. Due to the need of a high pH, in situ measurements of glucose are not possible with the proposed three-electrode setup. To solve this, an additional porous electrode (initially developed as "electrochemical oxygen filter"[4]) was included in the system as a second working electrode thus allowing glucose to be detected in less alkaline environments.

**Results and discussion.** A nanostructured Ni catalyst electrode successfully detected glucose at varying concentrations. Parameters optimized for the highest glucose sensitivity were applied when preparing the nanostructured Ni catalysts on a microelectrode. Coupling the Ni catalyst electrode with an additional porous cathode in a four-electrode setup was found to increase selectivity during in-situ glucose detection tests by increasing the pH of the environments. The successful demonstration of nanostructured Ni catalysts coupled with localized pH increase by electrochemically induced production of hydroxide species indicates that this method is a viable candidate for implementation and scale-up testing. This glucose detection paradigm has the potential to increase accuracy and decrease costs in lifesaving glucose testing.

# Influece of Lithium on Phase Transition of Amorphous Iridium Oxohydroxide for Oxygen Evolution Reaction.

M. Falsaperna,[1] S. J. Freakley[1]

[1]*University of Bath, Bath, United Kingdom*
[*]*sf756@bath.ac.uk*

**Introduction.** Electrolysis is one of the most promising methods for the production of hydrogen *via* water splitting. However, the sluggish oxygen evolution reaction (OER) leads to cell overpotentials higher than the thermodynamic value, 1.23 $V_{RHE}$, with energy losses up to 53%.[1] While iridium oxide, $IrO_2$, has proven to be one of the most promising materials to achieve OER in acidic media, obtaining catalysts with lower overpotentials is still necessary, with a focus on the fine balance between activity and stability. Synthesising $Ir(O)_x(OH)_y$ in the presence of alkali metal salts has been shown to affect the morphology and composition of the catalyst surface, with an effect on its electrocatalytic properties.[2] We have developed a facile synthesis method to produce nanocrystalline lithium iridate, $Li_2IrO_3$. This material has shown remarkable activity and stability towards OER, with the former comparable to that of amorphous $Ir(O)_x(OH)_y$, breaking the delicate relationship between high activity and low stability.

**Experimental/Methodology.** Our novel approach allows for the synthesis of nanocrystalline Liintercalated iridium oxide, Li-$IrO_x$, *via* heat treating amorphous $Ir(O)_x(OH)_y$ (500°C, 3 hours), previously obtained in the presence of $Li_2CO_3$ following a procedure described by Esquius *et al.*[2] The product is then washed with 1 L cold and 1 L hot water and left to dry in open air. Linear scanning voltammetry (LSV) and chronopotentiometry (CP) are used in a 3electrode setup containing 0.1 M $HClO_4$ electrolyte to investigate the electrocatalytic activity and the stability of the catalyst, respectively. The material was characterised using XRD, STEM, *operando* XAS and XPS.

**Results and discussion.** Following the synthesis of the amorphous $Ir(O)_x(OH)_y$, residual $Li^+$ is shown to suppress the formation of rutile $IrO_2$ upon thermal treatment and leads to a transition to a nanocrystalline Li-layered iridium oxide, whereas the removal of residual $Li^+$ results in the formation of rutile $IrO_2$ (**Figure 1a**). High resolution aberration corrected transmission electron microscopy shows the lithiumintercalated iridium oxide is polycrystalline with nanocrystalline domains. The Li-intercalated phase shows electrocatalytic activity comparable to amorphous iridium oxide while exhibiting a remarkable stability, similar to that shown by rutile $IrO_2$ (**Figure 1b** and **1c**). These results suggest the incorporation of metal alkali in the structure of the catalyst leads to improved stability while retaining significant activity towards OER, potentially offering the opportunity to produce highly active and durable electrocatalysts for industial applications.

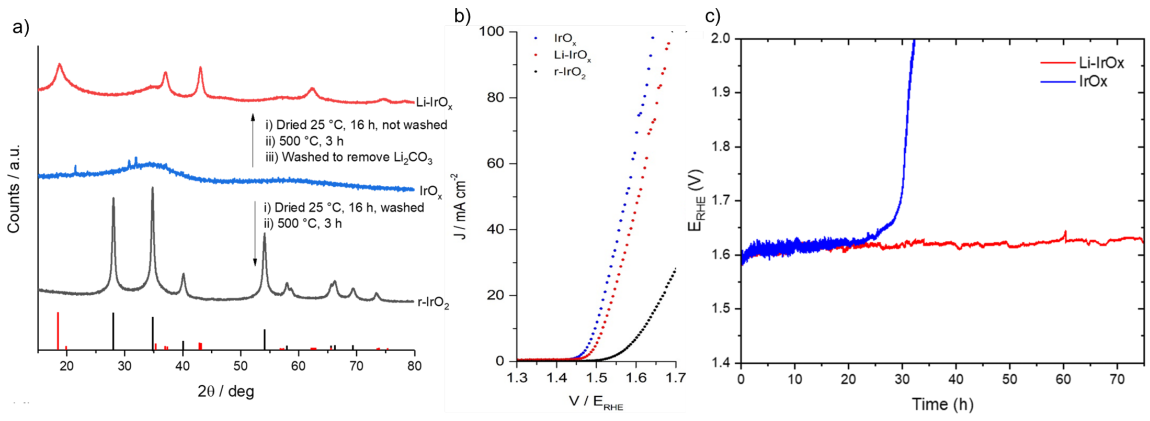

**Figure 1.** a) XRD pattern (Cu $K_\alpha$ = 1.5046 Å) of amorphous $IrO_x$ heat treated in the presence\absence of residual $Li^+$. Black and red references patterns of rutile $IrO_2$ and β-$Li_2IrO_3$, respectively. b) LSV (1.2-1.7 $V_{RHE}$, 5 mV $s^{-1}$) of $IrO_x$, Li-$IrO_x$ and rutile $IrO_2$ and c) Stability of Li-$IrO_x$ and $IrO_x$ (CP, 10 mA $cm^{-2}$, 75 h).

**Introduction.** As the price of oil has climbed fivefold from 1990 to the present, it is clear that our dependence on energy sources is unsustainable in light of rising energy consumption and the accompanying depletion of fossil fuel deposits [1]. There are challenges to using renewable energy, at least in its most frequent forms now. Common renewable energy technologies rely on the sun, wind, or fuels, all of which have drawbacks in terms of reliability, quantity, and even environmental friendliness. In this light, fuel cells are, and will continue to be, among the most efficient and reliable methods of generating electricity from renewable sources. Polymer Membrane Electrolyte Membrane Fuel Cells (PEMFCs) convert chemical energy directly and efficiently into electricity and water as the only by-product. However, for this to be accomplished in a productive manner, these PEMFCs require very efficient electrodes [2].

Advances in fuel cells and renewable fuel use alternatives have rekindled interest in portable fuel cells in recent years. Their primary benefits include higher power densities per unit active area due to a simple anode reaction, and cleaner combustion, both of which are not present in competing for portable fuel cells. In response to these tendencies, a consortium composed of two academic institutions and a business economic actor has set out to construct ethanol-fueled, noble metal-free anode fuel cells for portable devices within the next several years. However, this is only the beginning of our collaboration; much more work has to be done on the project. Consequently, only results from the initial period are shown here.

**Experimental/methodology.** In this work, different Ni/$SnO_2$ materials were produced using a literature-documented synthesis method [3]. In short, the hydrothermally generated $SnO_2$ materials are utilized as supports for Ni-based electrocatalysts. The deposition-precipitation process was used for this aim. Thus, a nickel inorganic salt (nickel(II) chloride hexahydrate) was dissolved in Milli-Q water, and then *in situ* reduction of Ni nanoparticles with hydrazine monohydrate was performed at room temperature while using vigorous magnetic stirring. Then, the desired amounts of mesoporous $SnO_2$ were added to create the final products containing different concentrations of Ni. In order to characterize these composites, a number of different techniques, including TG-DTA, XRD, SEM, TEM, textural analysis (BET), Raman and X-ray photoelectron spectroscopies, were utilized in this study. These Ni/$SnO_2$ were then mixed with carbon-based powders available for purchase to create electrodes via an electrospray deposition method. The electrode depositions were done with a homemade tool developed for that specific reason. The finished cell's cathode was made out of commercially available Pt/C electrodes.

**Results and discussion.** A reliable and consistent performance (peak power density ~35 mW $cm^{-2}$ obtained at 90 °C) of the final cell fueled with ethanol can be attained with the as-prepared anode materials due to their (*i*) high porosity suitable for ethanol transport, (*ii*) sufficient electronic conductivity, (*iii*) chemical stability and high C and CO tolerance (ensured by well-defined chemical states that do not undergo major changes) in a reducing fuel atmosphere, (*iv*) compatibility with other ethanol fuel cell components, (*v*) ease of fabrication, and most importantly (*vi*) low cost. As a result of our initial stage research, we conclude that using Ni/$SnO_2$-based anodes in the development of our industrial prototype (hence referred to as BEC) has the potential to be a game-changing technique for generating electricity in the future.

# Electrochemical ammonia synthesis via nitrogen reduction coupled with hydrogen oxidation in a continuous-flow reactor

Xianbiao Fu,[1] Ib Chorkendorff[1]*

[1] *Department of Physics, Technical University of Denmark, Kongens Lyngby, Denmark.*
**Corresponding Author's E-mail address: ibchork@fysik.dtu.dk*

**Keywords:** lithium-mediated nitrogen reduction, flow cell, hydrogen oxidation

**Introduction.** Ammonia ($NH_3$) is an important chemical for society to produce fertilizers, pharmaceuticals, polymers, and other chemicals. Electrochemical ammonia synthesis is regarded as a promising route to complement the Haber-Bosch process for the distributed production of fertilizers in small-scale devices powdered by renewable electricity.[1] After rigorous quantitative (*i.e.* gas purification and quantitative isotope measurements) investigations, lithium-mediated nitrogen reduction reaction (Li-NRR) was validated as the only currently reliable route for electrochemical ammonia synthesis.[2,3] Although significant progress has been made to achieve high FE and current density[4,5], most Li-NRR studies have the limitations of sacrificing solvent as protons for ammonia synthesis and difficulties in scaling up production in batch-type electrochemical cells (*i.e.*, one-compartment cells and autoclaves).

**Experimental/methodology.** Here, lithium-mediated electrochemical ammonia synthesis was carried out in a three-chamber flow cell at 1 bar and the effective area of the flow field was 25 $cm^2$.[6] The stainless-steel cloth (SSC) with a pore size of 30 μm was used as a gas diffusion electrode (GDE) to overcome the mass transport limitation of $N_2$ and $H_2$. The PtAu alloy catalysts on the SSC substrate (PtAu/SSC) were used for hydrogen oxidation reaction (HOR) at the anode side. The solution of 1 M lithium tetrafluoroborate ($LiBF_4$) in THF contained varying concentrations of 0 to 1 vol. % ethanol as an electrolyte. A syringe pump was used to flow the electrolyte with 1 ml/min flow rate.

**Results and discussion.** We here show that the classical catalyst Pt does not work for stable HOR (deactivated in a few minutes) in the organic electrolyte, while PtAu alloy is essential for reducing the anode potential (anode potential: 0.6 V, cell voltage: 4.3 V) avoiding the decremental decomposition of the organic electrolyte. The PtAu alloy demonstrated long-term stability and high activity of HOR in the Li-NRR organic system. *Operando* mass spectrometry of deuterium ($D_2$) oxidation demonstrated that hydrogen oxidation can continuously provide protons for ammonia synthesis and confirmed the recyclability of ethanol as a proton shuttle. Benefitting from the robust PtAu anode catalysts, the potential cycling method and trade-off strategy of the proton/nitrogen limited region, record high faradaic efficiency of up to 61% and energy efficiency of 13% were achieved at 1 bar of nitrogen.

# Polymer monomer enhanced electrocatalysts for hydrogen and oxygen evolution in alkaline water splitting

Tzu Hsuan Chiang*, Hsin-Hsiang Hsieh

*Department of Energy Engineering, National United University, Miaoli, Taiwan*

**thchiang@nuu.edu.tw*

Abstract

Enhancing hydrogen production and efficiency from renewable energy sources such as solar cells, wind, and hydro-energy combined with water electrolysis [1] is a positive development for many investigations. Due to alkaline water electrolysis (AWE) has the advantages of using non-noble metal catalysts, low concentration of 30-40% KOH electrolyte, and providing high long-term stability [2]. The study prepared a bifunctional electrocatalyst as FeCuMo-Schiff base. The electrocatalyst was prepared from a mixture of poly (methyl methacrylate), metal precursors (Fe, Cu, and Mo), and a Schiff base. They were then using electrophoresis to coat on nickel foam. This study is focused on different amounts of PMMA contact with the metal Schiff base. It used a kind of polymer monomer as poly (methyl methacrylate) to enhance the hydrogen evolution reaction (HER) and oxygen evolution reaction (OER) in alkaline water splitting. The results obtained 50 mg of PMMA added that can enhance HER and OER performance of the $Fe_{0.5}Cu_{0.5}Mo_{0.5}$-Schiff base, as shown in Fig. 1. The HER and OER electrocatalytic activities in alkaline water splitting are also better than the commercial electrocatalysts 20 wt% Pt/C and $RuO_2$.

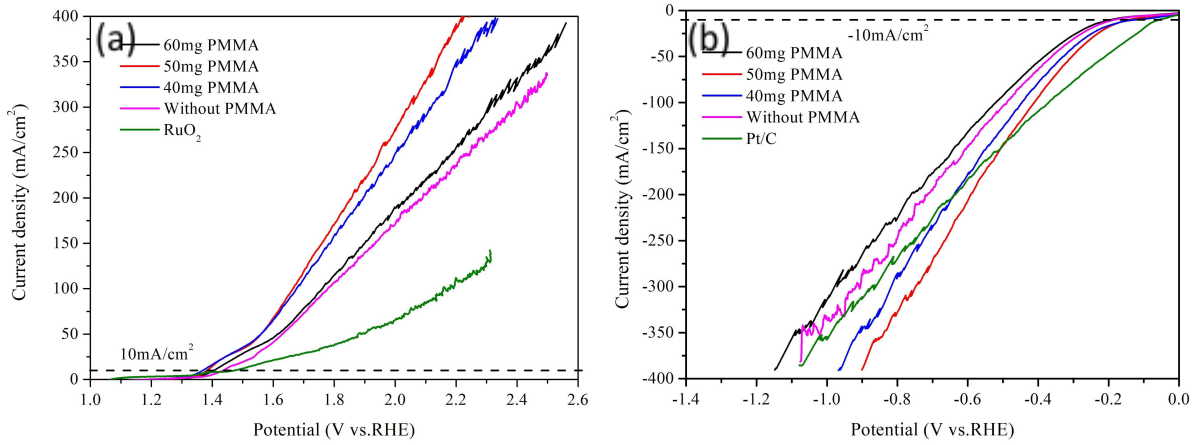

Figure 1. Polarization curves of (a) OER and (b) HER for Fe0.5Cu0.5Mo0.5-Schiff base content with different amounts of PMMA monomers.

*Direct conversion of ammonia ($NH_3$) to hydrogen ($H_2$) in a fuel cell has the potential to realize a carbon-neutral world in transportation and distributed-power applications. Most fuel-cell research has involved the use of $H_2$ as the fuel; however, the practical generation and storage of $H_2$ remains an important technological hurdle. Ammonia is an alternative energy carrier not only with a high energy content but also with a facile condition to use. Nevertheless, degradation of anode materials occurs during operation, leading to performance loss and preventing this simple fuel in practical applications. Here we include lanthanum strontium ruthenium titanate (LSRT) into state of the art nickel cermet anodes and investigate catalytic activities of ammonia conversion in high temperature fuel cells. The cell performane is compared with two kinds of ceramic cells, one oxygn-ion conducting and another proton conducting, using $NH_3$ as a fuel. We demonstrate that presence of LSRT is beneficial to a proton-conducting cell with a high activity toward $NH_3$ conversion and a more structure stability during nitridation. Besides, a stable anode catalyst depends on an optimum metal-support interaction for dehydrogenation of $NH_3$ and subsequent associative $N_2$ desorption. Further studies are needed to understand the synergistic effect brought about by both metal and the support electrolyte. This will in turn allow to design an effective material capable of carrying out $NH_3$ cracking reactions for fuel cell and potential energy applications.*

**Keywords:** Ammonia, fuel cell, nickel, LSRT, nitridation

**Introduction.**

Current ceramic fuel cells have received considerable attention for application in mobile and residential distributed power generation [1]. Most of them deliver stable performance using highly pure hydrogen ($H_2$) derived from fossil fuels via complex reactions and separation processes. Although $H_2$ is a promising clean fuel for energy production, its low volumetric density and high flammability pose a challenge in storage as well as transportation. Recently, ammonia ($NH_3$) has been regarded as a potential fuel source for a high energy density (~ 4 kWh/kg) and its safety to transport. Ammonia can be liquefied at a relatively facile temperature (20 °C) and a pressure (8.6 bar), yielding a higher volumetric density as compared to hydrogen. Traditional ceramic fuel cells capable of achieving high power densities are based on oxygen-ion conductors (Solid Oxide Fuel Cell; SOFC) operating at high temperatures (~ 800 °C). The high temperature operation not only allows a fast reaction kinetics in the SOFC without noble metals or precious catalysts but also make possible a direct conversion of ammonia into electricity.

Nevertheless, state of the art nickel anodes in high tmperature fuel cells experiences degradation when $NH_3$ is used as a fuel. In the past, alternative anodes have been attempted by doping or alloying the Ni cermet anode with another transition metal (M) such as Iron (Fe) and Chromium (Cr) [2]. The resulting Ni-M cermet is revealed to be an effective anode for $NH_3$ cracking and subsequent hydrogen oxidation. The incorporation of second metal promoted the anode durability via formation of metal nitride, thus suppressing the Ni agglomeration during operation. In the present work, we modify the Ni anode by doping with lanthanum strontium ruthenium titanate (LSRT) perovskite and study the effect of dopant. Catalytic properties of the LSRT for ammonia decomposition in a reactant gas simulating anode atmosphere are investigated. The addition of LSRT into the anode is beneficial to cell performance since exsolution of ruthenium (Ru) metal is expected to occur on the perovskite (LSRT) in a reducing atmosphere and Ru is an active $NH_3$-cracking catalyst. On the other hand, protonic ceramics (e.g. doped barium cerates) can conduct protons through their lattice with lower activation energies and higher ionic conductivities than the SOFC at

moderate temperatures at 600 °C. We incorporate the modified anode in a protonic ceramic fuel cells (PCFCs) and provided valuable information to design an effective anode material for a direct $NH_3$ fuel cell.

**Experimental/methodology**

Catalyst preparation

$BaZr_{0.2}Ce_{0.7}Y_{0.1}O_{3-\delta}$ (BZCY)

A protonic ceramic scaffold, $BaZr_{0.2}Ce_{0.7}Y_{0.1}O_{3-\delta}$ (BZCY), was synthesized and used as the electrolyte for a PCFC in this study. The synthesis was conducted by a solid-state reaction using precursors of barium carbonate (BaCO3, 99.8%), zirconium oxide (ZrO2, 99.9%), cerium oxide (CeO2, 99.9%), yttrium oxide (Y2O3, 99.9%) (All from Alfa Aesar) [3]. The precursors were weighed according to a stoichiometric molar ratio of Ba : Zr : Ce: Y = 1 : 0.2 : 0.7 : 0.1 and mixed in ethanol under ball milling. The mixture was then dried at 80 °C overnight and calcined at 1100 °C for 10 h. The obtained powder was crushed and grinded in the mortar for fabrication of an electrolyte.

Characterization

Catalytic activity on ammonia decomposition was evaluated by temperature-programmed reaction with an on-line mass spectrometer. Mass/electron ratio (m/e) in the MS were selected for $H_2$ (2), He (4), $NH_3$ (17), $H_2O$ (18), $N_2$ (28), and $O_2$ (32). The phase composition of crystalline components on the catalyst was investigated by X-ray diffraction (XRD) analyses. The assignment of the various crystalline phases was based on the JPDS powder diffraction file cards. The morphology of the as-synthesized BZCY and LSRT catalyst was characterized by scanning electron microscope (SEM) equipped with an energy-dispersive X-ray spectrometer (EDX) and transmission electron microscope (TEM).

**Results and discussion.**

Figure 1 presents MS profiles of gaseous species from ammonia decomposition on different anode materials upon ramping temperature to 800 °C. The result shows that ammonia decomposes around 350 °C on all NiO-containing anodes while a complete conversion was achieved in the range of 550-800 °C (Also the conversion vs. temperature was plotted in supporting information, Fig. S1). Doping LSRT onto the anodes delayed the complete conversion, especially on the LSRT-NiO/YSZ, whose conversion temperature was raised to about 800 °C. On the other hand, H2 and N2 were the only gaseous products in the NH3 decomposition. The addition of LSRT not only caused a hump in the H2 MS profile at high temperatures but also produced a higher ratio of H2/N2 on both SOFC and PCFC anodes. For example, the ratio of H2 to N2 was increased from 2.0 (NiO/YSZ) to 2.3 (LSRT-NiO/YSZ) and from 1.6 (NiO/BZCY) to 2.4 (LSRT-NiO/BZCY), which was closer to 3, a theoretical value in NH3.

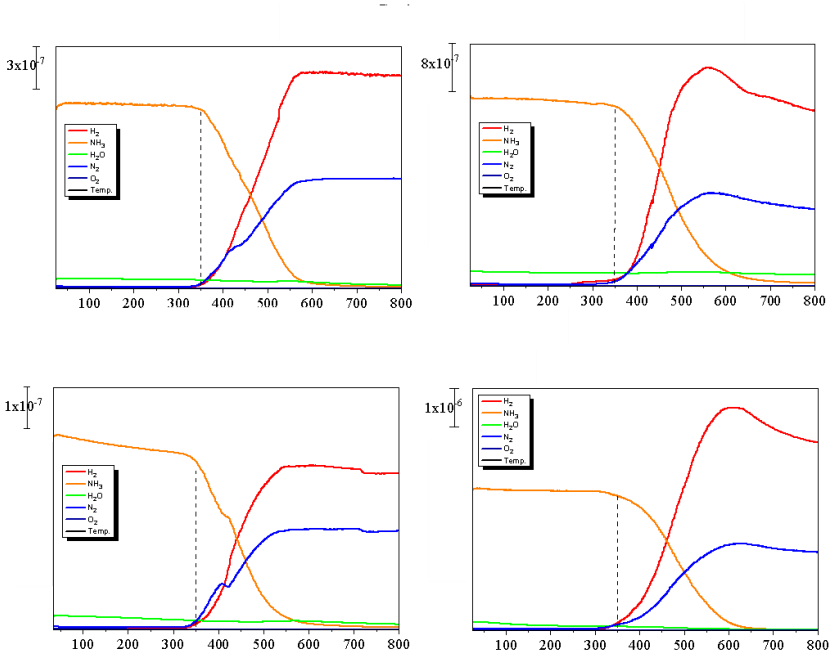

Figure 1 Temperature-programmed reaction activities of $NH_3$ decomposition on a) NiO/YSZ, b) LSRT-NiO/YSZ, c) NiO/BZCY, and d) LSRT-NiO/BZCY anode catalyst

# Simple and cost-effective surface modification for large area NiO electrode of Molten carbonate electrolysis cell

Yeeun Kim, Bo-Ram Won, Jae-ha Myung*

*Department of Materials Science and Engineering, Incheon National University, Incheon 22012, South Korea*

**Introduction.** Molten carbonate electrolysis cell (MCEC) is one of the efficient and economical electrolysis technology for hydrogen production, because of the high operating temperature (600-650 °C).[1] However, facile coating technology for uniform nanocatalyst dispersion on large-area electrode sheets remains insuficient. In this study, we modified the surface of large area NiO electrode by decorating metal nanoparticles such as La and Co [2,3] uniformly via dip-coating, which is cost-effective fabrication procedure for the mass production. The porous NiO electrode sheets were fabricated by tape-casting and laminating process, and their porosity was controlled by adjusting ratio of pore former and laminating pressure. The electrode sheets were dip-coated into the suspensions including La and Co precursors and calcined to modify electrode surface. The oxide nanoparticles composed of each element on the electrode surface were observed. The amount of coated catalyst affected by ion concentration of the ions in suspensions and the number of dip-coating cycles. This study provides an insight for feasible strategy for customizing surface properties of the large-area electrode for hydrogen production.

**Experimental/methodology.** The porous and large area (100 $cm^2$) NiO electrode sheets were fabricated by tape-casting and laminating process. The tape-casting slurries with pore former of 15, 25, 35 wt% were prepared by two steps ball milling. The fabricated electrode sheets were cut into an appropriate size (5 $cm^2$) and dip-coated 1, 3, and 5 times into suspensions including La and Co precursors, respectively. The ion concentrations of the suspensions were 0.1 M and 0.5 M. The heat treatment was performed at 80 °C for 2 h after one cycle and finally at 500 °C for 3 h.

**Results and discussion.** The microstructures of electrode surfaces coated by different elements were investigated using SEM-EDS analysis. We evaluated catalyst content and coating homogeneity depending on ion concentration of suspension (0.1 M, 0.5 M) and cycle number of dip-coating (1, 3 and 5 times). Fig. 1 shows the surface of the electrode uniformly coated by nanoparticles of a granular form. The atomic fraction of Co was higher than that of La in all cases. The amount of catalyst (La, Co) coated on the electrode sheets was increased as the number of coating cycles and concentration of ions in suspensions increased. This indicates the amount of catalyst coated on the electrode can be controlled by the number of coating and ion concentration in suspensions.

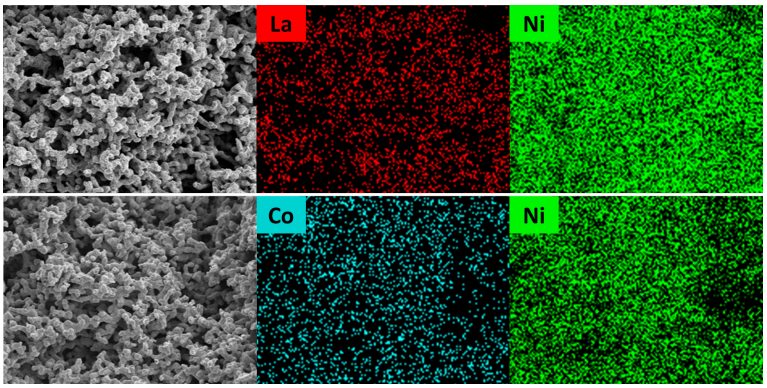

**Figure 1 SEM micrographs of the surface of coated NiO electrode with corresponding EDS mapping.**

# Controlling the growth of nanoparticles from exsolution modeling based on cation diffusion limitation.

Yo Han Kim, Somi Lee, Yeeun Kim, Jae-ha Myung*

*Department of Materials Science and Engineering, Incheon National University, Incheon 22012, South Korea*

**Introduction.**

In-situ exsolution method has attracted much attention in preparation of supported nanoparticles as electrocatalysts. Unfortunately, growth of exsolved particles can be limited by diffusion, reactant and strain; Therefore, considerable metal atoms and cations remain in the inner bulk even under reduction condition at high temperatures. In this study, we suggest a diffusion-limited exsolution mechanism to control exsolution and overcome growth limitation. The endogenous nanoparticles in the reduced oxide were observed with an unbalance particle distribution, which is expected to be critical evidence of cation diffusion limitation. An exsolution model for particle growth was driven from the classical nucleation and diffusion theories, relating to cation concentration and reduction conditions. To demonstrate this model, we designed a titanate perovskite oxide system that can control the cation doping level. The exsolution trend depending on the Ni doping and reduction conditions corresponded with our modeling, providing insight for optimizing particle growth. Based on our experimental and theoretical results, we optimized the Ni exsolution on the electrode scaffold for solid oxide fuel cells. Single cells with an exsolable anode exhibited lower polarization resistance and higher power density than the undoped anode cell. In addition, an electrochemical switching technique leads to immediate enhancement of cell performance by applying an electrochemical potential, which promotes cation diffusion/exsolution.[1,2]

**Methodology.**

The modeling of exsolution phenomenon begins from Fick's laws of diffusion. The model based on an assumption in which the rate determining step of exsolution growth is cation diffusion toward the surface due to the fast reduction rate of cation.

**Results and discussion.**

The solution of Fick's second law is written as:

$$C(x,t) = C_0 \mathrm{erf}(x/2\sqrt{(Dt)}), \quad (1)$$

Where C is concentration and $C_0$ is initial concentration. x is the displacement and t is the reduction time. The diffusion in solid oxides is a thermally activated process as shown in Eq. 2.

$$D = D_0 \exp[-(E_a/RT)], \quad (2)$$

where $D_0$ is the maximum diffusivity, $E_a$ is the activation energy for diffusion and R is the gas constant. The extent of exsolution ($n_M$) on the surface can be driven:

$$n_M = (2N_A C_0)\times\sqrt{(tD_0 \exp[-(E_a/RT)]/\pi}), \quad (3)$$

where $N_A$ is the Avogadro's number. This theoretical result suggests that the extent of exsolution affected by the initial cation concentration, reduction time, and temperature, which are the key factors in controlling particle growth.

# Zeolite-templated synthesis of N-doped carbon using pyridine for the oxygen reduction reaction

S. Kokuryo[1*], K. Miyake[1], Y. Uchida[1], N. Nishiyama[1]

[1] *Graduate School of Engineering Science, Osaka University, Toyonaka, Japan*

**Keywords:** ORR, N-doped carbon, pyridine, zeolite

**Introduction.**

Recently, proton-exchange-membrane fuel cells (PEMFCs) have been expected as sustainable conversion systems of energy. However, the sluggish kinetics of oxygen reduction reaction (ORR) occurring at the cathode in PEMFCs restricts the cell performance[1]. Currently, Pt- and Ru-based catalysts are used commercially but are very expensive. Therefore, the development of low-cost and high-efficient catalysts for ORR has been desired. Recently, designing carbon-based electrocatalysts has been attractive as a promising candidate to solve the above problems. In particular, N-doped carbon materials have shown excellent activity for ORR[2]. It has been reported that edge Pyridinic-N sites on graphene are effective active sites. Herein, we synthesized N-doped zeolite-templated carbon using pyridine as C and N sources and investigated the activity for ORR.

**Experimental/methodology.**

In a typical carbon deposition process, 0.3 g of zeolites were heated under continuous He flows by raising the temperature to a certain carbon deposition temperature at an increasing rate of 10 K $min^{-1}$. Once the target temperature was reached, pyridine steam was carried by He gas for 6 h. Then, the obtained carbon-zeolite composites were treated with NaOH and HCl to remove the zeolite template. The obtained carbon product was washed with distilled water and dried at 90 °C, and then, they were calcined at 1100 °C under $N_2$ flow. The obtained catalysts were named Py-T (T is the carbon deposition temperature [°C]).

To evaluate the catalytic activity of the synthesized samples for ORR, Linear sweep voltammetry (LSV) measurements under alkaline conditions using 0.1 M KOH were conducted.

**Results and discussion.**

We observed that the crystallinity of zeolite decreased with increasing carbon deposition temperature. XRD measurements and EDX analysis confirmed that the zeolite template in every sample was almost completely removed after NaOH and HCl treatments. Rotating ring disk electrode voltammetry was used to evaluate the electrocatalytic activity of Py-T in the ORR. The catalytic activity and the selectivity of 4-electron direct reduction of $O_2$ to $H_2O$ were found to enhance with increasing carbon deposition temperature, as shown in Fig. 1. However, the catalytic performance of Py-900 was slightly inferior to that of Py-800 because of the breaking of the zeolite structure during the high-temperature carbon deposition process.

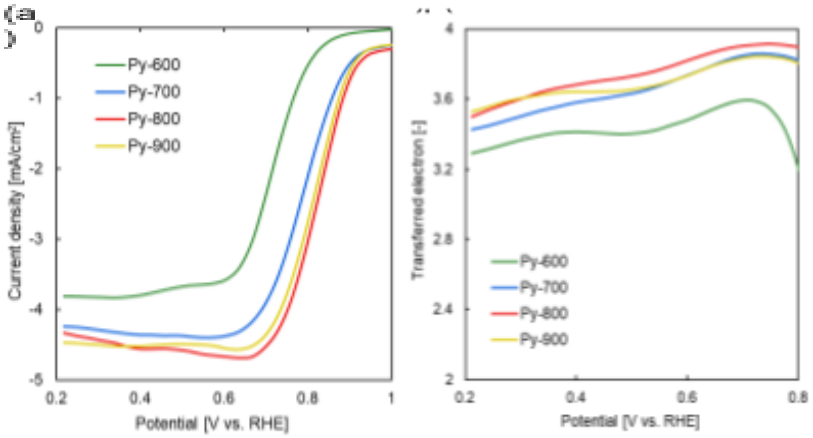

Fig. 1 (a) LSV curves, and (b) number of electrons transferred during ORR of Py-T.

**Introduction.** In conventional water electrolysis, the hydrogen evolution reaction (HER) is coupled with the oxygen evolution reaction, requiring high cell potentials while not generating any value. Coupling the HER with an electrochemical organo oxidation, e.g. HMF oxidation to FDCA, enables hydrogen production at lower cell potential while enabling the production of value-added products on the anode.[1] Realizing this, new electrode materials have to be developed to enable selective and efficient electrooxidation at current densities comparable to industrial HER.[2] We herein investigated the electrochemical oxidation of HMF as an exemplary reaction using a novel Fe-modified Ni-foam (NF) at industrial current densities.[3,4]

**Experimental** Fe-modified NF were prepared by treating a cleaned NF with a mixture of $H_2O_2$ and $FeCl_3$. Electrochemical measurements were performed using a Gamry Interface 1010 B electrochemical workstation with an H-type cell, which was separated by a Nafion 117 membrane. For more experimental details see Ref. 4.

**Results and discussion.** Modification of the NF with a mixture of $H_2O_2$ and Fe-precursors results in the formation and homogenous distribution of nanosheet-like structures on the surface of the Ni-foam. Combined analysis by XRD, XPS, and XANES, identifies those surface species as α-FeOOH and NiFe layered double hydroxide phases. Utilizing linear sweep voltammetry (LSV), current densities of up to 1 A $cm^{-2}$ could be achieved by adding 100 mM HMF in 1 M KOH, demonstrating the potency of the as-prepared NF electrode. Constant potential electrolysis at 0.53 V vs. Hg/HgO and subsequent analysis with HPLC and NMR demonstrate FDCA yields beyond 90 % at faradaic efficiencies (FE) beyond 95 % while maintaining a well-closed carbon balance throughout the reaction. These results were maintained for 6 consecutive cycles, demonstrating the stability and reproducibility of this process. In addition, the performance of the electrode was tested in a flow H-cell configuration. Current densities of several 100 mA $cm^{-2}$ could be maintained over a prolonged time when providing a sufficient supply of the organic substrate. Realizing that the instability of HMF in an alkaline electrolyte is a major challenge for industrial applications, we also investigated the alkaline degradation of HMF. At elevated alkalinity, the Cannizzaro reaction is the decisive degradation step of HMF, competing with humin formation. By optimizing the degradation conditions, ~80 % of the initial HMF could be maintained after the alkaline transformation to the Cannizzaro products (DHMF and HMFCA), which are both stable at elevated substrate and KOH concentrations. Constant potential electrolysis at 0.50 V vs. Hg/HgO confirms the simultaneous oxidation to FDCA. Furthermore, the stability of the Cannizzaro products allowed the "indirect" oxidation of HMF to FDCA at unprecedentedly high concentrations of substrate and base, 0.25 M and 5.0 M, respectively. Constant potential electrolysis enables the formation of FDCA at FE of ~95 % and yields of > 90 %, introducing both Cannizzaro products as stable HMF equivalents.

# Towards higher $NH_3$ Faradaic efficiency: Selective-poisoning of HER active sites by co-feeding CO in NO electroreduction

M. Li[1], J. Verkuil[1], S. Bunea[1], R. Kortlever[2], A. Urakawa[1*]

**Introduction** Direct electroreduction of nitric oxide offers a promising avenue to produce valuable chemicals, such as ammonia, which is regarded as an essential building block for fertilizer production.[1] Direct NO conversion to ammonia in a proton exchange membrane (PEM) is advantageous compared to H cells mainly because: a) it overcomes the limitation of low NO solubility in water, and b) it can be operated in a continuous manner.[2] However, at a high current density, the NO reduction reaction is limited by the competing hydrogen evolution reaction (HER). Herein, we report a CO-mediated selective poisoning strategy to enhance the Faradaic efficiency (FE) towards ammonia while suppressing the HER.

**Experimental/methodology** Electrochemical measurements were conducted in a PEM electrolyzer with a geometric catalyst-coated area of 4 $cm^2$ and a Nafion 115 membrane. At the anode chamber, $IrO_2$ was used as the catalyst with 2 $mg/cm^2$ loading and MilliQ water was supplied. Five different cathode catalysts (Cu/C, Ru/C, Pt/C, Pd/C, and Ag/C with 40 wt.% metal loading on carbon black) were investigated. 2.5% NO or 2.5% NO and CO were supplied continuously at the cathode side.

**Results and discussion** As depicted in Figure 1, the FE is strongly dependent on the metal and the applied cell potentials during NO electroreduction. In the presence of only NO, Pt/C and Pd/C showed a lower FE towards $NH_3$ compared to $H_2$ due to the dominating HER. Cu/C showed 78% FE towards $NH_3$ at -2.0 V due to the stronger binding affinity to NO* compared to H* (**Figure 1a**). With the co-feeding of CO, the FE of Cu/C towards $NH_3$ was improved by 12%. More strikingly, for Pd/C, FE towards $NH_3$ improved by 95% (**Figure 1d**). Moreover, the current density of all the catalysts and FE towards $H_2$ decreased, while FE towards $NH_3$ was improved (**Figure 1b and 1e**). This behaviour can be attributed to the change of the microenvironment on the catalyst surface resulting from the selective and competitive binding of CO* to H* binding sites (**Figure 1c and 1f**). As a consequence, the NO* coverage increased on the surface compared to H* coverage, resulting in an improved FE towards $NH_3$ while suppressing the HER.

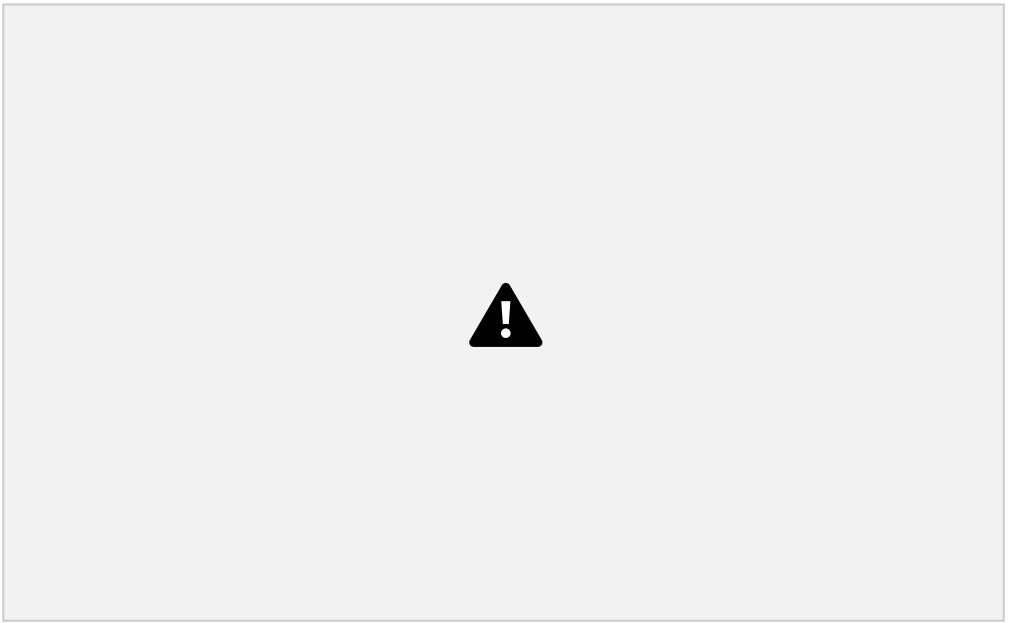

**Figure 1. Faradaic efficiency at -1.9 V, -2.0 V, and -2.1 V of various catalysts in (a) NO electroreduction, and (d) NO electroreduction + CO. Total current density vs cell voltage of various catalysts in (b) NO electroreduction, and (e) NO electroreduction + CO. Schematics of (c) NO electroreduction and (f) NO electroreduction + CO on Pd.**

# Function-coordinated Electrocatalysts for Carbon Dioxide Reduction

Yuhang Li*, Chunzhong Li

*East China University of Science and Technology, Shanghai, China*
**yuhangli@ecust.edu.cn*

**Keywords:** Electrocatalyst, Function coordination structure, Carbon dioxide reduction, Value-added chemicals

**Abstract:** The electrochemical reduction of carbon dioxide enables the storage of intermittent renewable energy in the form of chemical bonds. Further progress is required in the electrocatalysts which facilitate the conversion chemistry. The functional coordination structures of the electrocatalysts have been regarded as important factors for the catalytic performance of carbon dioixde reduction. By using the oxygen-containing functional groups of water-soluble polymers, we have regulated the reaction microenvironment for catalyst synthesis, and created the cluster-sized catalysts with rich oxygen donors [1-3]. We found out that this kind of metal oxide catalysts exhibited excellent activity and selectivity for carbon dioxide reduction. Further, we have proposed a strategy to improve catalyst stability for carbon dioxide reduction, that is, by enhancing the oxygen transfer processes in the micro-region of electrode/electrolyte interface. By optimizing the electrolyte formula to match the catalytic materials, the applicant promoted the stability of the oxygen-containing active sites in metal oxide catalysts, thus achieving a cathode energy efficiency of more than 75% at high current density for carbon dioxide reduction [4-6]. Recently, we have proposed to couple the processes of cathode and anode reactions, and devised a redox-mediated electrocatalytic reactor. This reactor realized the efficient production of ethylene oxide from carbon dioxide with low energy input and high conversion rate [7].

**Keywords:** Solution Combustion Synthesis, Fluorine-doped lanthanum strontium cobalt ferrite, electrochemical $CO_2$ reduction

**Introduction.** The tremendous usage of fossil fuels and the subsequent $CO_2$ emission pose environmental pollution. The electrochemical reduction of $CO_2$ ($CO_2$RR) is an effective strategy to concurrently reduce $CO_2$ emissions and manufacture of chemicals and fuels. However, $CO_2$RR is difficult due to the inherent stability of the C=O bond, particularly at low temperatures [1]. Thus, the development of catalysts with excellent mixed ionic and electronic conductivity, redox cycle stability and high durability is necessary.
Perovskite-based oxides have been indicated among the best performing materials, due to their high conductivity and structural stability [2]. In recent years, fluorine-doped perovskites, where O is partially replaced by F, attracted much attention owing to their high of $CO_2$ adsorption capacity and surface oxygen vacancies concentration [3]. This study deals with the investigation of $La_{0.6}Sr_{0.4}Fe_{0.8}Co_{0.2}O_3$ (LSCF) perovskites doped with two different molar concentration of F, added to increase the oxygen vacancies and, thus, the electrochemical reduction activity. Two preparation strategies, Solution Combustion Synthesis (SCS) and citrate method have been used.

**Experimental/methodology.** Two F doped-LSCF perovskites, with composition, $La_{0.6}Sr_{0.4}Fe_{0.8}Co_{0.2}O_{2.9}F_{0.1}$ and $La_{0.6}Sr_{0.4}Fe_{0.8}Co_{0.2}O_{2.8}F_{0.2}$, and the undoped $La_{0.6}Sr_{0.4}Fe_{0.8}Co_{0.2}O_3$ reference compound, were prepared by SCS and citrate method. In both methodologies metal nitrates were used as metals precursors, while $NH_4F$ was used as fluorine source. The final materials were calcined at 900 °C for 4 hours at ramp rate of 10 °C/min. All samples were characterized by X-ray diffraction (XRD) and Rietveld refinement, $N_2$ physisorption, $H_2$-temperature programmed reduction (TPR), X-ray photoelectron spectroscopy (XPS). The electrocatalytic activity was investigated by electrochemical impedance spectroscopy (EIS) after deposition on a $Ce_{0.8}Sm_{0.2}O_{2-x}$ (SDC) electrolyte. The EIS spectra were collected from LSCF/SDC/LSCF symmetrical cells between 500 and 900 °C employing Methrohm Autolab impedance analyzer (AC voltage of 0.3 V) equipped with a ProboStat from NorECs.

**Results and discussion.** XRD characterization evidenced an increased cell volume and larger microstrain of the perovskite structure as function of the fluorine molar concentration, suggesting insertion of the dopant into the lattice. Preliminary ORR analyses were carried out in air. The improved performance of the F doped material, in terms of surface exchange and oxygen bulk diffusion, was confirmed for the

$La_{0.6}Sr_{0.4}Fe_{0.8}Co_{0.2}O_{2.9}F_{0.1}$ achieving area specific resistance (ASR) values as low as 0.1 Ω $cm^2$ at 805 °C, and 0.4

Ω $cm^2$ at 705 °C.

**Introduction.** The development of the new technology for biorefinery and hydrogen production is one of the most interesting topics for both academic and industrial points of view. Herein, we demonstrate the concept of electrocatalyst development for the simultaneous biomass-derived compound upgrading and hydrogen production via electrochemical approaches. The highly efficient electrocatalysts for both anodic and cathodic parts have been extensively designed for maximizing the catalytic performance with low energy consumption. It is well-known that the Ni-based catalysts have been reported as highly efficient heterogeneous catalysts for electrochemical oxidation of 5-hydroxymethylfurfural (5-HMF). [1,2] However, Ni alone lacks catalytic stability. Indeed, various carbon materials have been coupled with Ni to improve its catalytic performances due to the synergistic effect of carbon and Ni to improve conductivity and electronic structure of active sites. This contribution describes the fabrication of nickel decorated carbon nanotubes (NiCNTs) via chemical vapor deposition (CVD) methods from bioethylene *via* dehydration of bioethanol as a carbon source. [3,4] The fabricated NiCNT electrodes act as bifunctional electrocatalysts on both anode and cathode sides for efficient HMF oxidation coupled with hydrogen generation.

**Experimental/methodology.** To fabricate working electrodes, the nickel-CNT composite powder was dispersed onto compressed nickel foam (NiCNTs/NF). The electrochemical properties of NiNCTs/NF were investigated with an autolab/PGSTAT 10 potentiostat using a two-electrode setup, NiCNTs/NF as working electrodes for both cathodic and anodic sides. The anodic compartment consisted of a certain amount of HMF in 1 M potassium hydroxide (1M KOH), while the cathodic compartment contained 1 M KOH. To start the catalytic study, a certain amount of HMF was dissolved in the solution. The reaction mixtures for both HMF oxidation and hydrogen production were analyzed using high-performance liquid chromatography (HPLC) equipped with PDA detector and C-18 column. The amount of hydrogen ($H_2$) production and its Faraday efficiency were measured by gas chromatography (GC).

**Results and discussion.** Figure 1 shows the kinetic curves of HMF electrooxidation over NiCNTs at a constant potential of 1.45 V vs NiCNTs/NF . For the mechanistic point of view, HMF oxidation can be taken place via HMFCA as an intermediate, which can further transfer to FFCA. After 2 hours of the reaction time, a dramatic increase in FDCA selectivity to 95 %, and 100 % HMF conversion was obtained . Interestingly, the cathodic part initially produced hydrogen at a modest rate of 33 µmol $mg^{-1}$ $h^{-1}$ . Furthermore, the hydrogen generation rate was significantly increased to 75 µmol $mg^{-1}$ $h^{-1}$ when the reaction time is extended to 2 hours, as illustrated in Figure 1B. This strategy can illustrate the rational design of highly efficient electrocatalyst for valorizing the biomass-derived compounds to high-value-added chemicals through electrochemical process.

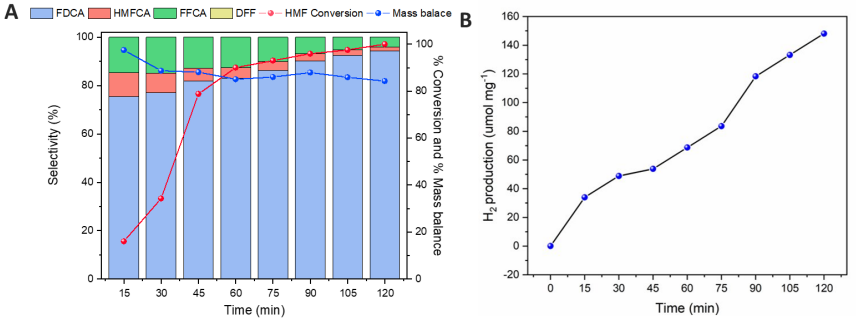

**Figure 1** Kinetic Study of NiCNTs/NF at 1.45 V (vs. NiCNTs/NF) A) for electrooxidation of HMF and B) HER in 1 M KOH.

**Introduction.** Oxygen evolution reaction (OER) is the counter reaction of valuable reduction-type reaction such as $CO_2$ electroreduction in aqueous solutions. OER is one of the bottlenecks for overall reactions because it requires high overpotential. Many candidate materials were proposed for OER catalysts under alkaline conditions, because the OER readily progresses at high pH. However, most OER catalysts lose the activity due to the surface amorphization and cation leaching under neutral conditions, although the neutral conditions are necessary for $CO_2$ reduction.[1] Brownmillerite (BM) -type $Sr_2GaCoO_5$, which was categorized oxygen-deficiency-ordered perovskite (PV) -type oxide, was reported to maintain its activity for a long time under neutral conditions. [1] In this study, BM-type $Ca_2FeCoO_5$ which is highly active in alkaline conditions[2] was synthesized with different Co/Fe ratios, and its activity and durability were investigated by electrochemical measurements in neutral conditions.[3]

**Experimental/methodology.** Oxides precursors were synthesized by the sol-gel method[3] using nitrates of Ca, Fe and Co, and citric acid (molar ratio = 2 : 2−$x$ : $x$ : 4, 0 ≤ $x$ ≤ 1.25). The precursors were calcined at 1073 K for 6 h to obtain CFCO-$x$. Chronopotentiometry at 4.7 mA $cm^{-2}$ were performed using a three-electrode system. The oxide powders, acid-treated acetylene carbon black and neutralized 5 % Nafion® solution were dispersed into ethanol. The thus formed ink was dropped on a carbon paper to prepare a working electrode with the catalyst loading 0.2 mg $cm^{-2}$. A Pt foil and Ag/AgCl/KCl (satd.) were used as counter and reference electrodes, respectively. An electrolyte containing 0.4 M $NaH_2PO_4$, 0.6 M $Na_2SO_4$ and NaOH (pH 7) after $N_2$ bubbling was employed. Crystal phase of CFCO-1 and -1.25, before and after durability test for 24 h was analyzed by HR-TEM.

**Results and discussion.** Fig. 1a shows time courses of overpotential against OER at 4.7 mA $cm^{-2}$ at pH = 7. The overpotential of BM-type CFCO-1 in the initial period was lower than those of PV-type $LaFe_{0.5}Co_{0.5}O_3$ and $SrFe_{0.5}Co_{0.5}O_3$, suggesting that BM-type CFCO-1 possessed higher activity for OER in the neutral solution compared to PV-type oxides. The increase in overpotential was slow for CFCO-1, whereas that was apparent on PV-type oxides within a few hours. Furthermore, the overpotential in CFCO-1.25 increased little over 80 h. Fig. 1b-e shows HR−TEM images of (b), (c) CFCO-1.25 and (d), (e) CFCO-1; (b) (d) are before, and (c) (e) are after chronopotentiometry for 24 h. Lattice fringes attributed to BM-type structure were observed on the surface of CFCO-1.25 and CFCO-1 before OER reactions. After OER reactions for 24 h, many BM-type nanocrystals were dispersed in an amorphous matrix near the surface of CFCO-1.25, whereas the BM phase was not observed in CFCO-1. These results suggest that the maintenance of BM phase contributed to the durability of CFCO-1.25, and this is supported by the reported stability of $Sr_2GaCoO_5$ with BM structure. [1] Thus, the BM-type structure played key roles for the OER in neutral pH range, as well as the Co content itself affects the nature of catalyst.

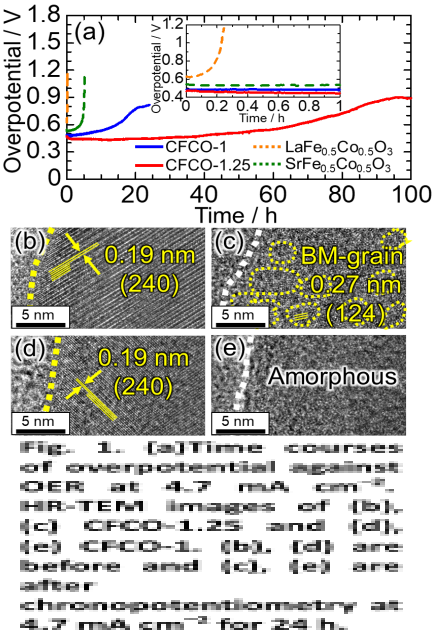

Fig. 1. [a]Time courses of overpotential against OER at 4.7 mA $cm^{-2}$. HR-TEM images of [b], [c] CFCO-1.25 and [d], [e] CFCO-1. [b], [d] are before and [c], [e] are after chronopotentiometry at 4.7 mA $cm^{-2}$ for 24 h.

**Keywords:** MOF, Nanoparticles, Overall Water Splitting, Tailored Multifunctional Electrocatalysts.

**Introduction.** Water splitting is one of the key processes for many applications related to energy storage and conversion. This process combines two half-cell reactions to produce hydrogen and oxygen gases, namely the hydrogen evolution reaction (HER) at the cathode and the oxygen evolution reaction (OER) at the anode. The benchmark HER electrocatalysts are platinum (Pt)-based materials, but these are not good for OER, whereas iridium and ruthenium oxides are the state-of-art OER electrocatalysts. Unfortunately, they show insufficient activity toward HER.

**Results and discussion.** Based on that, herein we report a straightforward, efficient and robust synthesis of mono- and bimetallic nanoparticles, promoted through a commercially available metallic source. For instance, the Wilkinson complex in order to prepare $Rh_2P$ nanoparticles, which have high crystallinity and are coated with graphitic carbon patches.[1] The resulting materials have been tested in electrocatalytic HER and OER processes at acid, alkaline and neutral media, providing superb HER activity and competitive OER performance, particularly at neutral and alkaline media, compared to the benchmark HER and OER electrocatalysts Pt and $RuO_x/IrO_x$, respectively (Figure 1a).[2]

Besides, supported Fe-doped Pd-nanoparticles (NPs) have been prepared via soft transformation of a PdFe-MOF.[3] The thus synthesized bimetallic PdFe NPs are supported on FeOx@C layers, which are essential for developing well-defined and distributed small NPs. The application of this material (PdFe@FeOx-C) as a multifunctional nanocatalyst for the electrocatalytic water splitting process has been investigated with promising results, compared with those obtained for previously mentioned benchmarking catalysts, in terms of favorable intrinsic activity, wide pH window and high stability (Figure 1b).[4]

**Keywords:** electrochemical oxygen reduction reaction, Fe-containing CNTs doped with nitrogen

**Introduction.** Deng et al. [1] experimentally and computationally demonstrated that the interaction of Fe nanoparticles (NPs) encapsulated inside carbon nanotubes (CNTs) with the graphitic walls of the CNTs might lead to a decreased local work function on the carbon surface. In addition, doping nitrogen into the carbon lattice might further reduce the local work function. The reduced local work function at the carbon surface with iron sitting below was expected to enhance its ORR activity. A series of the composites containing N-doped carbon materials and Fe NPs embedded in CNTs was synthesized via chemical vapour deposition (CVD) with acetonitrile (as carbon and nitrogen source) at 600 or 700 °C for 30 minutes in the presence of metal oxides derived from layered double hydroxides (LDHs) of various (low (Fe/Al = 0.25) marked as L or high (Fe/Al = 0.67) marked as H) concentrations of iron ions in MgFeAl systems, having constant Mg/(Fe+Al) atomic ratios, equal 3. The samples were treated with hydrochloric acid in order to remove inorganic compounds such as metal/metal oxides, which were not anchored to the carbonaceous component.

**Experimental/methodology.** The physicochemical features of the obtained composites were described by means of several techniques including powder X-ray diffraction (XRD), elemental analysis (EA), volumetric nitrogen soprtion, X-ray photoelectron spectroscopy (XPS), Raman spectroscopy, scanning electron microscopy (SEM) and X-ray fluorescence (XRF) analysis. The performance of the composites for oxygen reduction reaction (ORR) was evaluated in 0.1 M KOH by means of cyclic voltammetry (CV) and linear sweep voltammetry (LSV) in an electrochemical cell in conventional three-electrode configuration using glassy carbon disk covered with the studied sample as a working electrode, Pt wire and $Ag/AgCl/KCl_{sat}$ electrode as counter and reference electrodes, respectively.

**Results and discussion.** Depending on the composition of LDHs ($Mg_3Fe_{0.2}Al_{0.8}$ or $Mg_3Fe_{0.4}Al_{0.6}$) and/or synthesis temperature, the resulting N-doped carbon materials consisted of plate-like particles and carbon nanotubes of various contributions. As a result the obtained carbon materials had different concentrations of nitrogen, contents of Fe species and specific surface areas. The composites of N-doped carbon materials with Fe NPs were active in the electrochemical reaction of oxygen reduction in alkaline medium. Judging by the value of limiting current, the following order of the ORR selectivity was observed: C-MgFeAl-L-600-30 < C-MgFeAl-H-600-30 < C-MgFeAl-L-700-30 < C-MgFeAl-H-700-30 in line with increasing population of CNTs, decreasing exposure of graphitic edges ($I_{D1}/I_G$ ~ 3.5, 2.7, 2.4, 2.2) and diminishing contribution of amorphous carbon ($I_{D3}/I_G$ ~ 0.85, 0.61, 0.44, 0.35). The number of electrons involved in ORR calculated by Levich equation was equal 2.0, 2.3, 2.4, 2.9. This trend in selectivity might be due to enhanced interaction of Fe NPs and carbonaceous layers, which was especially pronounced in the sample prepared at 700 °C using $Mg_3Fe_{0.4}Al_{0.6}$ LDHs containing the highest population of Fe species, i.e. 4.1 wt. % (determined by XRF). To verify the impact of Fe content in LDHs on the ORR performance of the composites, additional sample was prepared at 700 °C using MgFeAl LDHs with very high Fe content (Fe/Al = 1) marked as VH. The limiting current and number of electrons were comparable for C-MgFeAl-VH-700-30 and C-MgFeAl-H-700-30.

**Keywords:** electrochemical oxygen reduction reaction, carbon materials doped with nitrogen

**Introduction.** Defects in graphitic lattice, both structural and induced by dopants (for example nitrogen in N-doped carbon materials), are beneficial as they result in (a) increasing specific surface area, (b) creating catalytic sites, (c) creating anchoring sites for active species to construct composites. Defective sites in the carbon framework play an important role in electrocatalysis as defects are often active sites [1-3]. A series of the composites containing N-doped carbon materials and iron nanoparticles (NPs) embedded in carbon nanotubes was synthesized via chemical vapour deposition (CVD) with acetonitrile (as carbon and nitrogen source) at 600 or 700 °C for 180 minutes in the presence of metal oxides derived from layered double hydroxides (LDHs) of various (low (Fe/Al = 0.25) marked as L or high (Fe/Al = 0.67) marked as H) concentrations of iron ions in Mg-Fe-Al systems, having constant Mg/(Fe+Al) atomic ratios, equal 3. The samples were treated with hydrochloric acid in order to remove inorganic compounds such as metal/metal oxides, which were not anchored to the carbonaceous component.

**Experimental/methodology.** The physicochemical features of the obtained composites were described by means of several techniques including powder X-ray diffraction (XRD), elemental analysis (EA), volumetric nitrogen soprtion, X-ray photoelectron spectroscopy (XPS), Raman spectroscopy and scanning electron microscopy (SEM). The performance of the composites for oxygen reduction reaction (ORR) was evaluated in 0.1 M KOH by means of linear sweep voltammetry in an electrochemical cell in conventional three-electrode configuration using glassy carbon disk covered with the studied sample as a working electrode, Pt wire and Ag/AgCl/$KCl_{sat}$ electrode as counter and reference electrodes, respectively.

**Results and discussion.** Depending on the composition of LDHs ($Mg_3Fe_{0.2}Al_{0.8}$ or $Mg_3Fe_{0.4}Al_{0.6}$) and/or synthesis temperature, the resulting N-doped carbon materials consisted of plate-like particles and carbon nanotubes of various contributions. As a consequence the obtained carbon materials had different concentrations of nitrogen, populations of functional N-containing groups, contents of Fe species, specific surface areas and pore diameters. The carbon materials differed not only in the total pore volume and the contribution of micropores and mesopores but also in geometry of mesopores. The composites of N-doped carbon materials with Fe NPs were active in the electrochemical reaction of oxygen reduction in alkaline medium. The number of electrons involved in ORR calculated by Levich equation was equal 2.5, 2.3, 2.4, 2.5. The ORR performance of the samples was roughly comparble. However, more precise analysis of the experimental data revealed essential differences and important correlations. Judging by the value of kinetic current, the following order of the ORR activity was observed: C-MgFeAl-L-600 < C-MgFeAl-H-700 < C-MgFeAl-L-700 < C-MgFeAl-H-600 in line with increasing value of onset potential: - 0.03 V < - 0.02 V < + 0.01 V < + 0.03 V. This trend in activity was consistent with increasing interaction of metal (Fe) NPs encapsulated inside CNTs with graphitic walls of CNTs and growing contribution of pyridinic nitrogen (both supported by XPS) as previousely reported in the literature [4, 5].

# Low iridium content mixed-metal oxides for acidic OER in PEM-water electrolysers

T. Prölß[1], T. Franken[1*]

[1] *Friedrich-Alexander-Universität Erlangen-Nürnberg (FAU), Institute of Chemical Reaction Engineering (CRT), Group of Catalytic and Electrocatalytic Systems and Processes, Erlangen, Germany.*
[*] *tanja.franken@fau.de*

**Keywords:** water electrolysis, catalysis, electrocatalysis, OER, rotating-disc-electrode

**Introduction.** The production of green hydrogen via PEM-water-electrolysis is an important part of the energy transition towards renewable energies. Hereby the rate-determining step, the oxygen evolution reaction (OER), is currently catalysed by $IrO_2$. Iridium however is very expensive. The high price limits its broad applications. Therefore, electrolysers using pure $IrO_2$ cannot fulfil the growing demand of green hydrogen. As there is no known stable non-noble-metal catalyst with sufficient activity[1], it is necessary to develop novel OER catalysts that maintain high activity with significantly lower Ir-loading. Our approach is to disperse iridium in an atomic dispersion to gain full accessibility of Ir sites and enhance the activity per mass of iridium.

**Experimental/methodology.** We achieve this by embedding iridium in mixed-metal-oxides like perovskites or spinels. To obtain the desired composition, the catalysts are synthesized from their respective precursor salts via a modified sol-gel route and calcinated in air. The successful inclusion of different amounts of iridium in the non-noble oxide crystal structure is proven by XRD and ICP measurements. The OER-activity and stability is subsequently determined by half cell experiments with a rotating-disc-electrode (RDE) in acidic electrolyte.

**Results and discussion.** Through fine-tuning of the perovskite and spinel cation-composition, highly stable and active OER-catalysts can be obtained. By substituting non-noble octahedral cations in the different lattice structures with iridium we receive finely dispersed and distorted $IrO_6$ octahedrons. Based on XRD measurements we show the variation of unit cell and reflex shift caused by the incorporation of different iridium-amounts in the non-noble mixed-metal oxide precursors. We show the OER activity for the catalysts with different iridium contents (figure 1a). The activity per mass of iridium is strongly dependent on the share of iridium in the oxide (figure 1b). By long time electrocatalytic RDE measurements the stability in dependence of the iridium content is discussed as well. Additionally, the influence of different crystal structures on the iridium activity in acidic OER is discussed. Iridium doped mixed-metal-oxides are a promising new group in acidic OER catalysis. Through interactions between the iridium and their neighbouring non-noble metals it is possible to enhance both, the activity per mass of iridium and the catalyst stability.

[3]*Centre of Excellence for Interdisciplinary Research, University of Szeged, Szeged, Hungary*
[*]konya@chem.u-szeged.hu

**Keywords:** electrochemical nitrate reduction, ammonia production, cobalt oxyhydroxide, electrocatalysis

**Introduction.** The electrocatalytic reduction of nitrate ($NO_3RR$) to ammonia is a promising route for the efficient and sustainable conversion of a hazardous environmental pollutant ($NO_3^-$) to a valuable chemical feedstock ($NH_3$) under ambient conditions. To this end, the synthesis of highly active and selective electrocatalysts is essential [1].

**Experimental/methodology.** Here, we employed a simple solvothermal method to prepare oxygen-deficient W-doped CoOOH nanostructures (Ov-W-CoOOH) and studied the role oxygen vacancies play in $NO_3RR$ on transition metal oxyhydroxides. Linear sweep voltammetry was carried out to evaluate nitrate reduction activity under alkaline conditions in the presence of 0.1 M $KNO_3$. UV-vis spectrophotometry was employed for product analysis.

**Results and discussion.** Ov-W-CoOOH nanostructures showed practically 100 % nitrate conversion in $NO_3RR$ with high Faradaic efficiency and substantial stability towards ammonia production. The improved performance of the oxygen-deficient W-CoOOH was attributed to the reduced energy barrier for $NO_3^-$-to-$NH_3$ by oxygen vacancies. DFT calculations revealed a much lower adsorption energy of $^*NO_3$ on $O_V$-FeOOH (200) with (−0.02 eV) than that on FeOOH (200), along with a decreased hydrogen adsorption free energy. The latter implies that $NO_3RR$ is more likely to occur than the competing HER, moreover, the byproducts NO and $NO_2$ are hardly generated due to the high energy barriers of their release [2]. The importance of defects in $NO_3RR$ mechanism on W-CoOOH was experimentally studied by the controlled formation oxygen vacancies, and the resulted improved performance holds promise for the production of ammonia from nitrate-containing wastewater sources.

# Understanding the role of Ag in Cu-Ag bimetallic catalysts in electrochemical Fischer-Tropsch synthesis

Floriane A. Rollier, Marta Costa Figueiredo, Emiel J.M. Hensen
*Inorganic Materials and Catalysis, Chemical Engineering and Chemistry, Eindhoven University of Technology*

Growing environmental concerns resulting from the combustion of fossil fuels constitute a strong driving force for developing technologies to produce sustainable chemicals and fuels. Electrochemical reduction of CO (CORR) or $CO_2$ (CO2RR) to chemicals such as $C_1$ (methane, methanol) and $C_{2+}$ products (ethylene, propylene, ethanol, propanol, etc.) using green electricity can contribute to this energy transition[1]. CO as a constituent of several waste streams such as steel manufacturing flue gas is a particularly interesting reactant. As the exhaust of blast furnaces is considered an irreducible source of $CO_x$, converting such carbon-based waste into chemical building blocks helps reducing greenhouse gas emissions. Moreover, sustainable CO can also be obtained by a recently commercialized technology that electrochemically reduces $CO_2$ to CO[2]. CO is also known to be a key intermediate in the formation of $C_{2+}$ products in $CO_2$RR[3]. Alternative to conventional CO hydrogenation (Fischer-Tropsch synthesis), we considered here an electrochemical variant to obtain products with C-C bonds. As such, electrochemical conversion of CO to light hydrocarbons and oxygenates can reduce our dependence on fossil resources.

It has been reported that the selectivity and activity towards $C_{2+}$ products can be increased by alloying prevalent Cu catalysts with Ag for $CO_2$ electroreduction[3,4]. CO spill-over, surface strain and electronic effects have been proposed to explain the positive effect of Ag[5,6]. However, the precise role of Ag along with the Cu-Ag interactions in these bimetallic systems remain under debate, especially for the case where CO is electrochemically reduced. As CORR constitutes a pivotal step in C-C coupling processes, we investigated the role of Ag in Cu-Ag electrocatalysts in the production of $C_{2+}$ products from CO. Sol-gel synthesis was used to obtain nanoparticle catalysts with varying Cu-Ag composition. Chronoamperometry revealed that the presence of Ag impacts the catalytic performance with optimum $C_{2+}$ selectivity obtained at a Cu:Ag ratio of 90:10 (Fig. 1). To understand the interactions between Cu and Ag under reaction conditions, we studied the catalysts using operando X-ray absorption (XAS) and quasi in situ X-ray photoelectron spectroscopy (XPS) with the goal of defining structure-activity relationships in CORR to $C_{2+}$ products. The formation of a Cu-Ag alloy was excluded by bulk sensitive characterization techniques such as XAS. However, the XPS analysis pointed to clear differences in Ag dispersion at the catalyst surface depending on composition, which likely influences the amount of Cu-Ag interface sites. These findings help to explain the differences in catalytic performance as a function of Cu:Ag ratio.

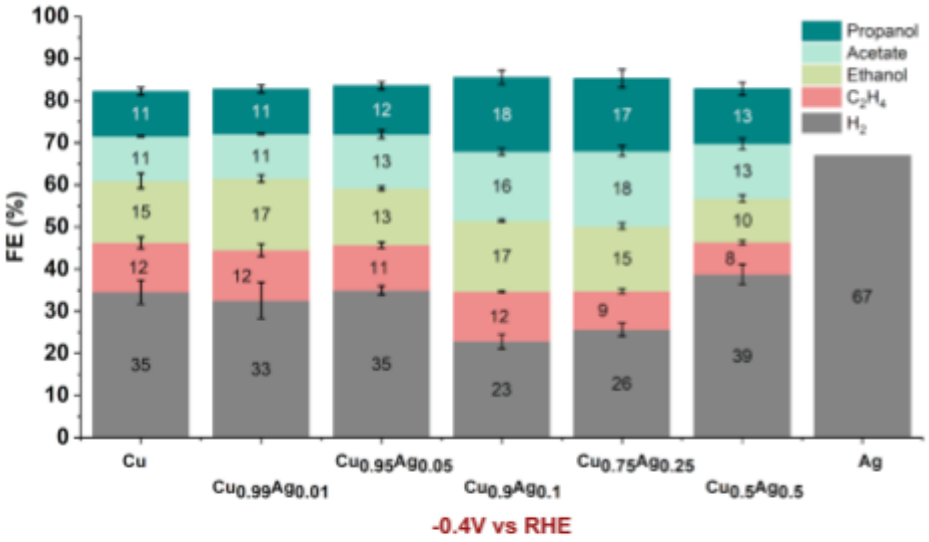

**Figure SEQ Figure * ARABIC 1 - Faradaic efficiencies of majored products formed on different Cu-Ag compositions (1h of CORR at -0.4 V vs RHE in 3M KOH)**

# Enhancement of Selectivity during Electrocatalytic Reduction of Carbon Dioxide at Copper Centers Supported onto Nonstoichiometric Oxides

Iwona A. Rutkowska*, Anna Chmielnicka, Pawel J Kulesza

Faculty of Chemistry, University of Warsaw, Pasteura 1, PL-02-093 Warsaw, Poland
*ilinek@chem.uw.edu.pl*

Of particular interest to the preparation of advanced catalytic materials is efficient utilization of catalytic sites (metal and metal oxide nanostructures, their stabilization and intentional activation, as well as organization into two-dimensional arrays, ultra-thin films or three-dimensional networks (e.g. through sequential deposition) on electrode surfaces. They can form nanosized materials with well-defined composition, structure and thickness that exhibit desirable electrocatalytic properties (e.g. toward reduction of $CO_2$). We explore here the ability of polynuclear inorganic metal oxo systems to stabilize and functionalize metal (e.g. copper) nanostructures. Here certain nanostructured metal oxides of zirconium, titanium, zinc or tungsten have been demonstrated to influence supported metal centers in ways other than simple dispersion over electrode area.

Our research interests concern development of systems for the electrocatalytic reduction of carbon dioxide in acid media[1]. A hybrid catalytic system composed of copper(I)-oxide-derived copper-nanocenters immobilized within the network tungsten oxide nanowires has exhibited electrocatalytic activity toward $CO_2$-reduction in acid medium (0.5 mol $dm^{-3}$ H2SO4). The catalytic system facilitates conversion of $CO_2$ to methanol and is fairly selective with respect to the competing hydrogen evolution. The preparative procedure has involved voltammetric electroreduction of $Cu_2O$ toward formation and immobilization of catalytic Cu sites within the hexagonal structures of $WO_3$ nanowires which are simultaneously partially-reduced to mixed-valence hydrogen tungsten(VI,V) oxide bronzes, $H_xWO_3$, coexisting with sub-stoichiometric tungsten(VI,IV) oxides, $WO_{3-y}$. After the initial loss of Cu through its dissolution to $Cu^{2+}$ during positive potential scanning up to 1 V (vs. RHE), the remaining copper is not electroactive and seems to be trapped within in the network of hexagonal $WO_3$. Using the ultramicroelectrode-based probe, evidence has also been provided that partially-reduced non-stoichiometric tungsten oxides induce reduction of $CO_2$ to the CO-type reaction intermediates. The existence of copper sites dispersed in WO3 improves electron transfers and charge propagation within the hybrid catalytic layer. The enhanced tolerance of the catalyst to the competitive hydrogen evolution during $CO_2$-reduction should be explained in terms of the ability of HxWO3 to consume protons and absorb hydrogen as well as to shift the proton discharge at Cu toward more negative potentials. But the capacity of $WO_3$ to interact with catalytic copper and to adsorb CO-type reaction intermediates is expected to facilitate removal of the poisoning CO-type adsorbates from Cu sites. On mechanistic grounds, the existence of hydrogen-rich partially-reduced tungsten oxides, $H_xWO_3$, which contain large population of delocalized electrons and monoatomic H, or coexisting protons and electrons, $H^+ + e^-$, is likely to induce hydrogenation of CO-type adsorbates on Cu to form -$CH_2OH$ intermediates followed by protonation. The hybrid Cu/$WO_3$ system, while exhibiting better selectivity toward $CO_2$ reduction, relative to hydrogen evolution (proton discharge), is also characterized by improved durability, relative to pristine $Cu_2O$-dervided copper.

**Keywords:** Mo-doped mixed oxide composite, Pt, strong metal-support interaction, XPS, electrocatalysis

**Introduction.** Composites of titania-based mixed oxides and carbon denoted as $Ti_{(1-x)}M_xO_2$-C (M = Mo) have recently been identified as promising novel support for Pt electrocatalysts in polymer electrolyte membrane fuel cells (PEMFCs) [1]. The carbonaceous part of the composite ensures the required high surface area and good electrical conductivity of the catalyst, the $TiO_2$ component helps to stabilize Pt particles against dissolution and/or sintering driven by electrooxidation of the carbon, while the dopant metal cations incorporated into the titania improve the conductivity and provide valuable co-catalytic function, thus the composite supports can mitigate the known drawbacks of the current state-of-art Pt/C systems. The strong metal-support interaction (SMSI) phenomenon can occur in the composite supported electrocatalyst due to the interaction of Pt and the mixed oxide, generally manifesting itself in decoration of the metal particles by ultrathin layers of the support material upon annealing under reductive conditions [2]. The aim of this work is to evaluate the SMSI phenomenon as a possible strategy for tailoring the properties of the electrocatalysts in terms of stability and activity.

**Experimental/methodology.** A 20 wt.% Pt/50 wt.% $Ti_{0.8}Mo_{0.2}O_2$-50 wt.% C electrocatalyst prepared on Black Pearls 2000 carbon functionalized with $HNO_3$ and glucose was reduced at varying temperatures between 150-450 °C in $H_2$ in order to induce SMSI. Cyclic voltammetry and $CO_{ads}$ stripping voltammetry were used to assess the electrocatalytic properties and the stability of the reduced catalysts compared with the parent one and commercial reference Pt/C catalyst. The hydrogen oxidation reaction (HOR) and the oxygen reduction reaction (ORR) were measured by rotating disk electrode (RDE) to evaluate the kinetic behavior of the systems. Structural characterization by XRD and TEM, completed by XPS measurements combined with *in situ* $H_2$ exposure experiments was performed in order to understand the interaction between the oxide and the Pt nanoparticles [3].

**Results and discussion.** Electrochemical investigations revealed good activity and tolerance against CO poisoning for both the parent Pt/$Ti_{0.8}Mo_{0.2}O_2$-C catalyst and its reduced counterparts, which was explained by atomic closeness of Pt and easily reducible Mo species as confirmed by TEM. Partial encapsulation of Pt by mobile Mo species was suggested by a slight decrease of the electrochemically active surface area (ECSA) of Pt at reduction temperatures above 150 °C; XPS investigations indeed indicated appearance of ionic Mo directly adsorbed on the Pt surface in this temperature range. Besides, the stability of the reduced catalysts assessed by ECSA changes during a 10,000-cycle stability test significantly improved with respect to not only the commercial Pt/C reference but also to the parent Pt/$Ti_{0.8}Mo_{0.2}O_2$-C catalyst. The systematic variation of the reduction temperature, accompanied by the thorough characterization of the reduced catalysts allowed selection of the most promising treatment conditions and interpretation of the results in terms of structural changes of the catalysts.

# Transition Metal Phosphide-Based Materials for HER and OER reactions

N. Spera, J. P. S. Sousa*

International Iberian Nanotechnology Laboratory, Braga, Portugal
*Juliana.Sousa@inl.int

**Keywords:** phosphides, HER, OER

**Introduction.** Water electrolysis is a promising technology to produce the high-purity of hydrogen due to its environmental friendliness. However, the best electrocatalysts for this process—which include the hydrogen evolution reaction (HER) and the oxygen reduction reaction (ORR)—often contain scarce and expensive noble metals, substantially limiting the potential for these technologies to compete with fossil fuels. The considerable challenge is to develop robust electrocatalysts composed exclusively of low-cost, earth-abundant elements that exhibit activity comparable to that of noble metals [1, 2]. Transition metal phosphides are receiving intense attention due to their abundance in the Earth's crust and comparable catalytic properties to noble metals. The main goal of this project is to explore the properties of transition metal phosphides in order to achieve optimal catalytic performance with sustainable, earth-abundant materials. Active catalysts are required to minimize the overpotential necessary to drive the oxygen (hydrogen) evolution reaction. The doping of phosphides with aluminium (Al) and magnesium (Mg) can have a positive effect on the electrocatalytic activity. The doping will have significant and diverse effects on the electronic structure, the position of the Fermi level, and the curvature of DOS near the Fermi level.

**Experimental/methodology.** Fe- and Ni-based phosphides with high efficiencies toward electrochemical $H_2$ and $O_2$ evolution reactions were prepared. It was performed, a systematic doping of Ni (Co and Fe) P with Al and Mg. The doped phases were characterized to establish bulk crystal structures, the dopant atom distributions, and the resulting bulk electronic structures. The performance of the electrocatalyst was investigated in terms of activity (hydrogen and oxygen production rates) and stability.

**Results and discussion.** Self-supported electrodes comprising carbon black integrated with transition metal phosphides electrocatalysts were fabricated by one-step phosphorization treatment.

It has been proven that P atoms in the TMPs play crucial roles for HER. The negatively charged P can act as a base to trap positively charged proton during electrochemical HER. So for the same metal phosphides, increasing the atomic percentage of P may effectively improve the corresponding HER activity. However with the continuously doping P into metals, electrically conductive metals gradually become semi-conductive or even insulated metal phosphides. The reason is that P atoms will restrict the electron delocalization in metal, resulting in weakened conductivity, resulting in a weakened electronegativity. Furthermore, in almost all of the phosphides occurred the oxidation of its surface, resulting in the formation of P (V) and metal oxide (high-valence state). This as-formed non-active oxide would clearly block the access of the proton to the active site and lower the conductivity, which will cause fast degradation in performance. So is very important to determine the optimal amount of P to be present in TPMPs.

**Keywords:** electrochemical nitrate reduction, electroless coating, boron carbon nitride (BCN), electrocatalysis

**Introduction.** Ternary boron carbon nitride (B-C-N or BCN) integrates the merits of the widely-known 2D materials, graphene and hexagonal boron nitride (hBN). BCN materials have drawn attention for their physical and chemical properties, like tunable band structure (band gap between 0 and 5.5 eV by adjusting heteroelement composition) and hence adaptable electrical properties, thermal stability and chemical inertness [1, 2]. This promise diverse possible applications, and since the heteropolar B and N bonding largely stimulates electroactivity, BCN structures are likely to be used in electrochemical energy applications as well. In this study, the performance of a Cu/BCN heterostructure was studied in the electrochemical reduction of nitrate ($NO_3RR$) towards a valuable chemical feedstock, ammonia.

**Experimental/methodology.** BCN powder was synthesized through a hybrid method of combining mechanical alloying and calcination. Mechanical alloying was carried out in a planetary ball mill at 450 rpm for 6 h with the subsequent calcination at 500 °C for 2 h under argon atmosphere. Copper layer was deposited onto the as-synthesized compound using electroless plating with and without a prior surface activation using $Pd^+$ cations, and a core/shell Cu@BCN structure was obtained. $NO_3RR$ activity was evaluated via linear sweep voltammetry under alkaline conditions in the presence of 0.1 M $KNO_3$, while the corresponding product distribution was determined by UV-vis spectroscopy.

**Results and discussion.** X-ray diffractometry showed that either $Cu_xO$ or highly crystalline elemental Cu was formed on the pristine BCN during electroless plating with and without $Pd^+$ surface activation, respectively. The morphology of the obtained heterostructures was studied by scanning and transmission electron microscopy (TEM), and the formation of a non-uniform copper-oxide layer was found in the the former, while a more uniform polycrystalline copper core/shell structure in the latter case. The deposition of copper-based layers then introduced improved activity in electrochemical nitrate reduction, making these structures promising Cu-based electrocatalysts for high-performance ammonia production from nitrate-containing wastewaters [3].

**Keywords:** Water electrolysis, Hydrogen evolution reaction (HER), Molten salt electrolyte, Electrocatalysis

**Introduction.**
Excess electrical energy from renewable resources has to be stored in the form of electricity-based energy carriers and fuels, one particular example is hydrogen from electrolysis. Most of the research is carried out in aqueous electrolytes at room temperature (or slightly elevated temperatures) and atmospheric pressure, so-called Low Temperature Electrolysis (LTE). Another interesting approach is to implement proton-conducting salts as electrolytes. This method can be used at higher temperatures, compared to LTE, in ranges between 200 and 400°C and is therefore referred to as Medium Temperature Electrolysis (MTE). The potential for alternative, cost-effective electrode and electrocatalyst materials is very promising, compared to common noble metals (e.g., Platinum) implemented in LTE. We have already successfully carried out corresponding investigations in the MTE range and successfully proven specific carbide materials to be better than platinum under these conditions [1, 2]. The present contribution shows an attractive approach to studying MTE systems including a detailed investigation of different materials.

**Experimental/methodology.**
A novel electrolyzer construction was developed for elevated pressure and temperature electrocatalytic applications (i.e., MTE) and electrochemical characterization, see figure. This setup is safer and more flexible for the exploration of electrolysis under those elevated temperature and pressure conditions, e.g., water electrolysis in molten salt electrolytes for MTE (this work). Some of the experiments include proton conductivity measurements and eutectic system characterizations of dihydrogen phosphate based salt mixtures ($MH_2PO_4$, M= Li, Na, K).

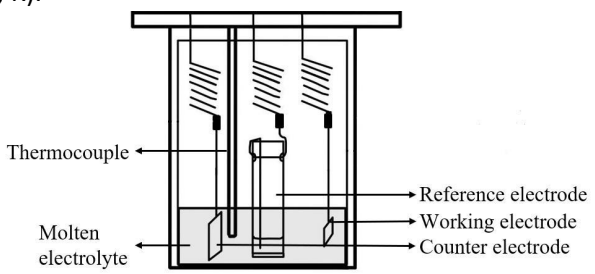

**Figure:** Setup for electrocatalytic measurements under medium temperature and elevated pressures.

**Results and discussion.**
The melting and thus the working temperature for the MTE could be adjusted with varying salt mixtures, giving higher process temperature flexibility for electrolysis implementation. Furthermore, a series of electrochemical characterization techniques including Linear Sweep Voltammetry (LSV), Electrochemical Impedance Spectroscopy (EIS), and Chronopotentiometry (CP) were implemented on different transition metal electrodes. The performance of these electrodes shows potential for implementation as low-cost alternative electrocatalyst supports in contrast to Platinum.

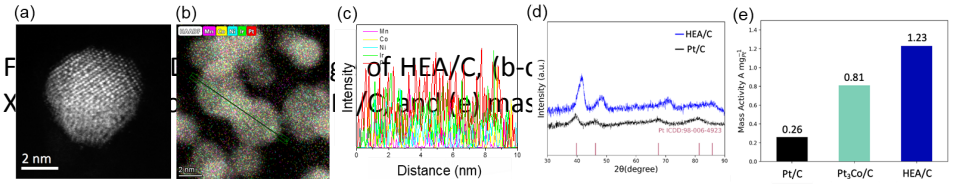
**Keywords:** Electrocatalysts, Oxygen reduction reaction, High-entropy alloys, Proton exchange membrane fuel cells

**Introduction.**



Proton exchange membrane fuel cells (PEMFCs) have been regarded as a promising candidate for fuel cell electric vehicles (FCEVs). Yet, wide application of such technology is greatly dependent on the cost and performance of the oxygen reduction reaction (ORR) catalysts at the cathode. Recently, high-entropy alloys (HEAs) has come out as an emerging class of material for catalysis, and it is appealing for ORR. The multi-metal components could not only reduce the Pt usage but also optimize oxygen adsorption energy by finetuning various alloying composition at an intricate scale compared to conventional binary or ternary alloys, hence attaining high ORR activity.

**Experimental/methodology.**

The PtCoNiMnIr/C (HEA/C) was synthesized using seed-mediated wet-impregnation method, in which desirable amount of metal precurors were mixed with Pt/C followed by high temperature fast annealing under $H_2$/Ar. Structure and morphology of the catalyst was studied using various techniques, e.g., XRD, XPS, HAADF STEM, etc.. ORR performance of the catalyst was evaluated using a rotating disk electrode (RDE) setup, from which electrochemical surface areas and mass activities of the catalysts were obtained. In addition, advanced X-ray techniques e.g., XANES, EXAFS and valence to core XES were performed to further elucidate the strucutral-performance relationship of the catalyst.

**Results and discussion.**

Fig 1a shows the HAADF-STEM image of the HEA/C catalyst, which showed an interesting intermetallic strucuture. The corresponding line scan elemental profile from EDX also indicated an uniform elemental distribution on the HEA nanoparticles. (Fig. 1b-c) XRD pattern of the HEA/C showed a positive peak shift towards higher angle compared to that of Pt/C, which inferred a Pt lattice compression due to alloying. (Fig. 1d) Such lattice strain effect could lower the *d*-band centre of the Pt and weaken the adsorption of oxide species, hence improving the ORR activity. In terms of the ORR performance, the mass activity of the as-prepared HEA/C was found to be 1.23 A/mgPt (Fig. 1e), which was around 1.5 times higher than that of $Pt_3Co$/C (0.81 A/mgPt) and 4.9 times higher than that of commercial Pt/C catalyst (0.26 A/mgPt). This result has shown that by alloying Pt with multiple metal elements to form HEA, it could achieve superior ORR performance compared to binary Pt alloy and pure Pt. This could primarily due to the incorporation of multiple metal species, which allow precise tuning of the oxygen adsorption energy for more efficient ORR.

**wierzbicki@chemia.uj.edu.pl*

**Introduction.** Anion-Exchange Membrane (AEM) Fuel Cells (FCs) are a novel technology, which is a promising alternative to the proton exchange membrane (PEM) FCs, due to the alkaline medium of AEMs which allows the use of electrocatalysts free from Platinum Group Metals (PGM), which contributes to lowering the price of AEMFCs price in comparison to PEMFCs [1,2]. Nevertheless, the low stability of AEMs is still one of the factors hindering wide-scale AEM application. Radical-induced degradation was widely described for PEMs, however, is still not very well understood for AEMs [3]. Radical-based Reactive Oxygen Species (ROS), such as ˙OOH and ˙OH radicals are believed to have crucial on AEMs degradation processes [3-5].

**Experimental/methodology.** Electron Paramagnetic Resonance (EPR) spectroscopy was used as a primary technique in conjunction with spin trapping, as it allows the detection of short-living radicals formed during AEMFC operation. A micro-AEMFC employing Fumasep FAA-3-20 membrane and one of five cathode catalysts (Pt, Pd, low-PGM PdAg PGM-free $(MnCo)_3O_4$ and Ag) was fitted in an EPR spectrometer cavity, with DMPO spin trap placed on the investigated electrode.

**Figure 1.** EPR spectra recorded on cathodes of AEMFCs using $(MnCo)_3O_4$ **(A)** and PdAg **(B)** catalysts.

**Results and discussion.** The formation of ROS was confirmed on all of the investigated cathode catalysts. EPR spectra recorded on cathodes of AEMFCs using $(MnCo)_3O_4$ and PdAg catalysts are showcased in **Figure 1**. Both spectra exhibit hyperfine splittings characteristic for DMPO-OOH adducts. Additional experiments, conducted with $(MnCo)_3O_4$ catalyst exposed to isotope marked $^{17}O_2$, confirmed that the ˙OOH radicals are formed in the interaction of gaseous oxygen with the catalyst surface. The spectrum recorded on the PdAg (**Figure 1B**) catalyst exhibits additional peaks, indicated with the arrows, attributed to the DMPO-H adducts with hydrogen radicals formed due to $H_2$ diffusion through the membrane. The formation of ˙H and ˙OOH radicals at the cathode during the AEMFC operation is crucial for the understanding of AEM degradation. These findings suggest that it is necessary to develop catalysts containing radical scavenging additives and novel AEMs resistant to radical attack. Thus, in our future studies, we plan to investigate the efficacy of radical scavengers and the effect of the operating conditions on the radical formation in AEMFC.

**Keywords:** Ammonia, solid oxide fuel cell, direct ammonia solid oxide fuel cell, ammonia decomposition

**Introduction.** Transitioning into a sustainable energy system is a significant challenge in countries like South Korea; a densely populated country with energy-intensive industries with low potential for renewable energy. Green ammonia is a plausible solution to this problem where ammonia has one of the highest energy densities with well-established infrastructure. Direct ammonia-fueled solid oxide fuel cell (DA-SOFC) is a type of SOFC directly fed with ammonia fuel. Ammonia decomposes into hydrogen and nitrogen inside the Ni-rich anode of SOFC, and hydrogen is electrochemically oxidized to generate electricity with high efficiency. The exothermic operation of the fuel cell and the endothermic reaction of ammonia decomposition increases the efficiency even further making DA-SOFC one of the most attractive devices that use ammonia. DA-SOFCs perform as well as their $H_2$-fueled counterparts at temperatures > 750 °C but a significant performance drop is observed for the next generation SOFCs that run at < 650 °C.

**Experimental/methodology.** In this work, state-of-the-art thin-film SOFCs were tested for direct ammonia operation and were compared with a commercial SOFC. Thin-film SOFCs were fabricated by using the pulsed laser deposition method [1]. Electrochemical measurements, impedance spectroscopy, gas analysis, and 2D multiphysics modeling were performed to gain a comprehensive understanding of DA-SOFCs. Further, we focused on the development of high-performance DA-SOFCs through the introduction of thermally stable nano-sized ammonia decomposition catalysts.

**Results and discussion.** The electrochemical performance test and impedance spectroscopy results were compared between the ammonia and hydrogen operations on three different SOFCs. The performance of DA-SOFC dropped significantly with decreasing temperature and increasing cell performance. The lack of fuel at the electrochemical interface was expected from the impedance analysis. Total ammonia conversion at the cell outlet decreased from 80% to 20% as temperatures were lowered from 650 to 500 °C. Ammonia conversion and electrochemical reactions inside the cells were observed by developing a two-dimensional (2D) multi-physics numerical model. The model suggested that the lower ammonia conversion and mass transport limitations result in the low flux of the hydrogen fuel to the electrochemical interface. The results signified the importance of a better ammonia decomposition catalyst and facile gas transport channels. To further improve the performance of DA-SOFCs, thermally stable and active Ru catalysts were developed and introduced to the SOFCs. The cell showed improved ammonia conversion and DA-SOFC performance. We are also focusing on the detection of potential $NO_X$ emission, degradation of metallic components, and catalytic activity of metallic components of the SOFCs.

# Design of a perovskite oxide cathode for a proton-conducting solid oxide fuel cell

Penghui Yao, Yongdan Li*

*Department of Chemical and Metallurgical Engineering, Aalto University, Kemistintie 1, FI-00076 Aalto, Finland*

**Keywords:** Proton-conductive fuel cell (PCFC), Cathode $La_{0.5}Sr_{0.5}Mn_{0.9}Ni_{0.1}O_{3-\delta}$, Oxygen reduction reaction (ORR), Proton transfer.

**Introduction.** Effective technologies for clean and sustainable energy transformation are highly demanded for addressing the growing energy consumption and environmental pollution. The solid oxide fuel cell (SOFC) have drawn great attention as an efficient, clean, and sustainable energy conversion device[1]. However, high operation temperature (700-1000 °C) has limited their widespread application. In contrast, proton-conductive fuel cells (PCFCs) operate at lower temperatures (550-700 °C) than the conventional oxygen ion-conducting SOFCs. No fuel dilution needed is an additional merit for PCFCs due to the water formation on the cathode side. Nevertheless, sluggish cathode reaction kinetics at low temperatures has been a major challenge for their practical application[2]. High polarization and low electrocatalytic activity toward oxygen reduction reaction (ORR) deteriorate the cell performance. In this work, Ni doped $La_{0.5}Sr_{0.5}MnO_{3-\delta}$ is designed based on DFT simulation and synthesized as cathode material of a PCFC. The effects of the Ni-doping on the crystal structure, electronic configuration and oxygen vacancy formation. Moreover, the proton transfer and ORR mechanism are discussed.

**Experimental/methodology.** The electrolyte $BaZr_{0.1}Ce_{0.7}Y_{0.2}O_{3-\delta}$ (BZCY) powder was synthesized with a solid-state reaction method[3]. The electrolyte layer was coated on the anode with a dip-coating method. The electrolyte precursor slurry was obtained with ball-milling BZCY, sintering aid NiO, triethanolamine, polyethylene glycol 600, dibutyl phthalate and ethanol. After coating the electrolyte slurry on the anode surface, the anode-electrolyte bilayer was co-sintered at 1400 °C for 5 h. $La_{0.5}Sr_{0.5}MnO_{3-\delta}$ (LSM) and $La_{0.5}Sr_{0.5}Mn_{0.9}Ni_{0.1}O_{3-\delta}$(LSMNi) powders were prepared with a sol-gel technique. Lanthanum nitrate hexahydrate, strontium nitrate, manganese(II) nitrate, and nickel nitrate hexahydrate as the metal sources were dissolved in water. Subsequently, citric acid was added. The molar ratio of citric acid to metal ions was set at 1.5.

**Results and discussion.** LSMNi as cathode shows higher proton conductivity and ORR activity than the undoped LSM. The PCFCs with LSMNi exhibit low polarization resistance and high peak power density. The density functional theory simulations indicate that Ni doping decreases the oxygen vacancy formation and proton migration energy barriers, thereby improving the proton conductivity. The enhanced ORR activity is attributed to O p-band center close to Fermi level and the overlapping state of 3d orbitals of Mn and 2p orbitals of O, accelerating electron transfer during ORR steps. The adsorption energy of oxygen on the LSMNi surface is lower than that on LSM. This work provides a novel strategy to design cobalt-free cathode for a proton-conductive fuel cell.

# Electrocatalytic Hydrogenation of Olefinic and Carbonyl Compounds with Pd@Carbon Nanotubes at an Oil-Water Interface

Chenhui Han[1], Johannes Zenner[1,2], Jacob Johny[1], Nicolas Kaeffer[1], Alexis Bordet[1]*, Walter Leitner[1,2]

[*]*alexis.bordet@cec.mpg.de*

**Introduction.** Electrocatalytic hydrogenation (ECH) represents an attractive method to use electricity from renewable sources towards the electrification of the chemical sector, from biomass conversion to the production of fine chemicals. Protons from water are reduced electrochemically and directly transferred to unsaturated substrates under mild operating conditions (temperature and pressure), while avoiding the need for $H_2$ handling and storage.[1] However, in aqueous media this technique is limited by the low solubility of most organic substrates and the competing hydrogen evolution reaction. Organic electrolytes can improve substrate solubility, however their use is typically associated with significant ohmic losses.[2]

**Experimental/methodology.** To tackle these limitations, a Pickering emulsion-based ECH system was developed. Pickering emulsions consist of two immiscible phases, with one phase being dispersed into the other as micrometer-sized droplets. These droplets are stabilized by solid particles at their interface.[3] In the present work, organic substrates were dissolved in oil droplets (constituted of cyclohexane as organic solvent) surrounded by an acidic aqueous electrolyte. Pd nanoparticle-decorated carbon nanotubes (Pd@CNTs) were employed both as stabilizers for the Pickering emulsions and electrocatalysts (Figure 1a).

**Results and discussion.** The described configuration simultaneously benefits from the high ionic conductivity of the aqueous phase and good substrate solubility in the emulsion droplets. Electricity is transported from a silver cathode to the large oil/water interface via the conductive Pd@CNTs, where Pd nanoparticles enable the reduction of protons from the aqueous phase. These hydride species can then hydrogenate the substrates inside the oil droplets. The surface molecular modification of the CNTs proved critical to ensure sufficient contact between the cathode and the network of emulsion bubbles. The emulsion-based ECH system showed high mass specific current density (–148.1 $mA \cdot mg_{Pd}^{-1}$) and faradaic efficiency (95.0%) towards the production ethylbenzene from styrene (Figure 1b).[4] This approach was successfully extended to a variety of alkenes, aldehydes and ketones, and we further plan to explore the applicability of this strategy to an extended array of chemical transformations, such as the conversion of bio-oil and biocrude.

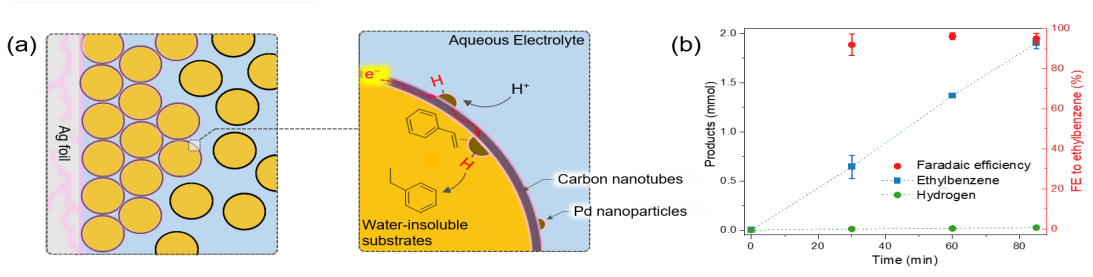

**Figure 1.** (a) Scheme of the Pickering emulsion based ECH system: Emulsion droplets are stabilized by CNTs, that conduct electricity from a silver electrode to Pd nanoparticles. The NPs catalyze the reduction of protons from water, which then hydrogenate organic substrates in the oil droplets. (b) Time-profile of the ECH of styrene to ethylbenzene using the presented ECH system (0.2 mmol styrene, 10 mg Pd/CNTs (4.7 µmol Pd), 10 mL cyclohexane, 75 mL 0.5 M $H_2SO_4$, 0.65 $V_{RHE}$, emulsification frequency 5 s/5 min, reactions were stopped after the passage of 386 C).

**Keywords:** Green hydrogen, Hydrogen evolution reaction, Alkaline water electrolyzer.

**Introduction.** Electrochemical production of green hydrogen, driven by electricity power derived from renewable energy sources, is a crucial technology to empower the energy transition towards climate neutrality.[1,2] In this scenario, alkaline electrolyzer (AEL) stacks have been robustly established at MW-scale for over a century, with single-stack capacities up to several MWs.[3] However, the energy efficiencies of commercial AELs, particularly at current densities above 0.5 A/cm$^2$, are still insufficient to make green hydrogen cost-competitive with fossil fuels.[4] In our work, we demonstrate that the main limitations of AELs can be overcome by systematically designing cost-effective cathode and anode with state of the art-like performances for alkaline water splitting reactions and using the recently validated commercial diaphragms for building performance-robust and safe AELs.

**Methodology of synthesis.** i) Chemical bath deposition of CuO nanoplate arrays onto metallic substrate (*e.g.,* Ti mesh); ii) Electroreduction of CuO nanoplate arrays; iii) Electrodeposition of Ru nanocrystals.

**Results and discussion.** We designed a cost-effective, highly performant and robust cathode (up to 25 cm$^2$ working area), consisting of catalytically active electrodeposited Ru nanoparticles (*ca. 53* μgRu/cm$^2$) on vertically oriented Cu nanoplatelet arrays grown on metallic meshes, namely, Ru@Cu-TM. The mass loading of Ru on cathode is 10 times lower than that of Pt used in proton exchange membrane electrolyzers (PEM-ELs), while achieving a current density of -0.2 A/cm$^2$ at a low overpotential of 85 mV (>200 mV for Pt/C) in 1M NaOH. Besides, we discovered that multistacked SSMs could be a simple and cost-effective anode to replace the well-performant NiFe anode screened by us for designing AELs, with unprecedented performance and long-term durability. Our optimized AELs, using commercial diaphgrams, can operate with current densities as high as 1 A/cm$^2$ at 1.69 V and operate at almost 6 A/cm$^2$ at 2.30 V. The latter reached record values reported for Pt group material-based proton-exchange membrane electrolyzers. Such a AEL could stably operate in a continuous (1 A/cm$^2$ for over 300 h) and intermittent modes with an estimated total cost of US$2.26/Kg$_{H2}$ for a 1 MW AEL plant based on the proposed electrode technology, hitting the worldwide targets of green hydrogen production for the coming decade (<US$2.5/Kg$_{H2}$).

# Shape-shifting exsolved nanoparticles in solid oxide cells

Somi Lee, Yo Han Kim, Yeeun Kim and Jae-ha Myung*

*Department of Materials Science and Engineering, Incheon National University, Incheon 22012, South Korea*
**Corresponding Author's E-mail address: mjaeha@inu.ac.kr*

**Introduction.** The exsolution method, which allows for the uniform growth and dispersion of nanoparticles on a support oxide, is a promising approach that offers unique stability against carbon coking and agglomeration. Controlling the shape of nano-catalysts improves catalytic properties by adjusting the crystallographic planes involved in the reaction and increasing the surface area.[1,2] However, shape control of nanoparticles in exsolution research has not been extensively studied. To achieve shape-shifting in the exsolution processes, considerable growth of nanoparticles are required to stabilize the surface of metallic particles. In this study, the surface of nanoparticles exsolved from perovskite oxide electrodes was controlled to the (111) plane by maximizing particle growth via electrochemical reduction.
**Experimental/methodology.** The perovskite oxides were synthesized by solid state reaction method including mixing regents, sintering at 1300 °C for 3 h, and grinding. The synthesized oxides were reduced in pure $H_2$ at high-temperatures of 600, 750, and 900 °C to achieve exsolution. The pristine and reduced samples were investigated using Scanning Electron Microscopy (SEM), Transmission Electron Microscopy (TEM), and $H_2$-Temperature Programmed Reduction (TPR) to verify exsolution behavior. The perovskite oxides were used as fuel-electrodes in solid oxide cells. Cell test was conducted using Electrochemical Impedance Spectroscopy (EIS) and Linear sweep voltammetry (LSV).
**Results and discussion.** As the size of the exsolved nanoparticles increased, their shape changed from spherical to polymorphic (Fig. 1). Despite optimizing the reduction conditions and oxide composition, controlling the shape of exsolved nanoparticles in the porous electrodes remains challenging due to nonuniform growth resulting from the oxide powders with different sizes and surface orientations/terminations. To overcome this limitation, electrochemical reduction was used to maximize the growth of exsolved particles in the oxide electrode. As a result, the shape of the nanoparticles grown to over 50 nm changed from spherical to polymorphic. The exsolution electrode with shape-controlled unit cells exhibited high power/current density in both fuel cell and electrolysis applications. These results not only maximize the growth of exsolved nanoparticles but also provide a strategy for controlling the shape of exsolution electrodes.

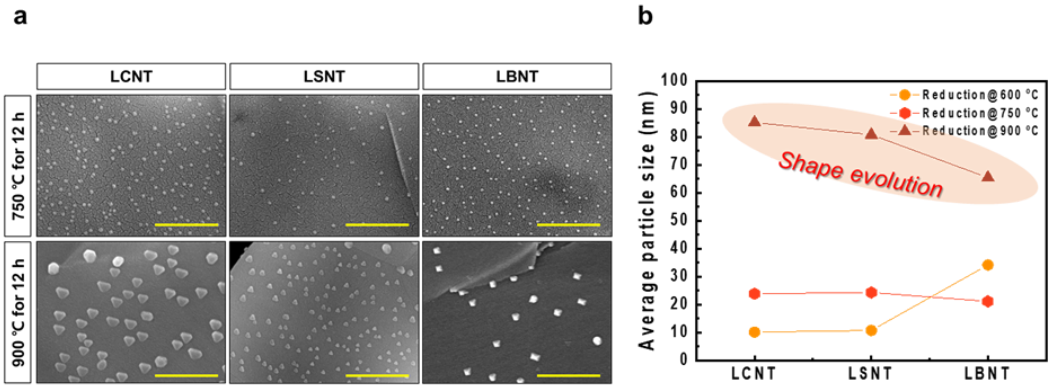

Fig. 1. Shape evolution of exsolved particles on reduced LMNTs. (a) SEM images of the reduced LCNT, LSNT, and LBNT at 750, 900 °C, respectively. (b) Average particle size of LCNT, LSNT, LBNT after reduction at 600, 750, 900 °C, respectively.

**Keywords:** two-dimensional, ethanol oxidation, trimetallic, dendritic, electrocatalysis

**Introduction.**

Fuel cell systems such as DEFC are in the spotlight as promising future energy sources. Currently, Pt catalysts are mainly used in fuel cells. This is because Pt is heat resistant and does not corrode well. However, Pt is expensive. Pt also has poor stability due to adsorption with surface toxic substances. Therefore, various efforts are being attempted to improve these problems and develop nanoparticles with improved catalytic activity. Alloying metals and controlling morphology are promising ways to synthesize nanoparticles that have improved electrocatalytic activity and stability. However, it has not been reported much because it is difficult to synthesize structured multimetallic nanoparticles. Herein, we synthesized trimetallic 2D nanosheets alloying Pd and Ag on Pt by adjusting amount of surfactant and reductant. The particles we synthesized have an ultrathin 2D sheet structure. 2D sheets are efficient to use as catalysts because they have a structure with a maximized surface area. In addition, the synthesized nanosheets have a dendritic edge and are rich in undercoordinated atoms. The changed intrinsic activity of the undercoordinated atoms at the edge can adjust the degree of interaction with the reactants to improve EOR activity. Moreover, the nanosheets can be expected to have an ensemble effect due to the interaction through alloys of three types of metals. Since silver has an oxophilic property, it is helpful in generating surface $OH_{ads}$ that prevent the generation of surface poisoning intermediates such as CO. We also synthesized nanoparticles with different compositions of metal to study the electrocatalytic activity of nanoparticles according to morphology and compositions. Through this, it was found that nanoparticles with a composition of $Pd_1Ag_1Pt_1$ have the most appropriate degree of adsorption with the reactant and have the highest activity in EOR.

**Experimental/methodology.**

To synthesize PdAgPt nanosheets, Pd, Pt, and Ag precursors were mixed with reductant and surfactant. The reaction solution was kept for 2 hours. The color of the solution containing nanosheets changed to black. By centrifugation 3 times, Nanosheets can be obtained. PdAgPt nanosheets with different compositions can be synthesized by controlling the volume of the metal precursors.

**Results and discussion.**

We synthesized trimetallic 2D nanosheets composed of Pd, Ag, and Pt. $Pd_1Ag_1Pt_1$ NSs with an ultrathin 2D structure were synthesized by adjusting the concentration of reductant and surfactant. X-ray diffraction (XRD) patterns and X-ray photoelectron spectroscopy (XPS) demonstrated that the synthesized nanosheets have an fcc crystal structure and a modified electron structure. We tested their electrocatalytic activity toward ethanol oxidation reaction, $Pd_1Ag_1Pt_1$ NSs showed the highest mass activity (10.442 mA $mg^{-1}$) and specific activity (27.4 mA $cm^{-2}$), compared to NSs with different compositions and commercial Pt/C catalysts, which attributed to their high surface area, many undercoordinated atoms, and optimized electronic structures. In the stability test, $Pd_1Ag_1Pt_1$NSs showed excellent properties due to the anti-toxicity, which corresponds to CO stripping test results.

**Keywords:** coordination polymer, Metal-Organic Framework, MOF-derived catalyst, in-situ X-ray diffraction, X-ray microtomography

**Introduction.** Metal-organic frameworks (MOFs) gained significant attention as catalyst precursors, since presynthesized MOFs can be reduced, and transformed into supported metal nanoparticles at elevated temperature or in a reductive electrochemical environment [1]. One of the main benefits of the technique is the ability to form highly dispersed nanoarrays with well-defined active sites [2]. Furthermore, the high degree of dispersion is accompanied by high activities per metal atom in the resulting catalysts, even at high total metal content. It has previously been demonstrated that MOF-mediated synthesis (MOFMS) can also be realized through electro-decomposition, where the decomposition of a silver coordination polymer resulted in a highly active $CO_2$-to-CO electrocatalyst. However, despite of the thorough structural characterization of the resulting catalyst, the mechanism of formation remained unknown [3].

**Experimental/methodology.** Here, the same Ag coordination polymer (Ag-CP) was grown directly onto the carbon microporous layer of a carbon cloth gas diffusion layer by a sequential layer-by-layer (LBL) method via the spontaneous reaction of $Ag^+$ and an organic linker, 2,5-pyridinedicarboxylic acid. The Ag-CPs with different loadings were then decomposed into well-defined carbon-supported Ag structures at high temperatures in inert, reductive and oxidative atmospheres. The formation mechanism of the metal nanostructures was followed by in-situ X-ray diffraction (XRD), thermal methods (TGA, DSC), electron microscopy (SEM, TEM) and X-ray micro-computed tomography (µCT).

**Results and discussion.** Our current work focuses on the thermal decomposition of Ag-CP, where TGA showed two distinct weight loss regimes at around 290 and 550 °C under nitrogen. The former corresponded with the disappearence of Ag-CP reflections along with the emergence Ag reflections in the high-temperature in-situ XRD patterns (Fig. 1a). The morphology of the formed silver-based catalysts strongly depended on the number of deposition steps (Fig. 1b.), but the impact of several further parameters on the structure, morphology and elemental composition were also investigated. We hope that the detailed mechanism of MOF-derived catalyst formation will further advance a field of catalysis.

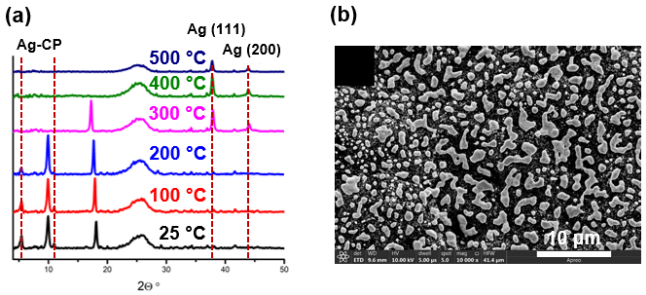

***Fig. 1.*** *In-situ XRD patterns recorded during the transformation of carbon-supported Ag-CP into Ag/C at the indicated temperatures (a), and Ag/C from the decomposition of 7 layers of Ag-CP at 500 °C under $N_2$ (b).*

**Keywords:** micromixer synthesis, MicroJet Reactor (MJR), Confined Impinging-Jet Microreactor (CIJMR), continuous-flow synthesis, precious metal nanoparticles, platinum nanoparticles, platinum nickel nanoparticles, core/shell nanoparticles, fuel cell catalysts

**Introduction.** In this contribution we report on an actual development in the field of fabrication and new application of micro-structured devices in chemistry enabling (multiphase) mixing, reactions and heat transfer which are not possible with standard devices. In the field of material syntheses micro-structured devices allow a strict control over process parameters offering the possibility to design materials with tunable properties such as particle size distribution, shape, composition and surface properties which contribute remarkably to the performance of catalytic materials [1].

**Experimental/methodology.** We implemented a new design of a CIJMR in the form of a cross mixing device analogous to the Synthesechemie (Dr. Penth) or Ehrfeld MicroJet Mixer (MJM) described by Dittert *et al*. [2]. The newly constructed MJR is completely dead volume free and allows the continuous preparation of nano-scale metal and metal chalcogenide particles by precipitation reactions from appropriate precursor solutions. Due to the short mixing times in the µs to ms range, crystallite nucleation and crystal growth are well separated from another and enable concentration limited particle growth and thus nanoparticle (NP) syntheses. To generate a deeper understanding of the processes within the MJR, modelling was performed by the CFD program ANSYS Fluent including chemical reactions (see Abstract K.Stöwe). Due to the flexibility of the concept the experimental setup can produce core-shell particles and other more complicated morphologies. It can also be broadened to syntheses in supercritical media as well as high-throughput approaches generating gradient libraries for high-throughput parameter screening.

**Results and discussion.** We started our research on the MJM with the syntheses of alternative support materials for fuel cell application to replace the standard carbon instable at typical operating conditions of PEMFC. Additionally, we applied this reactor concept by preparation of nano-scale sulfides, selenides and tellurides. We widened our expertise on precious metal NP in form of single element, mixed metal (alloys/intermetallic phases) or core-shell NP by investigating the system Pt – Ni. The stabilization of these particles was mostly achieved by chemical agents utilizing alkali metal hydroxides (Co4Cat process) [3]. As intended, the particle syntheses in the size range of 5 - 10 nm was successful while the stability of these particles was verified to be at least 10 weeks. Additionally, we also extended the reactor system and currently use a second MJR in series of the first reactor for the syntheses of either Ni@Pt or PtNi@Pt - NP. These particles are in the focus for applications as fuel cell electrocatalysts in the BMWK-funded project "ISyKat".

All in all, we will present a significant contribution for the development of new approaches for a more effective synthesis and screening of new functional materials for industrially relevant applications.

**Keywords:** MXene, MAX, Secondary battery

**Introduction.** Recently, Mxene, a two-dimensional transition metal compound, has been emerging as a new material in the field of in electrocatalysts, optical sensors, electronics, biomedical, electromagnetic, and energy storage devices because of metal-like electrical conductivity, ion adsorption and high chemical stability.[1-3] Based on these advantages, MXenes are used and tested for various applications, particularly in developing secondary battery techniques for advanced smart systems, electric cars and energy stroage sytmes.[4-9] There have been remarkable research achievements in the synthesis and application of MXene-based materials with new synthesis routes and novel structures. Herein, we demonstrate a fabication process of vandium MXene and its electircal charcteristics for the secondary battery.

**Experimental/methodology.** The basic mixing conditions were set to 2:1.2:0.8 in the molar ratio of V, Al, and C for the formulation of Max with vanadium metal as a raw material. For uniform mixing and MAX synthesis experiments, a ball mill mixing for 24 hours was conducted. To increase the reactivity between V, Al, and C during the heat treatment process, uniformly mixed raw materials are made into 50mm circular pellets through uniaxial compression and heat treatment is performed. For the etching chemical reaction of MAX, 10 g of MAX $V_2AlC$ was added to HF (100 ml) and reacted at 45 ℃ for 72 hours. Through an etching chemical reaction, the Maxine layer of the two-dimensional shape is peeled off, and the vanadium-based Maxine $V_2CT_x$ is recovered as an intermediate material.

**Results and discussion.** As a result of XRD analysis of the finally manufactured $V_2CT_x$, it was confirmed that a clear 2D peak appeared at about 7 degrees, verifying that $V_2AlC$ MAX was successfully exfoliated into $V_2CT_x$ MXene. From the AFM analysis results, it was confirmed that the MXene sheet had a thickness of about 2 nm or less. Constant current charge/discharge electrochemical experiments were performed on the coin cells manufactured using MXene in an aqueous electrolyte of 3 M $ZnSO_4$. The synthesized vanadium MXene-based anode showed an initial discharge capacity of 126 mAh/g at a current density of 0.1 A/g, and a maximum capacity of 145 mAh/g was achieved in the initial 5 cycles. As the cycle progresses, the capacity decreases to 130 mAh/g, 89% life stability and >99% coulombic efficiency was shown up to 100 cycles.

**Introduction.** The degradation of water pollutants by heterostructured photocatalysts has seen a great development during the last decades [1]. Indeed, the synthesis of composite photocatalysts solves two of the most highlighted drawbacks of photocatalysts, i.e., electron-hole recombination and visible light inactivity [2]. In addition, the use of photocatalysts enhances the formation of $OH^{\bullet}$ or $O_2^{\bullet-}$, fundamental for the advanced oxidation processes (AOPs) at the basis of the breakdown of covalent bonds in the organic molecules forming the pollutants [3]. Nowadays, microplastics (MPs), defined as plastic particles with a size lower than 5 mm [4], are some of the most worrying water contaminants [5]. One of the possible approaches for decreasing these entities in natural environment is the photodegradation. In this case, the polymer is converted to smaller molecules, which might be useful for subsequent reactions [6]. Up to now, few studies have been carried out on photodegradation of MPs and mainly by using $TiO_2$ [7], which is known to be unactive in visible light. Consequently, there is a need of new materials applied in this field and composites possess high applicability in the MPs degradation [6b, 8] due to the possibility of overcoming the most common disadvantages of photocalysts.

**Experimental/methodology.** For the synthesis of the composite $Co_3O_4$@$Co(OH)_2$, an hydrothermal one-pot method was used and, by changing the pH or the temperature, the isolated components ($Co_3O_4$ and $Co(OH)_2$) could be obtained. Finally, the obtained solids were characterized by using different techniques, i.e., XRD, XPS, SEM, TEM, among others. Then, the catalyst was added to an aqueous suspension of polystyrene MPs at a concentration of $2.5 \cdot 10^{-3}$ w/v %. After irradiation with a white light LED, the microplastics photodegradation was evaluated by SEM and weight loss and the formation of products by LC-MS.

**Results and discussion.** In this work, we could perform the one-pot synthesis of 0D/2D composite $Co_3O_4$@$Co(OH)_2$ and the two isolated components of the composite could be obtained by modulating the synthetic conditions. The composite showed activity in the photodegradation of MPs in water, meanwhile the hydroxide and the oxide had no activity in the above-mentioned reaction, demonstrating the relevance of the use of the composite. Indeed, compared to the original components, the hybrid material has different electronic structure, which makes the material more suitable for the photodegradation due to a better separation of the charge carriers, as demonstrated by photocurrent measurements, and allowing the formation of the radicals involved in the degradation as demonstrated by EPR.

**Keywords:** photocatalysis; in situ measurements; reactor design, optical absorption; $TiO_2$

**Introduction.** The photocatalytic activity of materials still cannot be determined by molecular simulations. Therefore, all photocatalytic activity of the materials is determined experimentally in laboratories. However, existing standard measurements are not free from disadvantages and the whole measurement is time-consuming [1–3]. The aim of this work was to design a new method for in situ measurements and to construct a new photocatalytic reactor, thus eliminating expensive laboratory equipment for testing photocatalytic activity, as well as several disadvantages, including the time-consuming process of testing photocatalytic activity.

**Experimental/methodology.** The in situ measurement method is based on a newly derived modification of the absorption Lambert-Beer law, which takes into account not only absorption but also light scattering on dispersed nano/microparticles and a new design of the photocatalytic reactor. For all experiments, the concentrations were set as $TiO_2$ P25 ($c$ = 1 g.L$^{-1}$), methylene blue (MB) ($C_o$ = 0.001 g.L$^{-1}$ , $V$ = 150 ml), source of radiation was 10 W high-power 365 nm LED chip. Experimental conditions were set in such way to avoid the photosensitization phenomenon.

**Results and discussion.** The functionality of the new method was demonstrated on the decomposition of methylene blue using $TiO_2$ P25 powder and 365 nm wavelength radiation according to ISO 10678 [3]. Comparison of two independent experimental measurements with each other and with a subsequent comparison using a standard method for the evaluation of photocatalytic activity confirmed the accuracy and good repeatability of the new in situ measurement method, without distortion of the observed kinetics data due to the presence of the photocatalyst, see Figure 1.

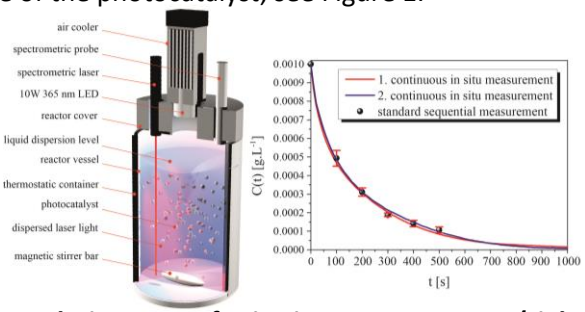

**Figure 1 (left) Novel photocatalytic reactor for in situ measurement. (right) Comparison of two independently measured simulant concentration versus time dependencies (— 1. measurement and — 2. measurement) with six points obtained by standard photocatalytic measurement method.**

**Keywords:** Layer-by-layer (LbL), plasmonic photocatalytic films, photoinduced synthesis, air treatment

**Introduction.** The LbL assembly method has received a growing interest in the last decades to design function-specific multilayer assemblies like catalytic thin films. It easily builds versatile multi-material films with tunable properties at nanoscale precision. The films are built via electrostatic interactions, by alternate deposition of oppositely charged species on a substrate, previously negatively or positively charged [1].

Here we show the promise of the LbL self-assembly for building porous, stable $TiO_2$ and plasmonic Ag@$TiO_2$ hybrid nanoscale films with a very good growth monitoring (thickness, homogeneity, catalyst content). We demonstrate that a catalyst-saving film with a single nm-size hybrid layer of $TiO_2$ and Ag nanoparticles at ultra-low $TiO_2$ content is highly promising for gas phase photocatalysis aiming at air depollution.

**Experimental.** For building multilayer PEI/(PSS/$TiO_2$)$_n$ films on model surfaces (quartz slide or Si wafer), positively-charged poly(ethyleneimine) (PEI) is used as an anchor polyelectrolyte to promote the film adhesion. Negatively-charged poly(sodium 4-stryresulfonate) (PSS) is deposited on the PEI layer and acts as a glue between consecutively deposited $TiO_2$ layers. In order to preserve the $TiO_2$ positive surface charges, PSS is dissolved in acidic milli-Q water. The LbL-assembled films are built by dipping successively the substrate in the polyelectrolyte solution or in the $TiO_2$ suspension, with intermediate rinsing with water.

**Results and discussion.** The LbL film growth is monitored on model surfaces by ellipsometry, in-situ quartz crystal microbalance, UV-Vis spectroscopy, AFM/SEM. It shows regular film growth with average thickness increase of 40 nm and $TiO_2$ density of 6 ± 1 µg/cm² per layer pair. The PEI/(PSS/$TiO_2$)$_n$ films show very good homogeneity, even for a single layer pair, *ie.* PEI/(PSS/$TiO_2$), and good porosity, allowing the $TiO_2$ crystallites to be available for the gaseous pollutant. They remain transparent, at least till n=10 layer pairs [2].

Ag@$TiO_2$ catalyst films were built on model surfaces by a new integrated *one-pot* approach combining a photoinduced radicalar synthesis of calibrated Ag nanoparticles (AgNP) and the LbL assembly of $TiO_2$ thin films. The AgNP photoinduced synthesis lies in the irradiation of a photosensitive formulation, where a chromophore acts as free radical generator upon UV-A light (365 nm). One free radical allows the reduction of $Ag^+$ to $Ag^0$ which associates further into clusters and forms AgNP, while a second radical controls size and shape. The key-point here is the use of the photosensitive formulation as LbL solvent for depositing the $TiO_2$ layer. It allows building single layer pair Ag@$TiO_2$ films with well-calibrated (2 nm) small size AgNP with narrow distribution, in intimate contact with the $TiO_2$ crystallites. The Ag/$TiO_2$ ratio can be tuned on-demand and the AgNP are located at the PSS/$TiO_2$ interface while the films remain transparent.

Optimized PEI/(PSS/Ag@$TiO_2$) thin films with Ag/$TiO_2$ ratio of 0.25 wt.% led to a drastic increase in TONs (16 fold) compared to the Ag-free reference film, with a quantum (photonic) yield increase of one order of magnitude. The catalytic film obtained by the one-pot photoinduced approach outperformed strongly PEI/(PSS/Ag@$TiO_2$) films obtained via other methods. Thanks to Time Resolved Microwave Conductivity, Electron Paramagnetic Resonance and UV-vis spectroscopy, the generation of a higher number of charge carriers was evidenced, what supported the hypothesis of a plasmonic near-field enhancement, thanks to the overlap of the AgNP plasmonic band and the catalyst absorption.

**Keywords:** core shell nanoparticles, plasmonic photocatalysis, electromagnetic near-field enhancement

**Introduction.**

The use of gold and silver nanoparticles to boost the activity of $TiO_2$ based photocatalysts by exploiting their plasmonic effect, has become a widely applied strategy to improve various solar light driven applications, such as photocatalytic air purification, self-cleaning surfaces, etc [1,2]. However, plasmonic metal nanoparticles like Au sinter together when treated at elevated temperatures, which is often required to calcine $TiO_2$ into the appropriate anatase phase. Here, these limitations are overcome by stabilizing plasmonic Au nanoparticles through the formation of a thin and uniform $TiO_2$ shell, that also directly acts as the semiconducting photocatalyst. The dependence of the plasmonic near-field enhancement on the $TiO_2$ shell thickness surrounding the Au core is further substantiated by means of surface enhanced Raman spectroscopy (SERS) using a probe of R6G molecules on Au@$TiO_2$ thin films.

**Experimental/methodology.**

The synthesis of gold nanoparticles (~55 nm) is a process based on the protocol in [3]. Encapsulation of Au nanoparticles with $TiO_2$ was performed with slight modifications based on procedure described in [4]. The material was characterized using HAADF-STEM, UV-Vis spectroscopy, SERS, XRD and theoretical electromagnetic simulations. Stearic acid degradation was performed to check photocatalytic activity using simulated light

**Results and discussion.**

In this work, Au@TiO2 core-shell nanoparticles have been studied by carefully varying the shell thickness at the nanometer scale. Slow hydrolysis of the titanium triethanolaminato isopropoxide precursor proved to be the key to accurately control the thickness of this TiO2 shell. Photocatalytic stearic acid degradation tests revealed that the photocatalytic activity decreases by a factor of 2 when increasing the shell thickness from 2 nm to 15 nm. This agrees with Finite Element Method numerical simulations that demonstrate that near-field enhancement, one of the main driving plasmonic effects, rapidly decays over just a few nanometers from the surface of a metal nanoparticle [5]. A significant reduction in enhancement factor of SERS for a thicker TiO2 shells does invariably prove plasmonic nanoparticles with thinner shell thickness benefit from a stronger contribution from near-field enhancement for photocatalysis. At the same time, a minimal shell thickness is required to ensure sufficient stabilization of the metal cores upon thermal annealing, as is studied by high resolution transmission electron microscopy. Results of photocatalytic activity in combination with SERS experiments and numerical simulations, prove that nanometer control over the shell thickness can lead to the most efficient use of the near-field enhancement effect of plasmonic nanoparticles in photocatalytic applications.

# Photocatalytic efficiency of VOC removal on $TiO_2$ nanotubes: Effect of layer thickness

J. Rusek, M. Baudys, M. Lhotka, J. Krýsa

*Department of Inorganic Technology, University of Chemistry and Technology Prague, Czech Republic*

**Keywords:** $TiO_2$, nanotubes, photocatalysis, volatile organic pollutants, hexane

**Introduction:**

$TiO_2$ nanotubes (TNT) seem to be an interesting photocatalytic material due to the high surface area and geometry enabling better separation of photogenerated charges [1]. This contribution deals with the preparation and characterization (morphology, texture properties) of TNT layers of different thickness. The objective was to find the relation between morphology, surface area and photocatalytic activity which was determined using hexane and acetaldehyde as model gaseous pollutants in a flow-through photoreactor.

**Experimental/methodology:**

TNT layers were prepared by anodic oxidation of Ti foil using a previously optimized procedure based on the work [2]. Prepared samples were characterized using SEM and also using Kr adsorption isotherm (expressed as adsorbed amount related to the geometric area). The photocatalytic activity was expressed as a conversion of hexane (acetaldehyde) using conditions according to the ISO 22197-2 standard method.

**Results and discussion:**

The thickness and photocatalytic properties of TNT layers, varying in anodization time, are summarized in Table 1. As expected, the nanotube thickness increased with increasing anodization time from approximately 2 to 13 µm. Typical morphology of the TNT layer is shown in Fig. 1, with a tube diameter ~100 nm and wall thickness 6-8 nm.

**Table 1: Thickness and photocatalytic properties of the TNT layers depending on anodization time.**

| anodization time (min) | TNT thickness (µm) | hexane conversion (%) |
|---|---|---|
| 15 | 2.3 ± 0.1 | 18 |
| 45 | 4.3 ± 0.2 | 25 |
| 90 | 10.3 ± 0.8 | 27 |
| 120 | 13.2 ± 0.5 | 29 |

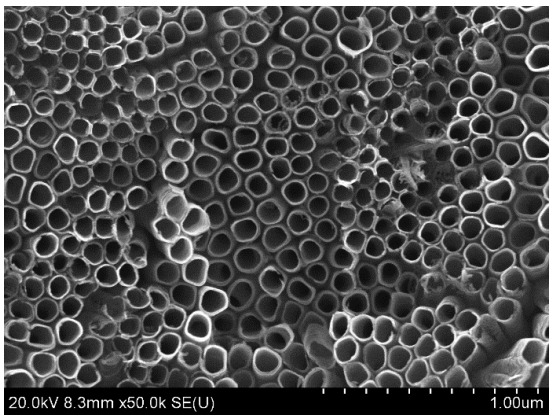

**Fig 1: SEM micrograph of the top morphology of the TNT layer prepared by anodization for 45 min.**

From TNT diameter and wall thickness, the geometrical area and the mass of $TiO_2$ for various TNT layers were calculated. Using Krypton adsorption isotherm (related to the geometric area), it was found that adsorbed amount increased with increasing TNT thickness. BET surface area, calculated from Kr adsorption, was for TNT layers of all thicknesses approximately 30 $m^2\ g^{-1}$. An increase of hexane conversion with TNT thickness from 18 to 29 % was discussed in view of increased surface area (either from TNT geometry or Kr adsorption measurement).

**Keywords:** methane photo-coupling, gold, titania**,** flow reactor

**Introduction.** The Development of technologies for methane valorisation to more useful carbon products is highly desirable but conventional thermocatalytic routes require a high temperature to break the strong C–H bond [1]. In this perspective, the direct photocatalytic non-oxidative coupling of methane (NOCM) has attracted research as it is possible to convert solar energy in chemicals in mild conditions avoiding the competitive and thermodynamically more favourable formation of coke. Currently, the majorities of photocatalytic methane coupling reactions are carried out in batch reactors but generally the performances are very low**.** In this work we have reported a continuous photocatalytic NOCM process using a new concept of flow reactor, with metal-decorated $TiO_2$ nanomembranes as photocatalysts [2]. The presence of a cocatalyst is crucial for promoting the activity of the semiconductor increasing the performances of photocatalytic $CH_4$ conversion [3].

**Experimental.** The metal nanoparticles (NPs) decorated $TiO_2$ (Au, Ag, Pd,) photocatalysts were prepared through photo deposition method irradiating standard $TiO_2$ P25 under UV light for 30 min. The amount of all metals was in 1% w/w. The as prepared samples were characterized by SEM. XRD and UV-vis analysis, were then deposited in a porous membrane and tested in the NOCM in a home-made cross-flow reactor equipped with a quartz window to allow the illumination (300W Xe lamp). The gaseous methane passes through the photoactive nanomembrane. Only one side is illuminated. The products were analysed by GC equipped with FID and TCD detector.

**Results and discussion.** In the present work different metals were examined for NOCM at ambient conditions (room temperature and atmospheric pressure), using a concept of reactor (working under a gas cross-flow) quite different from a conventional photocatalytic approach. The synergistic effect of combining this new flow reactor with a suitable cocatalysts was investigated. Results show that, among all metal NPs examined, Au is the most efficient in ethane production. Localized Surface Plasmon Resonance (LSPR) of Au NPs simultaneously accelerate the charge separation improving the light absorption in $TiO_2$ semiconductor, pushing the methane photo conversion and suppressing the overoxidation of $CH_4$ due to lattice oxygen of the support. The ethane production rate reached 95.3 micromol $g^{-1}h^{-1}$ in 5 hours of reaction with 50% of methane and a high selectivity to $C_2$ products was observed (>95%). The photocatalytic activity of $Au/TiO_2$ is two orders of magnitude higher than that of pure porous $TiO_2$. Blank tests were also performed, and no products have been detected when the reaction was carried out in inert gas or without light irradiation Due to the particular characteristics and conditions in the photoreactor, by combining it with the LSPR of Au nanoparticles, the efficiency in non-oxidative coupling of methane has been much improved.

**Keywords:** Photocatalysis; Lignin; C–C bond cleavage; radical intermediates

**Introduction.** Lignin is a major component of lignocellulosic biomass and a natural aromatic biopolymer, and thus, it is the most abundant source of renewable aromatics.[1] Through selective breakage of lignin C−O, C−C bonds, added-value aromatic compounds can be obtained.[1] Great efforts have been devoted to the study of lignin C−O bond cleavage in past decades and considerable success has been achieved.[1,2] In contrast, only a few research progress has been made in the selective cleavage of lignin C−C bonds. The cleavage of recalcitrant C−C bonds remains one of the key challenges for the valorization of lignin. Current studies on lignin C−C bond cleavage are mainly focused on thermocatalysis under relatively severe reaction conditions.[3] The conventional methods not only limit the activity but also lead to low product selectivity. Moreover, additional additives such as expensive oxidants or bases are needed in most cases.[3] Photocatalysis, which utilizes solar energy to drive chemical reactions as nature does for photosynthesis, is a promising method to challenge highly difficult reactions by conventional thermocatalytic approaches.[4] However, as a newly emerging and challenging topic, only a few reports have succeeded in breaking lignin C−C bonds by photocatalysis. Moreover, the current understanding of the reaction mechanisms and the knowledge about the photocatalyst structure-performance relation are very limited.

**Results and discussion.** We examined photocatalytic performances of some typical semiconductors including $BiVO_4$, $Cu_2O$, $CeO_2$, BiOCl, BiOI, CdS, and PCN for the conversion of 1,2-diphenylethanol (DPol), a lignin β-1 model compound, at room temperature. Limited activities with conversion lower than 5% were observed for most catalysts. Interingtly, PCN is very unique in catalyzing the cleavage of the $C_\alpha$−$C_\beta$ bond in DPol, benzaldehyde is the major product with a high selectivity of 68% and yield of 15% after 6 hours under simulated solar light irradiation. To increase the photocatalytic performance of PCN, we have synthesized a series of $Ag_3PO_4$−PCN heterojunction nanocomposites. Among these nanocomposites, 40$Ag_3PO_4$−60PCN (40wt% $Ag_3PO_4$−60wt% PCN) showed the highest benzaldehyde yield, reaching 86%, which was about 5.7 times higher than that of PCN. 40$Ag_3PO_4$−60PCN nanocomposites were powerful catalysts for photocatalytic cleavage of lignin $C_\alpha$−$C_\beta$ bonds. Aromatic aldehydes with high yields of 66%-95% were obtained from the conversion of various β-1 lignin model compounds.

Characterizations of the catalysts led to structural details of the Z-scheme within $Ag_3PO_4$−PCN composites. Control experiments with different atmospheres, *i.e.*, $O_2$ and $N_2$, and additives, *i.e.*, $Na_2C_2O_4$ as a hole scavenger, $NaIO_3$ as an electron scavenger, *i*-PrOH as a hydroxyl radical scavenger, and BQ (p-benzoquinone) as a superoxide radical scavenger, were performed. These control experiments have revealed three reaction pathways for the conversion of DPol. The primary pathway involves an electron-hole coupled photoredox process, which requires both holes and electrons with strong oxidation and reduction ability, respectively. The Z-scheme structure allows the $Ag_3PO_4$−PCN catalyst to have strong redox capacity and this is essential to the electron-hole coupled C−C bond cleavage.

**Keywords:** Photocatalysis, water remediation, Hydrogen, Graphene oxide

**Introduction.** Water remediation and $H_2$ production are two of the most pressing topics in photocatalysis. The most common material in this field is the titanium dioxide ($TiO_2$, titania), but the performance under the solar light must be improved. Furthermore, after the addition of the titanium in the EU critical raw materials, it is necessary to find alternatives to the titania and, in this context, the excellent redox properties of the cerium dioxide ($CeO_2$) can be a good solution. However, despite the lower band gap respect to the $TiO_2$, the $CeO_2$ has a really high charge recombination rate, so a modification, in order to avoid this phenomenon, it is mandatory. Amongst the strategies to enhance the charge separation, the employing of carbonaceous materials as the graphene oxide can be a perfuming strategy thanks to its peculiar properties such as high conductivity and visible light absorption in its reduced form (reduced graphene oxide, rGO). Thus, to make it capable to extend the charge separation lifetime and to absorb the solar radiation [1]. Here we report a method for a one-pot solar photo-reduction of the GO by $TiO_2$ or $CeO_2$, obtaining versatile hybrid materials [2]. The synthetized samples were tested on water remediation degrading a pesticide (the 2,4 dichlorofenoxyacetic acid) and in the $H_2$ production through glycerol photoreforming.

**Experimental/methodology.** The samples were prepared irradiating a GO solution in presence of the main catalyst ($TiO_2$ or $CeO_2$) in anaerobic condition. In the case of the $H_2$ production, a gold precursor was added in order to exploit a metallic co-catalyst. The materials were investigated in terms of rGO content, reduction degree and irradiation time employed for the reductive treatments. To achieve this characterization, were used UV-DRS, FTIR, PL, XPS, SEM and TEM images and finally BET surface area.

**Results and discussion.** The $TiO_2$-rGO composites showed the best results in terms of activity in the 2,4-D degradation (97% of degradation in three hours vs the 48% of the bare $TiO_2$ or the 60% of the conventional thermal reduced $TiO_2$-rGO, Fig, 1a). For the hydrogen production (Fig. 1b) it was obtained an increment of about 8 times with the $TiO_2$-based samples and about 40 times with the $CeO_2$-based ones compared to the bare $TiO_2$ and $CeO_2$. In this context, the photocatalytic activity is strongly influenced by the reduction degree of the GO, that in the case of $TiO_2$-based samples was favored by the strong photocatalytic features of titania, whereas in the case of ceria-based samples was facilitated by the continuous irradiation time.

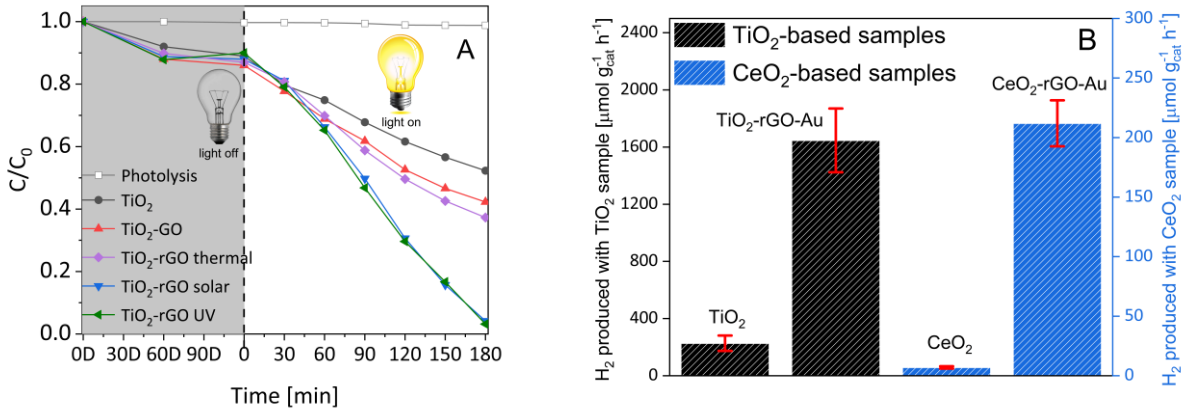

**Figure 1 In the left panel the photodegradation results, while in the right one the $H_2$ evolution after 6h**

**Keywords:** carbon sprehes, metal oxides, aminosilanes, CCU, adsorption, $CO_2$ photoutilization

**Introduction.** Worldwide carbon dioxide emissions of 34.9 $GtCO_2$ in 2021 resulted in an increase of 4.8% over the year 2020, while the Global Carbon Project report put the increase in global emissions in 2022 at 36.6 $GtCO_2$ [1,2]. While promising, technologies such as carbon capture and storage (CCS) and carbon capture and utilization (CCU) require continuous development and increased operational coverage. CCU facilities capture almost 45 $MtCO_2$ per annum. However, despite such impressive achievements, Net Zero Emissions may not be reached at these technologies' current rate of advancement [3]. Carbon dioxide can be converted to valuable chemicals (like methanol, formic acid or methane) in several technological approaches, of which the most developed are: catalytic, photocatalytic, electrochemical, biological and mineralization [4].

**Experimental/methodology.** Sample preparation methods: carbon spheres formation according to modified Stöber method (from resorcin and formaldehyde) and heat treated at 700 °C, activation with various chemical agents (selected bases and salts), carbon spheres modification with metal oxides (mainly $TiO_2$) and/or aminosilanes (APTMS, APTES etc.). Sample characterization methods: SEM-EDX, TG/DTG, XRD, FTIR, low-temperature $N_2$ adsorption/desorption (BET specific surface area, pore volume), $CO_2$ adsorption/desorption (ultramicropore volume and distribution, adsorption capacity).

**Results and discussion.** The unmodified carbon spheres obtained as part of the ongoing studies were characterized by a high adsorption capacity towards $CO_2$ (due to the highly developed specific surface area and the predominance of ultramicropores in the structure of the carbon materials). However, their photocatalytic activity was negligible (the photolysis effect works only). Activation of unmodified carbon spheres with alkalis and salts resulted in a significant increase in specific surface area and the development of a porous structure in the micro- and ultramicroporous range, translating into increases in $CO_2$ adsorption capacity, while $CO_2$ photoreduction efficiency remained low. Solvothermal, microwave-assisted or thermal modification of carbon spheres with semiconductors or aminosilanes resulted in a reduction in specific surface area and pore volume (due to blocking of pores by nano-$TiO_2$ or aminosilane molecules), which slightly reduced the $CO_2$ adsorption capacity, but on the other hand, definitely increased the efficiency of the $CO_2$ photoreduction. Hydrogen, carbon monoxide, and methane were mainly formed photoreduction products. Under specific conditions, green ammonia formation was found.

**Keywords:** Photocatalysis, 3-nitrophenol reduction, titanium dioxide

**Introduction**

The reduction of nitroaromatics is a common route to producing aminoaromatics. Amines, especially aniline derivatives are precursors of many valuable organic molecules with a wide range of applications. Nowadays, they are mainly obtained by hydrogenating the corresponding nitroaromatics. Nevertheless, the process can be demanding for functionalized nitro compounds containing unsaturated bonds. It has recently been shown that the photocatalytic reduction of nitroaromatic compounds to amines occurs with high selectivity even in the presence of various sensitive groups.[1] In such a reaction, $TiO_2$ is often considered as the photocatalyst. However, no studies so far explored what factors limit this process for $TiO_2$. We investigated the correlation between several intrinsic factors and the photocatalytic activity of various commercial anatase and rutile $TiO_2$ materials for the selective reduction of 3-nitrophenol.

**Results and discussion**

The (photo)electrochemical analysis revealed unequivocally the differences in interfacial electron transfer, charge recombination, reduction driving force, and methanol photooxidation efficiency for titania polymorphs. It appeared that all mentioned processes were phase-dependent and they contributed unequally to overall photocatalytic activity (Fig. 1.). In particular, methanol oxidation was the most efficient at the rutile phase, which overcame the critical limitation of the oxidation pathway and facilitated the reduction of 3-nitrophenol. On the other hand, the dark electron transfer efficiency was highest at the anatase phase, despite the lower driving force in this case. A thorough and systematic analysis of the discussed photocatalytic system (the photocatalyst and the reaction) will be presented.

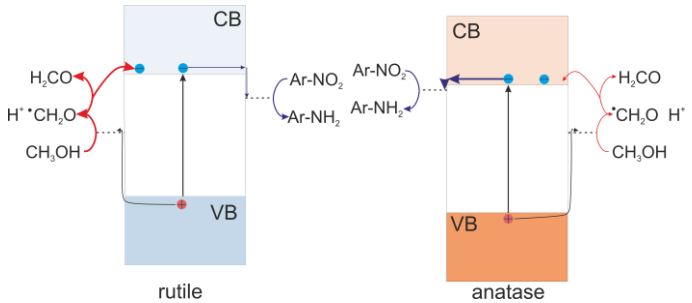

**Fig. 1.** Photocatalytic reduction of nitroaromatics with highlighted differences between rutile and anatase. The thickness of the arrows refers to the efficiency of the corresponding processes.

**Keywords:** photocatalytic $CO_2$ reduction, surface plasmonic effect, $CO_2$ adsorption, $SrTiO_3$-$SrCO_3$, NiO

**Introduction.** The world energy demand and the increasing atmospheric $CO_2$ concentration are current problems which require urgent actions [1]. Photocatalytic $CO_2$ reduction could be a promising solution for the aforementioned challenges, which is based on the design and application of highly efficient and selective photocatalyst materials. Beyond charge carrier generation and separation, $CO_2$ adsorption ability is also a decisive property towards efficient photocatalysts for $CO_2$ reduction [2], and it must be taken into account during catalyst design. In this work, the influence of Au photodeposition and NiO impregnation of $SrTiO_3$-$SrCO_3$ catalysts on their photocatalytic $CO_2$ reduction activity was studied.

**Experimental/methodology**. Herein four catalysts were prepared and assessed, namely hydrothermally synthesized $SrTiO_3$-$SrCO_3$ (STO-SCO, with ~17 wt. % SCO), NiO/STO-SCO, Au-STO-SCO and Au-NiO/STO-SCO. While the preparation of NiO/STO-SCO was realized by wet impregnation (~0.3 wt. % NiO), the decoration of the previously mentioned catalysts (i.e., STO-SCO, NiO/STO-SCO) with Au was performed by photodeposition (~1 wt. % Au). The as prepared catalysts were assessed by complementary methods, namely ICP-OES, SEM-EDX, TEM, XRD, DRS, nitrogen sorption, DRS, Raman, EIS and PC. The $CO_2$ reduction activity of the samples was evaluated in a high-purity gas phase photoreactor system [3] in batch mode. Furthermore, the elucidation of $CO_2$ reduction mechanism was supported via in situ DRIFTS $CO_2$ adsorption experiments.

**Results and discussion.** The efficiency of impregnation and photodeposition was proven by ICP-OES. The XRD patterns confirmed the presence of cubic $SrTiO_3$ and orthorhombic $SrCO_3$ crystal phases in all of the studied samples. Furthermore, the plasmon resonance band situated at 540 nm offered a preliminary indication about the size of Au NPs in the case of all Au-modified samples, which was further proven by TEM. The preliminary results provided by EIS and PC measurements confirmed the improved charge separation and transfer efficiency in the case of Au-STO-SCO and NiO/STO-SCO in comparison to STO-SCO.

While the selective $CH_4$ formation was detected in the case of STO-SCO and NiO/STO-SCO catalysts, $C_2H_6$ was produced over Au-NiO/STO-SCO with >99% selectivity during the photocatalytic $CO_2$ reduction experiments. Furthermore, the photocatalytic production of $H_2$ was observed only in the case of the Au-STO-SCO sample. The adsorbed species on the surface of the catalysts were evaluated via in situ DRIFTS in the dark and under light irradiation (λ=320-700 nm). Considerable spectral differences were recorded in the case of Au-containing samples under light irradiation (*vs*. without irradiation), which may be correlated not only to their light harvesting capability but also to the thermal plasmonic effect of the Au NPs. The unraveling of possible causes (i.e., activation of adsorbed $CO_2$, light induced oxygen desorption, etc.) for spectral differences under *vs.* without irradiation is an ongoing work for all of the studied samples. Current research efforts aim at the investigation of possible synergistic effects between the special features provided by the components (i.e., oxygen vacancies in STO-SCO and surface plasmonic effect of Au NPs).

**Keywords:** Composites, adsorbents, photocatalysts, ethylene, perishable fruits.

**Introduction.** The removal of ethylene from the atmosphere of storage chambers for perishable fruits is a critical factor in the agro-food industry to avoid ripening and the consequent economic loss [1]. Ethylene can be removed by adsorption or oxidised to $CO_2$. In this work, composite materials based on biocarbons (ACs) and $TiO_2$ are developed to obtain a synergistic effect between adsorption and photocatalytic oxidation. The physicochemical properties and nanostructure of the materials are optimised by adjusting the proportions of the phases and the conditions of the hydrothermal synthesis (T, time, concentration of reactants) and their influence on the ethylene removal processes is analysed under different experimental conditions (ethylene concentration, UV or Vis radiation, contact time, etc.).

**Experimental/methodology.** ACs are previously prepared by physical activation in steam from olive stones. Carbon-$TiO_2$ composites were prepared in a ratio of 1:1 , 1:2 or 1:3 by hydrothermal deposition at 150 °C for 48 h in 8 or 12 M solutions of NaOH to fit the $TiO_2$ nanostructure. Finally, the obtained powders were pre-treated at 300 °C in air atmosphere and deeply characterized (TG, gas adsorption, XPS, XRD, UV-Vis diffuse reflectance). Adsorption / photocatalytic experiments were carried out using a mixture of $C_2H_4$/Air/$H_2O$ with a $C_2H_4$ concentration of 50-1000 ppm and 50% of relative humidity (RH), using a medium-pressure mercury lamp (125 W, mod. 3010/PX0686) from Photochemical Reactors LTD., equipped with a glass water cooling jacket. The amounts of transformed $C_2H_4$ and formed $CO_2$, as unique reaction product observed, were monitored by GC (Shimadzu GC-2010 Plus) during the reaction time.

**Results and discussion.** ACs were microporous, while mesoporous $TiO_2$ nanorods or nanospheres were obtained depending on the synthesis conditions, mainly constituted by anatase or a mixture of anatase-brookite. ACs avoid the transformation into rutile of the nanoparticles. These $TiO_2$ nanostructures are also obtained inside the large cavities of ACs which confer a large micro/mesoporosity to the composites. The removal of ethylene by adsorption is mainly governed by the narrow microporosity of the samples, although can be favoured by the acidity of the surface ($pH_{PZC}$). The adsorptive performance of the samples decreases as the ethylene concentration in the flow, denoting the influence of the pore size distribution (activation degree) and the diffusion processes. It is noteworthy that all carbon-$TiO_2$ samples showed an enhanced absorption at wavelengths higher than 380 nm (visible range) in comparison with pure $TiO_2$, thus favouring also the photo-oxidation of ethylene. This process is selective to $CO_2$ and evidently, the activity of the samples is favoured using UV-Vis radiation regarding the near-UV-Vis one, and also by increasing the $TiO_2$ ratio in the composite up to 80% wt. The developed porosity of composites, their reduced band-gap and the fitted nanostructure and dispersion of the active $TiO_2$ phase improve their performance regarding pure fractions, confirming the synergetic effects between phases. The use of agricultural residues to produce the carbon phase and the activity of the composites under visible light, could favour the use of these type of materials in the development of filters and photoreactors, saving energy and resources in an environmental and circular economy concept.

**Keywords:** easily recoverable photocatalysts; olive mill wastewaters; environmental remediation.

**Introduction.** Olive oil production, one of Europe's most flourishing agricultural industries, generates olive oil, pomace, and olive mill wastewaters (OMWW). These latter, composed of *ca.* 80-83 wt.% water, 2 wt.% inorganic matter, and *ca.* 15-18 wt.% organic compounds (i.e., polyphenols, phenols, and tannins), require proper disposal treatments. In this field, the development of efficient strategies is fundamental. Heterogeneous photocatalysis has emerged for its efficiency, sustainability, and integration potential in water purification systems. Here, innovative, sustainable and efficient photocatalysts design is the key point [1]. In this work, we present our preliminary results related to the development of eco-friendly, easily recoverable three components material (bismuth oxybromide supported onto $Fe_3O_4$-alginate spheres) for the treatment of polyphenols representatives of the OMWW fraction.

**Experimental/methodology.** Advanced, easily recoverable materials were fabricated by co-precipitating BiOBr onto alginate spheres containing a $Fe_3O_4$ core (Fig. 1a). Targeted physico-chemical characterizations were carried out to elucidate the samples properties. Gallic acid (GA) was selected as a model polyphenol: its abatement was monitored in the dark and under solar or visible light irradiation [2]. Preliminary abatement tests of gallic acid were also carried out on BiOBr powders.

**Results and discussion.** When BiOBr was supported onto alginate spheres with the $Fe_3O_4$ core, it was able to produce photocatalytic activity as if used in powder form. Fig. 1b depicts a SEM micrograph showing the BiOBr morphology between flower- and plate-like. Fig. 1c summarizes a results selection obtained for the GA abatement onto $Fe_3O_4$-alginate-BiOBr. In the dark region, the higher the catalyst amount, the higher was the GA abatement due to GA adsorption onto the catalyst surface, thanks to the ability of Bi centers to coordinate GA. After 180 min of irradiation, full GA photodegradation is reached for 5 g catalyst and *ca.* 95% for 1 g. The comparison of these results (green triangles) with those obtained only in the dark (dotted black line) confirmed that the material operates an explicit photocatalytic activity.
The encouraging results as well as the great advantage of the easy recovery currently move our research efforts towards the optimization of these eco-friendly photocatalysts for olive mill wastewater treatment.

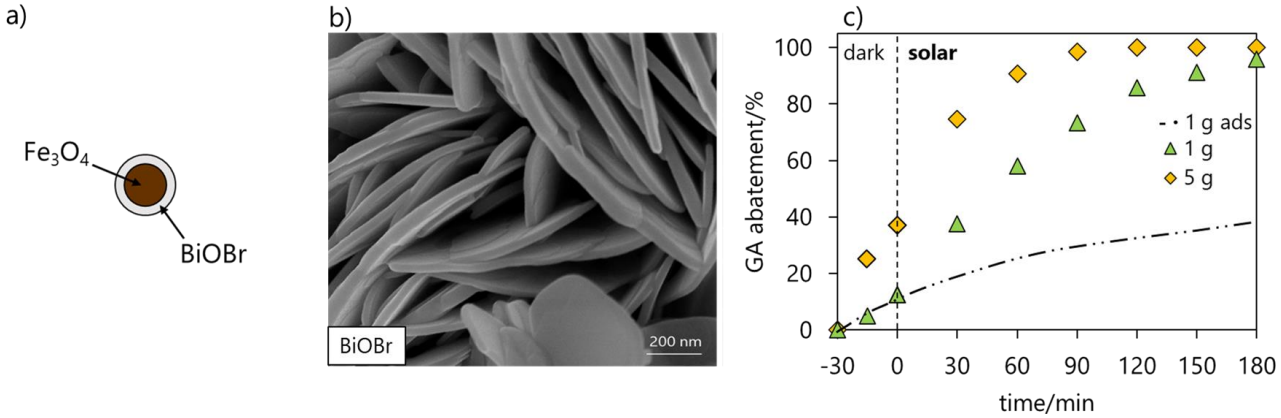

**Fig.1: a) BiOBr-alginate-$Fe_3O_4$; b) SEM micrograph; c) GA abatement tests (10 ppm) under solar light (35 W/m$^2$).**

# Photocatalytic Reduction of $CO_2$-to-CO using a CNQD·[Fe-p-TMA] Hybrid Assembly in Water

L. Mistry[1], L. Le-Quang[1], G. Masdeu[1], W. Björkman[1], H. Härelind[2*], M. Abrahamsson[1]

*[1]Chemistry and Biochemistry, [2]Competence Centre for Catalysis, Dept. Chemistry and Chemical Engineering, Chalmers University of Technology, SE-41296 Göteborg, Sweden*
**hanna.harelind@chalmers.se*

**Introduction.**
The ever-increasing atmospheric $CO_2$ puts focus on the possibility to convert $CO_2$ into organic fuels or value-added products, preferably using environmentally benign methods. However, to break the stable carbon-oxygen double bonds calls for the use of electrochemical or catalytic routes to overcome the thermodynamic barrier [1]. Thus, utilizing sunlight in a photocatalytic approach to $CO_2$ reduction is an attractive solution, in particular systems that operate under relatively mild conditions and without additional energy requirements. In this work we present an efficient and selective water-soluble photocatalytic system with an iron-porphyrin catalyst electrostatically coupled to functionalized carbon nitride quantum dots (CNQDs) for the reduction of $CO_2$-to-CO, using visible light. The hybrid assembly shows excellent performance under mild conditions with high TON and selectivity around 96 % in water.

**Experimental/methodology.**
Existing literature protocols were used in the preparation of the iron porphyrin catalyst, [Fe-p-TMA]·Cl [2] and the CNQDs [3]. The photocatalytic experiments [4] were carried out in a Pyrex glass photoreactor coupled to a mass spectrometer continuously measuring gaseous products *in operando*. The visible light was generated using a Xenon lamp combined with a UV and an IR filter allowing for the transmission of only visible light (400 – 700 nm, ~55 mW $cm^{-2}$ at 405 nm).

**Results and discussion.**
The photosensitizer-to-catalyst ratio was investigated by varying the concentration of [Fe-p-TMA] while keeping the CNQDs concentration constant. An optimal catalyst concentration of 1.0 µM was found, with a CO yield of ~200 µmol/h with high selectivity (~96 %, ~4 % $H_2$) for 10h irradiation, resulting in a $TON_{CO}$ of ~$10^5$ or $TOF_{CO}$ of ~12 $s^{-1}$. Increasing or decreasing the concentration of [Fe-p-TMA] resulted in a drop in CO formation. The mechanism for photo-induced $CO_2$ reduction using a sensitized iron-porphyrin catalyst is debated in literature [5,6]. Generally, it is agreed that the iron center is stepwise reduced to zero-valent, then forming an Fe-$CO_2$ adduct ($Fe^{I}$-$CO_2^{-}$ or $Fe^{II}$-$CO_2$). The Fe-$CO_2$ is then protonated, forming $H_2O$ and an $Fe^{II}$-CO intermediate. Photoexcitation of the QD and subsequent donation of a second electron results in cleavage of CO from the iron-porphyrin. In this work, we only observe the $Fe^{II}$ and $Fe^{I}$ states, *i.e.* no $Fe^0$ state. Thus, our results imply a mechanism with a CO formation route via a reversible $Fe^{II} \leftrightarrow Fe^{I}$ transformation induced by visible light irradiation of the CNDQ·[Fe-p-TMA] hybrid assembly in aqueous solution.

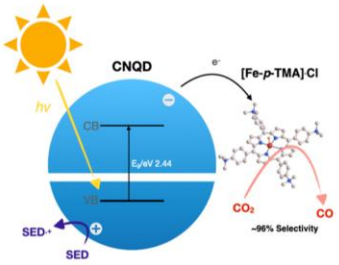

**Figure 1. Illustration of the photocatalytic system (retrieved from [4]).**

[*]*jan.schuetz@dsm.com*

**Introduction**

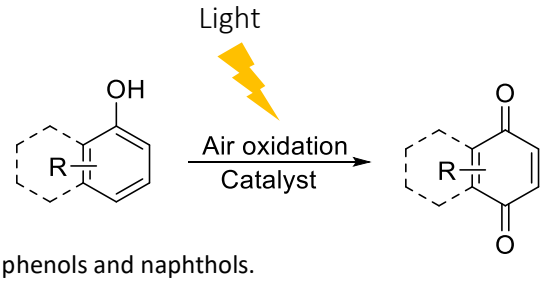

Photo-chemical processes are applied at DSM Nutritional Products since many years. The sigmatropic isomerization of 7-dehydrocholesterol to previtamin $D_3$ is carried out in a flow process under irradiation with ultraviolet light on industrial sclae. In the production of calcifediol (25-OH-vitamin $D_3$) a similar photo-chemical flow process is applied in the isomerization of 25-OH-7-dehydrocholestrol to calcifediol [1].

**Experimental/methodology**

A continuous flow photoreactor using visible light from high intensity LEDs and if required air overpressure was applied in the presented studies. The reactor design permits the use of low photocatalyst loadings to promote singlet oxygen generation and allows precisely controllable principal process parameters.

**Results and discussion**

In several research and development projects at DSM Nutritional Products photo-chemical and photo-catalytical processes were studied. Important examples are the *E*/*Z*-isomerization of 3-methyl-pent-3-enynes, compounds used in the manufacture of vitamin A acetate and astaxanthin and the E/Z-isomerization of vitamin A acetate (the final product is (all-*E*)-vitamin A acetate) [2]. Another examples is the [2+2+2] cycloaddition of alkynes and nitriles to a precursor in the synthesis of vitamin $B_6$ [3]. The oxidation of phenols and naphthols to their corresponding quinones was studied under photo-catalytic flow conditions (Scheme 1) [4]. Some of these quinones are intermediates in the manufacture of vitamin E and $K_3$. The method allows to oxidize phenols with high selectivity under mild reaction conditions using visible light. The reactor design permits low photosensitizer loadings to generate singlet oxygen. This efficient phenol oxidation might become a valuable part in a sustainable approach to vitamin E and related compounds.

Scheme 1. Photocatalytic oxidation of phenols and naphthols.

Herein selected aspects of industrial applications of photo-catalytical processes will be discussed.

**Keywords:** $TiO_2$ nanotube, iron, photocatalysis, Fenton, caffeine, water

**Introduction.** Photocatalysis and Fenton-based processes are well known advanced oxidation processes (AOPs), especially for the degradation of organic pollutants in water [1]. Titania ($TiO_2$) is one of the most popular photocatalyst which is interesting in the form of nanomaterials due their unique properties, like the high charge carriers transport in highly-ordered self-organized $TiO_2$ nanotube layers [2]. Fenton reagents including iron species and hydrogen peroxide are promising since they are low-cost along with high availability [3]. However, both these AOPs exhibit drawbacks (electron-hole pairs recombination, iron sludge production, etc.), that can be potentially limited by coupling $TiO_2$ and Fe within a single material. Therefore, this conference presentation aims first, to characterize the physico-chemical properties of synthezied Fe surface-modified $TiO_2$ nanotube layers (Fe-$TiO_2$) and then, to assess the contribution of each identified AOP triggered by Fe-$TiO_2$. To this end, their simultaneous coupling is discussed by investigating the performance of Fe-$TiO_2$ for the degradation of caffeine, a top pharmaceutical contaminant, in water.

**Experimental.** Fe-$TiO_2$ is prepared by electrochemical anodization of titanium foil (1.5 cm x 1.5 cm) followed by surface modification using spin-coating of Fe(III) precursor solution at different concentrations. The different Fe-$TiO_2$ are annealed at 450 °C for 2 h in air, and subsequently characterized by XRD, DRS, SEM, EDX and UPS. The generation of hydroxyl radicals (HO•) is analyzed by fluorescence spectroscopy (using 7-hydroxycoumarina as probe) while iron leaching is investigated by UV-VIS spectrocopy (using ferrozine complexation). The degradation of caffeine (20 ppm, pH = 3) by Fe-$TiO_2$ is performed in a batch photoreactor equipped of UVA light (1.3 mW/cm²) with the addition of 500 µM $H_2O_2$. The degradation extents and mechanism are investigated by HPLC and LC-MS, respectively.

**Results and discussion.** To fundamentally understand the coupling mechanism between photocatalysis and Fenton, Fe-$TiO_2$ with intermediate surface-concentration of iron (100 µM) is the optimal strategy since, in the extremes of the series (10 µM and 10 mM), the degradation of caffeine is governed exclusively by photocatalysis and Fenton-based processes, respectively. In the optimized Fe-$TiO_2$, the contribution of $H_2O_2$ photolysis, photocatalysis and Fenton-based processes in the degradation of caffeine (67% after 3 h) has been evaluated 4%, 23.5% and 39.5%, respectively. It is worth noting the Fenton contribution is due to the iron leaching (2.3 µM). HO• have been identified as the main active species during the degradation of caffeine. The main degradation by-products have been identified, thus leading to the proposal of hydroxylation, N-demethylation and imidazole ring opening as plausible mechanisms. To conclude, the strategy of coupling photocatalysis and Fenton-based processes is promising since it introduces the concept of photochemical versatility. Such an innovative approach could potentially reduce the cost of water treatment by introducing a synergy between the processes.

**Keywords:** ZnO/ZnS photocatalyst, Azo dyes, Antibiotics, Wastewater treatment, Environmental Protection

**Introduction.** The presence dyes and antibiotics in high concentrations found in natural water for long times resulted in carcinogenesis, mutagenesis, and respiratory toxicity in addition to other various side effects. Therefore, the complete removal of the organic pollutants including dyes and antibiotics is urgently needed. Various conventional treatment routes including adsorption face some drawbacks such as low efficiency, high cost, and creation of secondary pollutants. Alternatively, semiconducting photocatalytic method is a promising technique for purification of water without generation of any harmful product [1]. Photogenerated electron-hole recombination is an important factor limiting the efficiency of the photocatalyst. Therefore, the development of heterojunction photocatalysts has become an inevitable trend. Recently, the ZnO/ZnS heterostructures have been attracting significant interests from their predominant properties to combine ZnO and ZnS with lower photoexcitation threshold than individual components and decrease the recombination rate of electron-hole pairs by their physically separated band gap [2].

**Experimental/methodology.** The ZnO/ZnS heterojunction was prepared by thermal treatment of hydrothermally grown ZnS in air at various temperatures. The evolution of the structural and morphological transformation was investigated. The photocatalytic performance of the prepared ZnO/ZnS photocatalyst toward degradation of Reactive red 141 (RR141) and Congo red (CR) dyes was investigated. In addition, the photoactivity of the prepared photocatalyst toward degradation of two fluoroquinolone antibiotics namely ofloxacin (OFL) and norfloxacin (NOR) was also examined. Both simulated UV light (135 W) and natural sunlight were used. The exact concentration of the remaining pollutant was determined by spectrophotometric method.

**Results and discussion.** The ZnS-500 (ZnS calcined at 500 °C) contains the ZnO/ZnS heterojunction showing the highest photodegradation activity toward degradation of azo dyes (RR141, CR) and antibiotics (OFL, NOR) under both UV light and natural sunlight irradiation. The combination of ZnS and ZnO is the key factor regarding the enhancement of the photocatalytic performance by suppressing the recombination of photogenerated electron-hole pairs. The photodegradation of the pollutant follows the first-order kinetic model. The excellent recycling ability of the ZnO/ZnS photocatalyst was confirmed after five cycles of use. The prepared photocatalyst also shows good structural stability with the similar morphology after photocatalytic study. This work demonstrates that the ZnO/ZnS heterojunction photocatalyst has a high potential for detoxification of harmful organic pollutants inclouding dyes and antibiotics from the aqueous solution.

# Synthesis and Characterization of Ceria-Silica Nanocomposites for $CO_2$ Photocatalytic Reduction

Yi-Ru Zhao, Po-Chih Tsao, I-Hsiang Tseng*

*Department of Chemical Engineering, Feng Chia University, Taichung, Taiwan*

**Keywords:** $CeO_2$, $SiO_2$, $CO_2$, photocatalysis

**Introduction.**

The facile formation of oxygen vacancy and the redox capability of $Ce^{3+}/Ce^{4+}$ make ceria ($CeO_2$) a popular adsorbent or catalyst material [1-2]. The difference in the morphology of $CeO_2$ leads to various amounts of surface defects on $CeO_2$ [3]. In this work, process parameters were carefully tuned to obtain $CeO_2$ with different nanostructures (cube or rod). The combination of nanosized $SiO_2$ reduced the crystallinity of $CeO_2$ and created more defect sites on $CeO_2$.

**Experimental/methodology.**

In this work, the modified precipitation method combined with hydrothermal process was applied to synthesize $CeO_2$ nanoparticles with rod or cube crystallinity. For $CeO_2$-$SiO_2$ samples, various amounts of commercial $SiO_2$ nanoparticles were added during the above fabrication process. The precursor of $CeO_2$ was $Ce(NO_3)_3 \cdot 6H_2O$.

**Results and discussion.**

TEM images (Fig. 1) and XRD patterns (Fig. 2) confirm the morphology and crystallinity of $CeO_2$. The absorption edge of c-$CeO_2$ is at 430 nm, corresponding to the band gap of 3.10 eV. Red shift of the absorption edge is observed from r-$CeO_2$, that is 460 nm (2.85 eV), due to more oxygen vacancies. The addition of $SiO_2$ does not affect the optical property. Increasing NaOH concentration from 6M to 9M during precipitaion process improves the crystallinity of rods as well as enhances the production of methoanol (MeOH). In addition to MeOH, carbon monoxide and $H_2$ are detected from the photocatalytic reaction of $CO_2$ and $H_2O$. XPS and Raman spectra reveal that rod $CeO_2$ and samples containing $SiO_2$ exhibit more defects. EPR spectra confirm the presence of spin adducts (DMPO-OH), indicating the production of hydroxyl radicals from irradiated samples suspending in the spin-trap reagent (DMPO). The roles of oxygen vacancy and intermediate radicals in $CO_2$ activation and conversion are investigated in this work.

**Keywords:** Photocatalysis, Metal oxide catalysis, Oxidation.

**Introduction.** Photocatalytic oxidation of pollutants in the air has been the subject of substantial research and is considered to be a promising strategy to improve air quality [1]. In practical applications of this technology the photocatalyst will often be incorporated as a pigment into a paint formulation [2][3]. Hence, an understanding of how the photocatalyst is most optimally incorporated into the coating and which factors that impact performance is of vital understanding for the practical use of photocatalytic processes. Among volatile organic compounds (VOCs) alcohols are at the central class and due to their widely use they are responsible for the poor air quality. The photocatalytic oxidation of isopropanol at the presence of a photocatalyst powder has been investigated extensively [4]. However, the application of photocatalytic paints for this purpose still requires research since there are many parameters affecting the performance of this type of paint. For this purpose experiments were performed using coatings containing $TiO_2$, primarily in the form of nanoparticles, as the photocatalytic component. For the experiments that involve the study of the effects from multiple factors, factorial experiment design can be a useful tool and was used in these studies. In this work, the effect of three primary factors: the content of solid binder, the photocatalyst mass and irradiation intensity on three responses: the conversion of isopropanol, $CO_2$ formation from oxidation and the pseudo-first order rate constant after 3 hours of reaction, has been investigated.

**Experimental/methodology.** Simplified organic coating formulations were prepared on a flexible plastic substrate through dispersion of commercial $TiO_2$ nanoparticles in a waterborne acrylic using an ultrasonic processor. A tubular glass cell was chosen as a lab scale photoreactor which was equipped with two KBr windows for simultaneous IR analysis in transmission mode. An Arcadia 80 W D3 UV lamp was used as the source of irradiation. The radiation intensity was adjusted by changing the distance between the lamp and the photoreactor. Isopropanol was introduced into the photoreactor by injection of 1 µL The Design Expert software was used to perform factorial experiment design.

**Results and discussion.** The result show that the photocatalyst mass in the coating doesn't have a significant effect on across a wide concentration range. This shows that in a real coating system the photocatalyst particles can easily shield each other and negate the effect of larger concentrations. On the other hand the solid binder content and irradiation intensity had a significant impact on the isopropanol conversion. Decreased solid binder content, enhance the conversion of isopropanol and formation of $CO_2$. It can be concluded that a larger content of binder in the coating sample shields the photocatalyst and decreases the number of active sites and consequently decreases the generation of active radicals. As expected an increased irradiance intensity also raises the conversion. The results illustrate that the catalytic activity of the coating relies on the unshielded photoatalytic particles at the external surface of the coating and that methods for achieving the appropriate positioning of the catalyst within a coating medium are essential for the practical applications of photocatalysis.

# Synthesis of $WO_3$-Ag-AgCl films for application in continuous photocatalytic microreactors

P. H. Palharim[1,2*], T. Bürgi[2], A. C. S. C. Teixeira[1]

[1]*University of São Paulo, São Paulo, Brazil*

[*]*ppalharim@usp.br*

**Introduction.** As new environmental pollutants cannot be adequately removed by conventional water treatment techniques, they pose a significant risk to the aquatic ecosystem [1,2]. Therefore, advanced oxidative processes have shown promising results for wastewater treatment, particularly heterogeneous photocatalysis. Among commonly studied semiconductors, $WO_3$ is a material with interesting properties: its narrow band gap (2.5-2.8 eV) makes it active in the broad UV-visible range. Silver-based materials ($Ag_2S$, $Ag_2WO_4$, AgCl etc.) can be coupled to $WO_3$ to increase its photocatalytic activity at a low cost, while extending its absorption range into the visible spectrum and reduzing charge recombination [3,4].

The type of reactor is also important; although batch reactors are commonly used to evaluate the efficiency of these materials, their use is mainly restricted to laboratory investigations. Continuous microreactors allow an initial evaluation of different photocatalysts in reduced scale, and allow the study of scale-up [5]. Additionally, among the various charactterization strategies, vibrational spectroscopy is a valuable technique to provide information about adsorbate layers and in situ investigations of heterogeneous catalysis. In this context, this work aims to synthesize $WO_3$ films coupled with Ag-AgCl, evaluate their photocatalytic performances in microreactors under simulated sunlight using acetaminophen (ACT) as a model contaminant, and evaluate in situ spectroscopy analyses with tbe best materials.

**Experimental/methodology.** All materials were synthesized by the ultrasonic nebulization-pyrolysis/photoreduction method. A central composite experimental design was used to optimize the volume of solution containing the $WO_3$ precursor and the concentrations of $AgNO_3$ and NaCl deposited on the substrate. To evaluate the photocatalytic activity, the films were placed on a 3D-printed microreactor, subsequently sealed. A 5-mg $L^{-1}$ solution of ACT was fed to the reactor and the experiments were carried out with a $HgI_2$ lamp. Samples were collected over time and analyzed by HPLC using a C18 column and UV-vis detector. For the spectroscopic experiments, the catalyst was deposited onto an internal reflection element, which was placed in a flow-through cell mounted on an attachement for ATR (attenuated total reflection) measurements inside the sample compartment of a FTIR spectrometer.

**Results and discussion.** According to the central composite experimental design, the AgCl concentration is the most significant variable in relation to ACT removal, mainly after prolonged use of the material; while the volume of nebulized liquid containing the $WO_3$ precursor did not significantly affect ACT removal. The best material exhibit cracked plates and deformed nearly spherical particles, referred to as $WO_3$ particles, covered by small clustered spherical particles, identified as AgCl. Premilinarly in situ ATR analyses show that prolonged time of irradiation resulted in changes especially in the C-N-H and C=C chemical bonds. These results indicate that the heterojunction formed between $WO_3$ and AgCl may have resulted in a material with high photocatalytic activity under simulated sunlight.

**Introduction.**

In semiconductor photocatalysis for water treatment, $TiO_2$ has become the benchmark semiconductor material [1]. However, the excitation wavelength of $TiO_2$ falls in the UV region which represents only 5% of the solar radiation.[2] The reduced $TiO_2$ shows light absorption commonly across the entire visible spectrum until near-infrared due to the introduction of $Ti^{3+}$ and oxygen vacancies and is characterized by superior photocatalytic activity to pristine $TiO_2$ when irradiated with visible light.[3] Conventionally, the investigation of photocatalytic activity is performed in batch reactors, which are inexpensive and easy to operate, however, they predominantly require several hours of irradiation for each investigated material/condition. Contrary, photo microreactors are characterized by full pollutant degradation in less than 15 minutes, and when coupled with on-line analysis allow continuous monitorization and automation.[4] Despite these advantages, the use of continuous reactors in photocatalyst testing for water treatment is limited. In the context of intensified research for identifying efficient photocatalysts and collective effort for rational use of resources, there is a lack of sustainability assessment of the two screening methods. Consequently, this work aims (i) to investigate the effects of reduced $TiO_2$ synthesis and operational conditions on photocatalytic activity under visible light irradiation of batch and flow reactors and (ii) to compare the two screening methods by their testing throughput, consumption of reagents and electrical energy, and the reproducibility of acquired data.

**Experimental/methodology.**

The synthesis of defective $TiO_2$ is performed by the chemical reduction of $TiO_2$ with $NaBH_4$. A set of materials with tailored properties is prepared by varying the temperature and reduction time and is characterized by $N_2$ sorption, X-ray diffraction, Diffuse reflectance UV-vis spectroscopy, and X-ray photoelectron spectroscopy. The photocatalytic activity of the reduced $TiO_2$-based materials is tested in the degradation of phenol and imidacloprid at various operational conditions (e.g., catalyst loading, pH) using powdered materials in batch photoreactors and immobilized photocatalytic films integrated in microreactors. The flow microreactor is manufactured by 3D printing and allows the simple replacement of the photocatalytic film. The photoreactors are illuminated by in-house built LED light sources with emission at 394 nm, 467 nm, 520 nm, and 635 nm.

**Results and discussion.**

By varying the time and reduction temperature, colored $TiO_2$-based materials are obtained which are characterized by a 2-fold increase in the specific surface area and a decrease of the band-gap energy from 3.2 eV to 1.4 eV. Next, the photocatalytic activity of the synthesized materials will be investigated in batch and in flow. Finally, the sustainability of the screening methodologies will be assessed. The findings of this study are important for developing automatic screening and optimization platforms to accelerate the process of designing more efficient photocatalysts driven by visible light.

**Keywords:** graphitic carbon nitride, photocatalytic film, photo microreactor, pollutant degradation

**Introduction**

Graphitic carbon nitride (g-$C_3N_4$) is a metal-free photocatalyst which has recently attracted significant interest of many researchers. Thanks to its beneficial physical, chemical and electronic properties it has been applied in photo and electrocatalysis, for pollutants degradadion, for water splitting, in heterogeneous catalysis and meny others. The band gap of g-$C_3N_4$ (2.7 eV) is lower than for $TiO_2$ (3.2 eV), and and therefore it can potentially offer excellent light harvesting capabilities even in the range of visible solar light spectrum. In this contribution we focuse on development of g-$C_3N_4$ thin films and testing for pollutant photodegradation using a photo-microreactor with a slit geometry.

**Experimental/methodology**

In this work, the g-$C_3N_4$ was synthesized from supramolecular complex of melamine and cyanuric acid that was calcinated at 550°C to provide g-$C_3N_4$ of high photocatalytic activity, see [1] for details. The thin films of g-$C_3N_4$ were prepared from mixture of ball-milled g-$C_3N_4$ and a binder. The prepared thin films of average thickness 27 µm were subjected to surface modification by plasma treatment to provide excellent hydrophilic properties. The resulting photocatalytic films were examined in a microphotoreactor with a slit geometry and compared to conventional slurry tests in a batch photoreactor. Degradation of three selected antibiotics emerging as waste water pollutants was performed. The degradation products were analyzed by HPLC-MS and possible degradation pahts are drawn.

**Results and discussion**

The photocatalytic activity of g-$C_3N_4$ to catalyse photodegradation of Tetracycline as one of the three chosen antibiotics is shown in the Figure 1. The conversion of Tetracycline reached 87% after 75 min; the photolysis of TC was negligible. Degradation of TC in the photo-microreactor with a thin layer of g-C3N4 showed about 175x higher specific kinetic constant compared to the batch reactor ($k^*$ increased from 0.05 to 8.58 [$min^{-1}cm^{-2}g_{(g\text{-}C3N4)}^{-1}$]), indicating a vast improvement in the photodegradation process efficiency. The thin film photodegradation performance with with differrent polutants will be shown and discussed.

# Photocatalytic $H_2$ Generation on $TiO_2$-based Catalysts and the Effect of the Reaction set-up Configuration on the Photocatalytic Effiency

S. Y. Toledo-Camacho[1*], K. Wenderich[2], G. Mul[2], S. Contreras[1], F. Medina[1]. [1]*Departament d'Enginyeria Química, Universitat Rovira i Virgili, Tarragona, Spain.* [3] *Photocatalytic Synthesis Group, MESA+ Institute for Nanotechnology, University of Twente, Enschede, The Netherlands. *sandrayurani.toledo@urv.cat*

**Keywords:** Photocatalysis, Hydrogen, $TiO_2$, Photoreforming, Co-catalysts, Quantum effciency

## Introduction.

Our current wasteful lifestyle forces scientists to take up the challenge to develop more efficient materials to utilize the energy of renewable sources. Since Fujishima and Honda (1972), the $H_2$ photogeneration on semiconducting materials became a capable technology to produce other fuel sources rather than fossil fuels, but today, non-conventional methods are still not mature enough and inefficient [1]. In this work, we investigate the effect of different co-catalysts and the reaction set-up configuration on the activity of $TiO_2$ (commercial $TiO_2$ P25) and $TiO_2$ nanotubes (NT) for $H_2$ generation by photoreforming or water-methanol mixtures (50 vol.%).

## Experimental/methodology.

P25-$WO_3$ and NT-$WO_3$ supports were synthesized according to reference [2]. The metal (Pd or Pt) was incorporated by photodeposition and Cu by wetness impregnation. The three $H_2$ set up under study were: (i) simulated solar light $(SSL)_{300\text{ - }800\text{ nm}}$, (ii) $UVA_{300\text{ - }400\text{ nm}}$ and (iii) small scale (SS) system, HP Hg $lamp_{280\text{ - }700\text{ nm}}$ [3].

## Results and discussion.

In Figure 1 it is observed that Pd/P25 shows the highest $H_2$ evolution in all three reaction systems, where in SS- and SSL-system, Pd/P25 has the highest activity. Pd/P25-$WO_3$ presents same decreasing order, however, its activity is reduced compared to Pd/P25. For Pd/NT-$WO_3$, though it shows higher activity than Pd/P25-$WO_3$, its $H_2$ evolution is also importantly depleted compared to Pd/P25. Similar outcomes were found for the catalysts containing Pt and $WO_3$. Probably, the interaction between the metal (Pd or Pt) and $WO_3$ nanoparticles promotes byproducts adsorption on the catalyst, blocking the pathway towards $H_2$ [3]. When P25 is loaded with Cu and Pd, the catalytic activity also undergoes a decreasing. This negative activity exposes the absence of any synergy effect between both co-catalysts [4]. Still, in the SSL-system, Pd/P25-Cu was more active than all the catalysts containing $WO_3$, but, interestingly, its performance in the SS-system was the worst. In addition, Figure 1 shows the effect of the reaction set-up configuration on the final reading for $H_2$ evolution, under normalized conditions by the photon flux corresponding only to UV light (300 - 400 nm) ($I_{300\text{-}400\text{ nm}}$: $2.99\text{x}10^{-4}$ for SSL-, $8.33\text{x}10^{-5}$ for UVA- and $3.50\text{x}10^{-5}$ Einstein/min for SS-system). $H_2$ evolution per visible photon flux is also presented. The catalytic activity in the SS-system is fairly the highest, though, interestingly, its total φ (%) is closely similar or even lower than in UVA- and SSL-system. It reflects in the SS set-up there is a more effiencient interacion between catalyst and the inferior number of photon (light intensity) incoming to the reactor, whose small reactor into an enclosed chamber with an optical fiber allows a concentrated beam of photons. In the UVA- vs. SSL-system the vertical glass reactor irradiated with four elongated lamps around it probably favoured a better photon absorption than on a wider shape borosilicate reactor with irradiation on top, respectively.

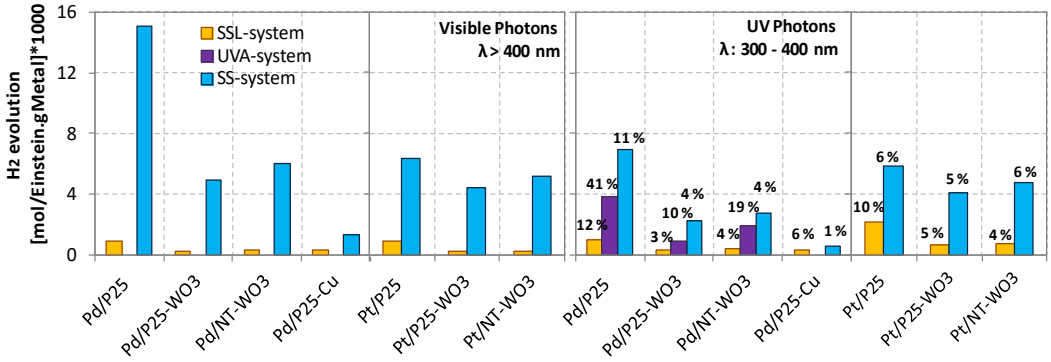

**Figure 1.** Photocatalytic $H_2$ evolution and Quantum Effiency, φ (%) in three different reaction set-up.

**Keywords:** Halogen bond activation; Sulfur vacancy; Polybrominated diphenyl ethers; Photocatalysis

As a class of halogenated flame retardants, polybrominated diphenyl ethers (PBDEs) are widely used in electrical products, furniture and textiles. Recently, as persistent organic pollutants, different levels of PBDEs have been detected in the atmosphere, soil, water and other environmental media. The environmental persistence of PBDEs has been shown to originate primarily from bromine atoms. Therefore, the activation of C-Br bond in PBDEs is particularly important for their debromination as well as for weakening environmental oxidation resistance.In this work, halogen bond targeted photocatalytic interface has been designed to activate C-Br bond, thereby improving the debromination efficiency of PBDEs photodegradation effectively.

Zinc indium sulfides $Zn_xIn_2S_{x+3}$ (x = 1, 2 and 3) with different sulfur vacancies concentration were constructed by a simple solvothermal method to achieve BDE209 debromination under irradiation. Under both UV (λ > 360 nm) and visible light (λ > 420 nm) irradiation, $ZnIn_2S_4$ has the most outstanding degradation ability to BDE209 (Figure 1a), attributing to its surface abundant sulfur vacancies. The introduction of sulfur vacancies can narrow the forbidden band of photocatalysts, thereby increasing their absorption and utilization of light. More importantly, the sulfur vacancies serve as active sites to facilitate the adsorption and activation of C-Br of BDE209. In addition, product analysis indicated that the removal of the first bromine atom of BDE209 on the sulfur vacancies was a *meta*-selective debromination process, which was the same as the debromination behavior on the oxygen vacancies (Figure 1b). Interestingly, the selectivity of meta-debromination on sulfur vacancies is as high as 70%, superior to that on oxygen vacancies. This is attributed to the larger vacancy space of the sulfur atom to accommodate the bromine atoms in BDE209, which helps to stabilize stabilization of the *meta*-bromine atomic adsorption configuration of BDE209 on sulfur vacancies. Meanwhile, the intermediate configuration is further stabilized under the assistance of the S···Br halogen bond by retained sulfur atom at the catalytic interface. This work sheds light on the great potential of sulfur vacancies in photocatalytic treatment of halogenated flame retardant pollutants.

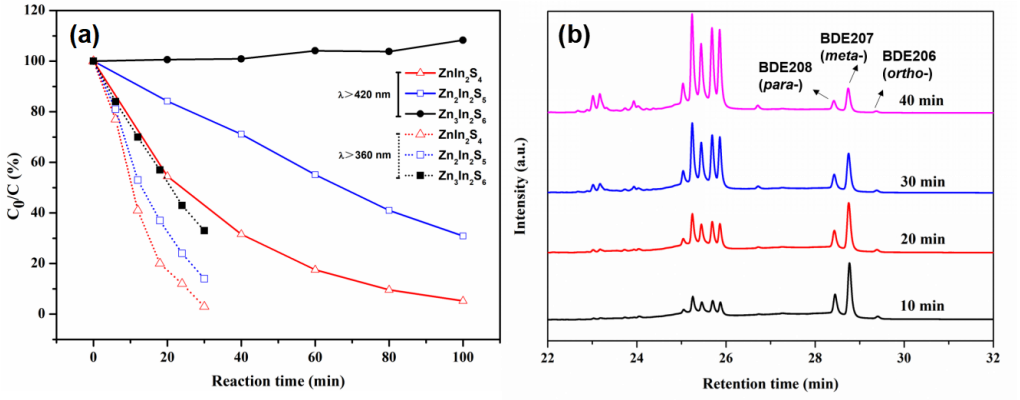

Figure 1 (a) Comparison of photocatalytic degradation of BDE209 over $ZnIn_2S_4$, $Zn2In_2S_5$ and $Zn_3In_2S_6$ in $N_2$-blanketed methanol system; (b) GC-μECD chromatograms of degradation products of BDE209 for $ZnIn_2S_4$ at 10, 20, 30 and 40 min.

**Keywords:** heterogeneous photocatalysis, continuous flow reactor, Au complexes, titania, surface plasmon resonance

**Introduction.** One of the most promising approaches to use water and organic compounds as sources of hydrogen is through solar photocatalytic reactions. Despite the simple nature of the idea and its potential technical viability, the currently available photocatalysts show too low hydrogen production yields in the range of sunlight. In order to increase the effectiveness of the light-to-hydrogen conversion, there is a substantial interest in creating new photocatalysts with improved light absorption [1-4]. In this study, various hybrid gold(I)/gold(0) complexes were loaded over titania and used as photocatalysts for hydrogen production, more specifically for ethanol dehydrogenation. The impact of the preparation technique [5] on the photocatalytic activity under UV and visible light was also analyzed.

**Experimental.** A conventional impregnation method and a mechanochemical method were used to anchor gold complex co-catalysts on $TiO_2$ with a mass loadings of 1%. An additional set of samples was prepared by incipient wetness impregnation with a co-catalyst load of 0.25% wt. Au, in order to analyze the effect of the different ligands of the complexes. Photocatalytic experiments were carried out at room temperature under atmospheric conditions in a continuous gas flow photoreactor (GHSV = 5600 $h^{-1}$). All the samples were characterized before and after reaction using UV-Vis spectroscopy, RAMAN spectroscopy, X-ray diffraction, XPS, and TPR.

**Results and discussion.** Photocatalytic experiments show an improvement of the activity of all samples compared to pure titanium dioxide (P90) under UV irradiation, as well as hydrogen generation capability under visible light. Generally, samples prepared by the mechanochemical method show lower photocatalytic activity than those prepared by impregnation, which is a good point in favour of the conventional method. The samples with Au(I)-based co-catalysts show a reaction profile in which the hydrogen production rate increases constantly until it stabilizes, which could be indicative of a possible rearrangement of gold from Au(I) to Au(0). This is confirmed by the UV-Vis spectra of the samples after reaction, as they show an absorption band corresponding to gold plasmon. In the case of the photocatalyst with Au(0)-based complexes, the reaction profile shows a decrease in hydrogen production prior to stabilisation, which is related to a reorganisation of the gold in the form of agglomeration of nanoparticles. The impregnated samples with a complex load of 1%, showed improvements in the activity, ranging from 18% to 74%, when irradiating with UV light compared to an $Au/TiO_2$ reference sample with a gold content of 1% by weight. A set of samples with the same amount of gold was prepared (0.25% wt.) in order to analyze a possible influence of the different ligands.

**Keywords:** ZnO thin films, Ag nanoparticles, photocatalytisis, antibacterial, sol-gel dip-coating.

**Introduction**

ZnO thin films doped with Ag nanoparticles (AgNPs) can be promising candidates for photocatalytic and antibacterial applications [1] due to their improved electron movility and decrease of the charge trapping compared to pure ZnO. The preparation of AgNP doped ZnO thin films involves the preparation and incorporation of Ag nanoparticles suspensions into a ZnO sol, which can be achieved through various synthesis methods, including sol-gel, sputtering, and hydrothermal methods. In general, the sol-gel method is a simple and cost-effective approach for the preparation of Ag-doped ZnO thin films [2].
Thus, in this work, we explored the most appropiate way to synthesize the suspensions of Ag nanoparticles and to incorporate them to ZnO sols. The deposition of Ag-doped Zn thin films was also studied by dip-coating together with the characterization of photocatalytic and antibacterial performance of the coatings.

**Experimental/methodology:** The Ag nanoparticles suspensions were synthesized using a chemical reduction method by adding silver nitrate to a solution of ethanol and polyvinypyrolidine. AgNPs doped ZnO was prepared by mixing zinc acetate dihydrate, ethanol, and diethanolamine and adding the previously prepared Ag nanoparticles suspension. The Ag-doped ZnO sol-gel solution was used for dip-coating glass substrates and Si wafer, which was then dried for 1 h at 80 °C and calcined at 450 °C for 1 h to obtain AgNP-doped ZnO thin film. The resulting thin films were characterized using different techniques such as X-ray diffraction, UV-Vis spectroscopy, and scanning electron microscopy. To evaluate the photocatalytic properties of the Ag NP-doped ZnO thin films, the photocatalytic degradation of methylorange (MO) was monitored using a solar simulator. The antibacterial activity of the thin films was evaluated by measuring the inhibition of bacterial growth and further bacterial colonization of the tested substartes. Representatives of G- and G+ bacterial strains as well as eukaryotic pathogens were tested in direct contact with thin layers. The adhesion of bacterial cells and their subsequent ability to form a biofilm were evaluated.

**Results and discussion:** The XRD analysis results indicated that the crystalline structure of the ZnO thin films was not affected by Ag doping. SEM images show that the coatings are crack-free, and there is no agglomeration of the nanoparticles. The UV–Vis spectra of AgNP doped ZnO showed a typical absorption band in the visible range with a maximum at ~406 nm associated with the absorption of the local surface plasmon resonance (LSPR) typical of spherical metallic Ag nanoparticles. The degradation of MO increases from 75 to 95% from ZnO to AgNP doped ZnO coatings after 3h irradiation. The addition of Ag nanoparticles provides additional active sites for photocatalytic reactions to occur, leading to an increase in the overall degradation ratio of organic pollutants. Thin films showed differences in colonization by microbial representatives, and it is possible to consider their antibacterial potential.

**Introduction.** Hot-dip galvanizing processes generate wastewaters containing high concentrations of Zn (~ 150-200 g/L), Fe (~ 60-150 g/L) and HCl (~ 10-80 g/L) [1-2]. The increasingly stringent regulations regarding the discharge of heavy metals into the environment, and the increasing demand upon the recycling/reuse of these wastewater after proper treatment have focused our interest on the recovery of Fe and Zn from these industrial effluents for the development of new materials for photocatalic applications. Here we report the synthesis of Fe-Zn oxides active in the photocatalytic degradation of dyes (Reactive Blue 21 and Novacid Blue G 200) in simulated and real wastewater under visible and ultraviolet light.

**Experimental/methodology**: bimetallic Fe-Zn oxides were synthesized by coprecipitation and the photocatalytic tests were performed in cylindrical glass reactors containing 200 mL of 20000 mg/L blue dye solution under Vis light by 3 h.

**Results and discussion.** The different synthesized oxides are mainly composed of Fe and Zn in similar proportions (30- and 40% w/w) with a Fe:Zn ratio of 1:1. These relationships obtained are only possible for $ZnFe_2O_4$ heterolinked with Zn, which was corroborate by XRD. The oxidized materials with $H_2O_2$ showed better BET area results than those oxidized with $KMnO_4$, therefore, the calcined materials at 450°C presented double the surface area than those calcined at 600°C. In addition, the band Gap obtained in all the syntheses was around 1.2-1.4 eV, these values are below than those reported in the literature for similar materials (1.3-3.1 Ev) [2-3]. The XRD patterns were similar for all the samples, identifying characteristic peaks of zinc ferrite nanocrystals ($ZnFe_2O_4$) with a cubic spinel structure. However, peaks associated with the ZnO phase are also observed, suggesting an incomplete incorporation of the $Zn^{2+}$ ions into the structure and evidencing that completely pure $ZnFe_2O_4$ was not obtained, which is consistent with the calcination temperatures used, since according to the literature this phase can be obtained completely pure at temperatures above 700 °C [3-4]. Dye degradation results (blue Novacido) of up to 100% were obtained for concentrations of water with real dyes from the ceramics industry. On the contrary, the degradation percentages for the reactive blue 21 with most of the materials were less than 40%, except with the K1.5-600, with which a degradation of 80% was obtained. Finally, the mineralization of dyes was thus evaluated through TOC measurements.

**Table 1.** Physicochemical characterization of the Fe-Zn based oxides and percentage of degradation.

| Oxide Code | Fe (%) | Zn (%) | Surface Area ($m^2/g$) | $pH_z$ | Band Gap (eV) | Novacid Blue G 200 Degradation (%) | Reactive Blue 21 Degradation (%) |

**Keywords:** ZnO, Photocatalyis, Dopant, Chemical bath deposition

**Introduction.** In one century, fresh water world demand has been multiplied by a factor of six [1] and hence new accessible and eco-efficient water treatment processes are needed. Advanced oxidation processes including heterogeneous photocatalysis are of high interest to address this challenge. Zinc oxide (ZnO) is a widely studied semiconducting material because it is non-toxic, bio-compatible, and offers a wide band gap energy (3.37 eV) that is favourable for electron-hole pair generation under UV light [2]. ZnO nanowires grown by chemical bath deposition (CBD), as an inexpensive, low-temperature and green chemistry compatible method, have emerged as highly promising. The extrinsic doping is an usual strategy to improve the photocatalytic activity through the generation of new energy levels in the bandgap aiming at limiting the electron-hole pair recombination [3]. However, the effect of extrinsic doping on the photocatalytic activity and processes of ZnO NWs is still highly debated and largely unknown.

**Experimental/methodology.** In this work, we investigate the extrinsic doping of ZnO nanowires with several elements such as Al, Ga, Cu, Sb and Cl using CBD [4-6] to assess their effects on the photocatalytic activity and processes. Several characterization techniques including scanning electron microscopy, X-ray diffraction, Raman spectroscopy, inductively coupled plasma-mass spectrometry (ICP-MS), and UV-visible absorption are performed to study the incorporation of dopants into ZnO nanowires and to deeply understand how it affects the photocatalytic reaction kinetics and processes during the organic dye degradation under UV light. The photocatalytic activity is followed by UV-visible spectroscopy to determine degration and kinetic rate. Ultra Performance Liquid Chromatography and ICP-MS are used to assay the dye degration pathway and ZnO NWs behavior.

**Results and discussion.** The effect of each dopant along with an additional thermal annealing to promote the degradation of Methtyl orange (MO) will be revealed and discussed in the light of its nature and optimal concentration. An influence of the nature of dopants on the MO degradation pathways and/or on the photocorrosion ability will also be reported and detailed.

# Inkjet printing of $TiO_2$ thin films doped with $Cu_xO$ for photocatalytic water splitting

**Keywords:** Photocatalysis, $H_2$, thin films, inkjet printing, heterojunction

**Introduction.**

Many key strategies to alleviate climate change focus on to the development of environmentally sustainable energy production and storage methods. Among these, utilizing $H_2$ as an energy vector (nowadays named "green hydrogen") clearly stands out [1-2]. In this respect, the catalytic decomposition of water into its elemental components triggered by light (i.e. photocatalytic water splitting) is an ideal candidate for future hydrogen production systems.

While powdered titanium dioxide ($TiO_2$) is one of the most widely studied catalysts, it has a band gap of 3.2 eV, and thus its absorption in the visible range is highly limited. Hence the composition and structure of $TiO_2$-based catalysts must be improved. Substantial efforts have been dedicated to the development of novel photocatalysts with enhanced visible light adsorption using different dopants [3], together with novel catalysts preparation techniques that may be incorporated in novel reactor architectures [4].

The objective of the present work is to prepare a series of photocatalysts based on the direct inkjet printing of nanoparticulate $TiO_2$ suspensions on suitable substrates, their subsequent modification by incorporating Cu species and the application of the resulting materials in the water splitting reaction under light irradiation.

**Experimental/methodology.**

The samples used in this study were prepared by direct inkjet printing of $TiO_2$ nanoparticles suspensions on microscope glass slides by applying the printing procedure for a different number of layers (ranging from 5 to 20) resulting in different thicknesses [5]. Some of the resulting $TiO_2$ films were subsequently doped with CuOx by impregnation with a $Cu(NO_3)_2$ solution followed by $NaBH_4$ treatment. The samples were placed into a quartz reactor containing a mixture of 7 mL of water and 1 mL of ethanol. The reactor was sealed with a rubber septum and the sample was irradiated for 6 h with a Hg lamp. The gas was analysed with a mass spectrometer after 6 h of reaction.

**Results and discussion.**

While the first results obtained in our study showed moderate $H_2$ production values after 6 h using only $TiO_2$ samples (0.2 µmol for the thin film prepared with 20 layers), incoporating Cu on the thin film enhanced $H_2$ production tenfold (1.9 µmol for the sample with 20 layers with incorporated Cu). The selection of a proper hole scavenger and the subsequent optimization of its concentration has allowed us to reach $H_2$ generation values which are very promising, which shows the applied value of our results.

# Efficient Removal of Antibiotics from Waste Water by Photocatalytically Active Supramolecular Organic–Inorganic Magnetic Composites

Sabina G. Ion, Octavian D. Pavel, Nicolae Guzo, Madalina Tudorache, Simona M. Coman, Vasile I. Parvulescu*, Bogdan Cojocaru*

Faculty of Chemistry, University of Bucharest, 4-12 Regina Elisabeta Av., 030018 Bucharest, Romania

**Keywords:** Hybrid composites, photocatalysis, antibiotics

**Introduction.** The complex chemical structure of the antibiotics and their biodegradation products made these very complicate pollutant residues. Their large diversity generated a large concern and, on these bases, considerable efforts have been made to identify an optimal treatment method for their removal. Among the various advanced oxidation processes, photocatalysis has emerged as a promising technology for wastewater treatment in general, and antibiotics removal in particular [1]. A key point in this scope is the identification of the photoactive structures capable to damage complex molecules with different chemical composition. With this aim we proposed a series of supramolecular organic-inorganic magnetic composites containing Fe or Zn-modified MgAl LDHs and M (Cu, Co, Fe, Ni)-phthalocyanine as photosensitizers. The activity of these photocatalysts was evaluated in the removal of *β*-lactam antibiotics from aqueous solutions under simulated light irradiation.

**Experimental/methodology.** The synthesis of Fe or Zn-LDH was carried out by the co-precipitation or mechanochemical method, using both inorganic and organic bases. The insertion of phthalocyanine started from a calcined LDH that has been mixed with a solution of M-phthalocyanine 3,4',4",4"'-tetrasulfonic acid. After the separation and washing, the solid was dispersed in a suspension of $FeCl_3$-$Fe_2(SO_4)_3$, and then precipitated with $NH_4OH$ and then the produced solid was magnetically separated, washed and dried.

**Results and discussion.** The resulted composites were fully characterized using textural, spectral, and diffractometric techniques. The removal of ampicillin and amoxicillin antibiotics occurred via a two-step process i.e. a concerted adsorption and photocatalytic degradation. The loading of the adsorbed ampicillin was related only to the surface charge density of the sorbent surface. For the LDHs, the ampicillin-related amoxicillin was found to adsorb predominantly through a chemisorption mechanism, following a pseudo-second-order kinetics. Under a solar simulator as irradiation source, the composites with Zn-LDH prepared by co-precipitation showed the higher activity. A degradation of antibiotics as high as 98% (sample P7, figure 1) corresponded to a higher amount of phthalocyanine and the presence of large pores (124 Å) [2].

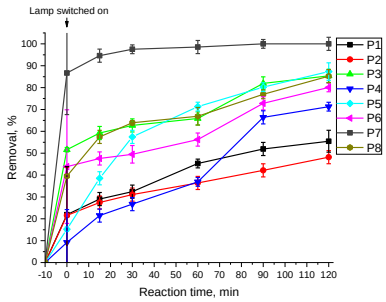

**Figure 1. Removal of ampicillin from water solution using a solar simulator as irradiation source.**

The degradation of β-lactam antibiotics followed two routes: hydroxylation and opening of the β-lactam ring. The ratio between these routes is influenced by the structure of the antibiotic and the nature of the catalyst.

**Keywords:** tin oxide; graphitic carbon nitride; photoelectrochemical properties, hydrogen evolution reaction.

**Introduction.** The hydrogen gas ($H_2$) has attracted attention because its environmentally friendly burn with no emission of greenhouse gases [1]. The n-type $Sn_3O_4$ has been recently applied for $H_2$ generation. To avoid rapid rate of charge carrier recombination and improve photoelectrochemical performance in $Sn_3O_4$, the heterojunctions with g-$C_3N_4$ can be formed to overcome charge recombination at the interfaces of two compounds.

**Experimental/methodology.** Herein, $Sn_3O_4$ and g-$C_3N_4$/$Sn_3O_4$ heterostructure were synthesized via the microwave-assisted hydrothermal method, while g-$C_3N_4$ was obtained by the heating 1.5 g of melamine. The g-$C_3N_4$, $Sn_3O_4$ and g-$C_3N_4$/$Sn_3O_4$ working electrode were prepared by the spin coating methodology. The photoelectrochemical tests for $H_2$ generation took place at a sealed photoelectrochemical reactor equipped with a quartz window (electrolyte: 0.1 mol $L^{-1}$ $Na_2SO_4$) and using solar simulator (300 W Xenon lamp). $H_2$ gas was identified and quantified using gas chromatography with a *thermal conductivity detector*.

**Results and discussion.** During photoelectrochemical experiments the g-$C_3N_4$/$Sn_3O_4$ presented highest photocurrent density of (1.2 mA.$cm^{-2}$). Transient photocurrent curves showed that the g-$C_3N_4$/$Sn_3O_4$ nanocomposite showed a quick response in the presence of light, indicating that the nanomaterial is sensitive to the UV-vis irradiation and presents faster charge separation [2]. The g-$C_3N_4$/$Sn_3O_4$ presented smaller resistance electron transport than that for the g-$C_3N_4$, $Sn_3O_4$, indicating that its charge transfer is faster as shown by Nyquist plots. The cumulative $H_2$ formation using all electrodes showed a stable production of $H_2$ for pure g-$C_3N_4$ and $Sn_3O_4$ materials within the investigated time period of 3 h, while for the g-$C_3N_4$/$Sn_3O_4$ a crescent generation of $H_2$ was observed until reach the maximum of 0.487 mmol $L^{-1}$. The $H_2$ production rate was nearly 4.4 and 4.8 times higher than the $H_2$ production using of g-$C_3N_4$ and $Sn_3O_4$ photoanode, respectively. This observation can be explained by the synergistic effect between $Sn_3O_4$ nanostructures and g-$C_3N_4$ nanosheets, in which the nanocomposite exhibited efficient separation of photoexcited electron–hole pairs, which decreased the recombination rate and therefore promoted higher $H_2$ generation.

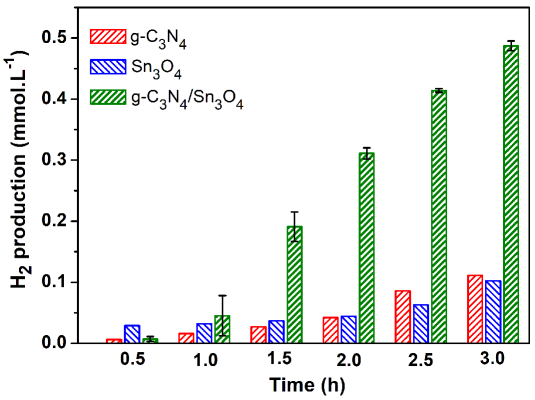

**Fig. 1. Assessment of products formed after 3 h of photoelectrocatalytic $H_2$ evolution at g-$C_3N_4$, $Sn_3O_4$ and g-$C_3N_4$/$Sn_3O_4$ heterostructure electrodes under bias potential of 0.8 V vs. Ag/AgCl.**

# Zeolite ZSM-5 Film-Supported Metal Oxides for Photocatalytic Decomposition of Volatile Organic Compounds

M.E. de Graaf[1,*], R.L. Riemersma[1], B. Baumgartner[1], R.J. Grijpma[1], A.-E. Nieuwelink[1], E.T.C. Vogt[1], E.M. Hutter[1], and B.M. Weckhuysen[1]

**Keywords:** photocatalysis, zeolite ZSM-5 films, volatile organic compounds,

**Introduction.** Harmful volatile organic substances (VOCs), which pollute many indoor environments [1], can be degraded by photocatalysts that absorb visible light. It is known that hybrid materials consisting of a zeolite support and a metal oxide are promising candidates for those degradation processes [1,2]. In addition, the zeolite support immobilizes the metal oxide nanoparticles (NPs) and provides a large surface area for the adsorption of VOCs. These materials can be incorporated in a coating that can be applied to walls or furniture as an air purifying coating. In this work, we use metal oxides supported on b-oriented zeolite ZSM-5 films to mimic a potential coating. We will show their optimization for VOC degradation and demonstrate a method to measure VOC photo-oxidation over film materials.

**Experimental/methodology.** Zeolite ZSM-5 films were synthesized (175 °C, 6 h) hydrothermally in a secondary growth medium (SGM) on glass supports (15x15 mm). The NPs were deposited by dropcasting. The fluoresent probe 2',7'-dichlorofluorescein (DCF) was used to assess the creation of radical oxygen species on $TiO_2$ NPs. A LED UV-lamp ($\lambda_{max}$=375 nm) was used to activate the NPs.

**Results and discussion.** A synthesis method for b-oriented zeolite films on glass has previously been developed in our group [3]. Herein, we have synthesised alumina-containing seeds (Si/Al=45) and grown these into continuous films using alumina containing SGMs (Si/Al = 45) (Figure 1A). This is promising since a higher alumina content can contribute to more efficient adsorption of VOCs. Next, these films were functionalized with cobalt oxide NPs (Figure 1B). Finally, we demonstrate a method by which we can evaluate the catalytic activity of our samples. Herein we use the fluorescent probe molecule DCF to assess the creation of radical oxygen species (ROS). Figure 1C shows that the fluorescence intensity increases over time, when a layer of $TiO_2$ NPs covered with a solution of DCF-precursor is illuminated with UV-light. This indicates that ROS are indeed being produced. We will apply this method to screen which zeolite films with deposited semiconductors are suitable for VOC photo-oxidation.

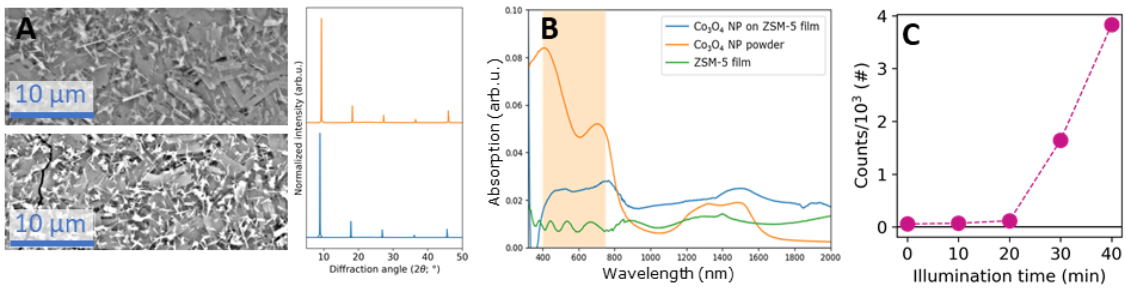

*Figure 1: A) SEM images and XRD patterns of continuous b-oriented ZSM-5 zeolite films (SGM Si/Al=45) grown from Si/Al=45 seeds, B) UV-VIS spectroscopy data of cobalt oxide nanoparticles (NPs) (orange), the ZSM-5 zeolite film without NPs (green), the ZSM-5 zeolite film with NPs (blue), C) Fluorescence intensity over time of DCF probe molecule on $TiO_2$ nanoparticles on a glass substrate.*

Since 2003, the use of tributyltin (TBT) in antifouling coatings is prohibited because of its toxicity towards marine environments(1). The last decade has seen the emergence of a new research area : environmentally-friendly antifouling coatings. Combined with a non-toxic, corrosion-resistant character and good chemical stability in saline conditions, the photocatalytic properties of $TiO_2$ make this oxide a good eco-friendly antibiofouling alternative for marine environments(2). But even if it is showing promising results in in vitro experiments(3), the limited exposure to sunlight in the sea and the restricted absorbance range (UV) of $TiO_2$ in the solar spectrum are important issues. To enhance the antibiofouling properties, a combination of morphological and physico-chemical properties of $TiO_2$ is investigated.

In this context, $TiO_2$ thin films have been synthesized using Aerosol Assisted Metal Organic Chemical Vapour Deposition (AA-MOCVD). Using precise parameters, nanometric petals assembly (forming microflower-like structures) are obtained, enhancing the reactive specific surface of the material and thus its photocatalytic properties. By tuning some parameters of deposition, it is possible to vary the size and density of the flowers, and to investigate their influence on both the photocatalytic and antibiofouling properties of the material.
$TiO_2$-$Cu_2O$ composite materials can be also synthesized by AA-MOCVD. This composite is expected to increase the photocatalytical activity through two phenomena. On one hand, according to Zhang et al.(4) , the substitution of $Ti^{4+}$ by $Cu^{2+}/Cu^{1+}$ in the $TiO_2$ lattice induces the creation of oxygen vacancies and additional impurity bands right above the valence band maximum of pure $TiO_2$, which results in a significant reduction of both band gap and the recombination rate of photoelectron–hole pairs, improving the photocatalytic performance and visible light absorption of $TiO_2$. On the other hand, the p-n heterojunction $TiO_2$-$Cu_2O$ promotes the electron-hole separation and slow down the charges recombination(5).

The films morphologies, composition and photocatalytic performances are going to be investigated using SEM, DRX and a photocatalysis test, as well as their antifouling properties during in vitro experiments and marine immersion.

**Keywords:** DRS UV-vis, Raman, DRIFT, spectroscopy, $TiO_2$, photocatalysts

**Introduction.** Heterogeneous photocatalysis belongs recently to the most studied environmentally friendly technologies for various applications. The most promising photocatalytically active semiconductor is $TiO_2$. In many respects (price, availability, low toxicity) the improving the properties of $TiO_2$is an interesting alternative for increasing quantum efficiency, decreasing the rate of electron-hole pair recombination, narrowing the bandgap. Electrochemical properties of photocatalytic material is closely related to its chemical, optical and textural structure. In this contribution, we provide an overview of the characteristics that can be obtained for photocatalysts by measuring DRS UV-vis, Raman and infrared spectra.

**Experimental/methodology.** Commercial (Sigma-Aldrich s.r.o., CR) and laboratory prepared (sol-gel method) $TiO_2$ photocatalysts were used as reference materials. The photocatalytic activity of the photocatalyst samples was tested by means of the amount of $H_2$ evolved during the photocatalytic decomposition of the aqueous methanol solution in batch reactor equipped by UV-LED solo P lamp with parallel beam optics ($\lambda = 365$ nm, 5 W). Diffuse reflectance (DR) UV-vis spectra of photocatalysts were measured in quartz cuvettes by using a GBS CINTRA 303 spectrometer (GBC Scientific Equipment, Australia). Samples were also studied by Raman spectroscopy using a Raman DXR Thermo Scientific DXR SmartRaman (Nicolet CZ s.r.o., CR) equipped by the Nd:YAG laser. Temperature resolved IR spektra were measured in DRIFT cell Praying Mantis™ by FTIR spectrometer Nicolet iS20 (both Nicolet CZ s.r.o., CR).

**Results and discussion.** The refelctance (DR UV-vis) was recalculated into the dependence of Kubelka–Munk function ($F(R\infty)$) on the absorption energy using the equation $F(R\infty) = (1 - R\infty)^2 / (2 \cdot R\infty)$, where $R\infty$ is the diffuse reflectance from a semi-infinite layer. The obtained spectra were transformed to the dependencies $(\alpha h\nu)^2$ or $(\alpha h\nu)^{1/2}$ against hv. Absorption coefficient ($\alpha$) is approximately equal to $F(R\infty)$. Depending on the sort of semiconductor the direct and indirect band gap energy values (Eg) were determined by extrapolating of straight line of $(\alpha h\nu)^2$ or $(\alpha h\nu)^{1/2}$ to zero. Raman spectra of studied photocatalysts determine the phase composition of $TiO_2$. In addition the exact position and the width of individual peak is affected by sizes of nanoparticles and a presence of defects of anatase structure. Structural changes of the precursors depending on the calcination temperature were studied using DRFT spectroscopy. The correlation between measured chemical, optical and textural properties and photocatalytic activity of tested photocatalysts were suggested.

# Application of Indirect Techniques of EPR Spectroscopy in Heterogenous Photocatalysis

Zuzana Dyrčíková, Kristína Czikhardtová, Dana Dvoranová*

Principle of the heterogeneous photocatalysis, as one the effective advance oxidation proccess (AOP) method, can be define as follows – *change in the rate of a chemical reaction or its initiation under ultraviolet (UV) or visible (VIS) irradiation in the presence of a substrate, the photocatalyst, that harvests light and is involved in the chemical transformation of the reaction partners*. One the most studied photocatalysts are metal oxides, such titanium dioxide or zinc oxide, however their Achilles' heel is absorption only in UV region. Nowadays the main target si preparation of photocatalyst active upon solar light. The modification with other semiconductors or metals/non-metals doing/decorating have been proposed to improve the charge carrier separation and better absorption in the VIS region. Novel photocatalytic materials are closely coupled with their potential photoactivity and capability of the generation of various reactive paramagnetic species and the electron paramagnetic resonance (EPR) spectroscopy represents a sensitive spectroscopic method that allows the detection and characterization of these paramagnetic centres in different semiconducting nanomaterials which are significant for their photocatalytic properties. Although EPR provides direct detection of free radicals, in photocatalytic investigations utilizitation of indirect techniques, such spin trapping, spin scavenging, oxidation of sterically hindered amines or photoreduction, is often applied (Fig. 1). The evaluation of the photocatalytic activity of individual titania structures is based on the nature and quantity of reactive radical intermediates generated in the irradiated semicondutor suspensions obtained by in situ EPR spectroscopy. Proper choice of suitable experimental conditions is crucial for their successful application in heterogeneous semiconductor systems and can help to gain a comprehensive picture of the photoinduced processes undergoing upon light exposure of the photocatalyst in suspensions [1-3].

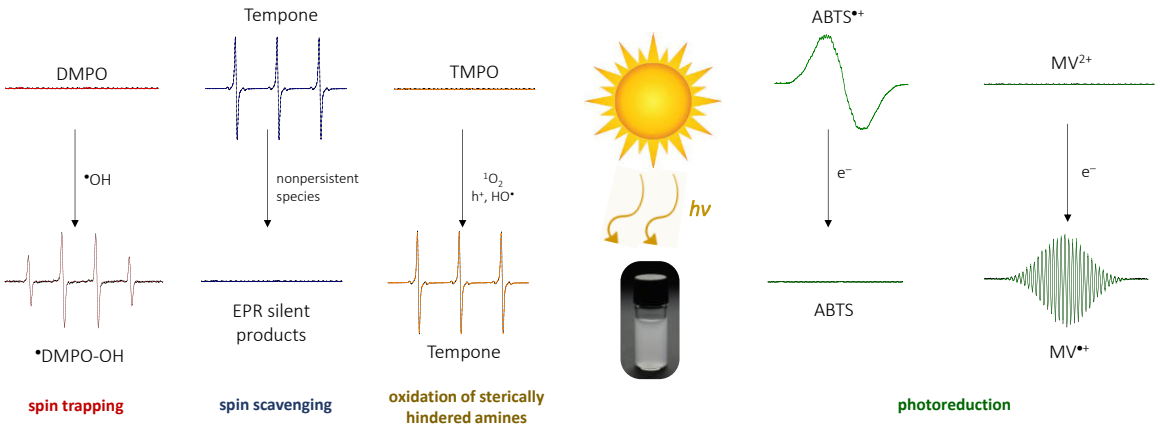

**Fig. 1** Scheme of selected indirect EPR techniques applied in the detection and characterization of transient paramagnetic species.

# Investigating the Transient Behaviors during Photocatalytic NO Oxidation

S.Ernam[1], D.Üner[1*]
[1]*Middle East Technical University, Ankara, Turkey*
[*]*uner@metu.edu.tr*

**Keywords:** Photocatalysis, NO oxidation, light intensity, water injections

**Introduction.** Photocatalytic NO oxidation reaction is a standard diagnostic tool for photocatalytic activity. The reaction can be used to investigate the bottlenecks of photocatalysis. One of the distinct features of photocatalytic NO oxidation is the transient period of NO conversion observed, following the beginning of illumination. NO conversion reaches a steady state only after a certain period of time, and the nature of this behavior depends strongly on parameters such as the illumination intensity and the concentration of the reactants, in particular the moisture content.

**Experimental/methodology.** Experiments were performed according to the protocols described by the ISO Standard (22197-1-2007). The experiment set up consists of three mass flow controllers to adjust a desired ratio of moist air, dry air and NO, a photoreactor which houses a catalyt coated flat plate and a $NO_x$ gas analyzer. In this study, $TiO_2$ P25 was used as catalyst. Illumination intensity and moisture content were varied independently to investigate their effects on the reaction behavior. Light intensity and humidty levels were measured with home made embedded devices using the FRDM K64F microcontroller board.

**Results and discussion.** Experiments revealed that at higher light intensities, the reaction starts with a very high conversion and needs longer times to reach its steady state at a lower conversion value. In contrast, experiments with low light intensities reach their steady conversion levels, proportional to the intensity, almost immediately after the reaction starts, as shown in Figure 1. The relationship between the steady state reactant conversion and light intensity is given as insert in Figure 1. Furthermore, the effect of water injections to the system was also investigated using a specially built relative humidity measurement device. The water injection transient data revealed the qualitative nature of the interactions. Effect of water injections on NO conversion and relative humidity at two different ilumination intensities can be seen in Figure 2. Finally, impact of time spent under reaction conditions without NO presence was studied. It was shown that humid air stream and illumination is significant for the transient period, as shown in Figure 3. The results of this study show that careful consideration has to be given to the experimental parameters for the accurate assessment of photocatalytic activity through NO oxidation reaction.

**Keywords:** photocatalysis; Fenton; synergy; $CuFe_2O_4$

**Introduction.** Due to the formation of highly reactive oxygen species, which have the ability to oxidize and mineralize organic molecules, advanced oxidation processes (AOPs) are effective at degrading organic pollutants in water [1,2]. Particularly in heterogeneous systems, photocatalysis and Fenton-based processes are among the most investigated AOPs. Copper ferrite ($CuFe_2O_4$) is known as promising photocatalyst due to its attractive energy band gap ($E_g$) in the visible light ($E_g$ = 1.7–1.9 eV), low cost, good photochemical stability and high specific surface area [3]. In addition, the advantage of such a material is the possibility to also trigger Fenton-based processes since $CuFe_2O_4$ contains Fenton active elements (Fe and Cu) [4]. The goal of this work is to assess a potential synergy between photocatalysis and Fenton-based processes which is scarcely described in the literature.

**Experimental.** In a typical synthesis, cupric and ferric nitrate precursors are combined with a surfactant (PEG) in a solution, which is then processed by hydrothermal method (160°C for 24 hours). The resulting powders are dried at 80 °C overnight and the crystalline phase composition and surface morphology of the materials is investigated by XRD and SEM, respectively. Different photochemical systems are investigated (type of light, type of radical precursor, etc.) and during the degradation of caffeine, and the contribution of the different involved photo-induced processes is determined.

**Results and discussion.**

Based on SEM and XRD analyses, the morphology and crystalline phase composition of $CuFe_2O_4$ is discussed: nanoparticles of spinel structure are confirmed. Concerning the degradation of caffeine, the effect of surfactant concentration is studied. Further, with PEG optimized concentration the efficient of different photochemical systems is compared, while the iron leaching is also studied to assess whether homogenous Fenton reaction has a significant role or not.

**Keywords:** Plasmonic photocatalysts, AuAg bimetallic gas-phase clusters , XAFS, $TiO_2$, Self-cleaning.

**Introduction.** Cluster beam deposition is employed for fabricating well-defined bimetallic AuAg plasmonic photocatalysts for visible light self-cleaning surface applications[1,2] to enhance their activity while facilitating a more fundamental understanding of their structual and catalytic properties.

**Experimental/methodology.** $Au_xAg_{1-x}$ clusters with compositions (x = 0, 0.1, 0.3, 0.5, 0.7, 0.9 and 1) spanning the metals miscibility range were produced in the gas-phase by laser ablation of bulk alloyed targets of the corresponding compositions[3] and soft-landed on $TiO_2$ P25-coated silicon wafers with an optimal coverage of 4 atomic monolayer equivalents.

**Results and discussion.** Electron microscopy images show that at this coverage most clusters remain well dispersed whereas EXAFS data are in agreement with the finding that the deposited clusters have an average size of *ca*. 5 nm and feature the same composition as the ablated alloy target.[3] A composition-dependant electron transfer from Au to Ag that is likely to impart chemical stability to the bimetallic clusters and protect Ag atoms against oxidation is additionally evidenced by XPS and XANES.[4]

Under simulated solar light, $Au_xAg_{1-x}$ clusters show a remarkable composition-dependent volcano-type enhancement of their photocatalytic activity towards degradation of stearic acid, a model compound for organic fouling on surfaces. The Formal Quantum Efficiency (FQE) is peaking at the $Au_{0.3}Ag_{0.7}$ composition with a value that is twice as high as that of the pristine $TiO_2$ P25 under solar simulator.[4] Under UV the FQE of all compositions remains similar to that of pristine $TiO_2$. A classical electromagnetic simulation study confirms that among all compositions $Au_{0.3}Ag_{0.7}$ features the largest near-field enhancement in the wavelength range of maximal solar light intensity, as well as sufficient individual photon energy resulting in a better photocatalytic self-cleaning activity. This allows ascribing the mechanism for photocatalysis in the visible mostly to the plasmonic effect of the bimetallic clusters through direct electron injection and near-field enhancement from the resonant cluster towards the conduction band of $TiO_2$. These results not only demonstrate the added value of using well-defined bimetallic nanocatalysts to enhance their photocatalytic activity but also highlights the potential of the cluster beam deposition to design tailored noble metal modified photocatalytic surfaces with controlled compositions and sizes without involving potentially hazardous chemical agents.

**Introduction**. Unpleasant odors are the most disturbing pollutants and the main reason for air quality complaints in urban and industrial areas. Odor emissions consist of various chemical components, some of which can be perceived at very low threshold levels.[1] Volatile organic compounds (VOCs) have been designated as the major odorant group. In particular, volatile fatty acids (VFAs) represent an important source of unpleasant odors that have been considered in many studies. Among them, propionic acid (PA) has attracted much attention as one of the leading compounds responsible for the odors-polluted environment.[2]

In this work, the effect of multi-decorated enhanced photocatalysts, for the PA decomposition, under visible light irradiation, was properly investigated.

**Experimental/methodology.** Micrometric $TiO_2$ by Kronos (identified as 1077) was multi-decorated by three noble metals (Ag, Pt, and Au) through a multistep approach. At first, Ag NPs from Ag-enriched wastewater solution were properly prepared by a previously developed method [3] and 8%Ag-$TiO_2$ photocatalyst was obtained by impregnation method and calcined in the air at 400°C. The final material underwent further decoration by the other metals (Pt and Au). A secondary decoration of Ag-$TiO_2$ was carried out by Au, Pt, and bimetallic AuPt NPs, prepared by chemical reduction. Also, in this case NPs were prepared from metals-enriched wastewater solution. The secondary decoration of Ag-$TiO_2$ was done by impregnation as well. All the prepared photocatalysts were characterized by targeted physico-chemical techniques. The PA decomposition tests were performed in a 5.5L Pyrex reactor containing 0.5 ppm of PA in the vapor phase, in the presence of 50 mg of each photocatalyst, under LED light irradiation (P= 2450 LUX) for 190 minutes. The progress of the reaction was monitored by an online GC/FID instrument.

**Results and discussion**. Figure 1 reports the results obtained in the photodegradation of PA by the prepared photocatalysts.

As expected, bare $TiO_2$ Shows no photoactivity towards PA degradation under visible light irradiation. The first decoration with 8%(wt) Ag NPs leads to a significant increase in photoactivity, reaching a percentage of PA photodecomposition higher than 40% in three hours. The effect of the secondary decoration is strongly related to the type of metal used. If, on the one hand Au@Ag-$TiO_2$ exhibits poorer activity with respect to Ag-$TiO_2$, on the other hand Pt@Ag-$TiO_2$ can decompose about 60% of PA in two hours.

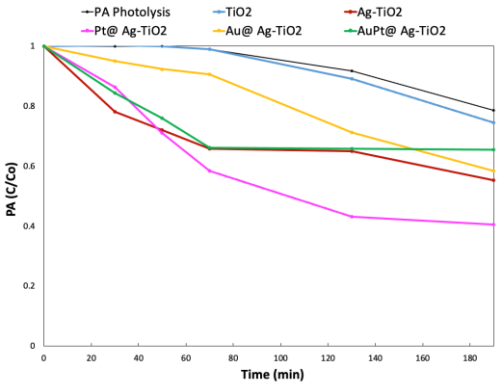

**Figure 1. Photoactivity graph of PA**

AuPt@Ag-$TiO_2$ photocatalyst balances the negative aspect of Au NPs with the positive ones of Pt NP, effectively showing the same activity of Ag-$TiO_2$.The enhanced photoactivity of Pt@Ag-$TiO_2$ could be ascribed to both the localized surface plasmon resonance (LSPR) effect from Ag NPs and the "Electron sink" effect from Pt NPs. In contrast, the poor performances of Au@Ag-$TiO_2$ are mainly due to the different transformation products (identified by GC-MS), which negatively affect the Au NPs.

# Green hydrogen generation from photocatalytic water splitting using PGM modified $TiO_2$

Naomi Harrisankar*, Eric van Steen

**Catalysis Institute, Department of Chemical Engineering, University of Cape Town, South Africa.*

*hrrnao001@myuct.ac.za

**Keywords:** Photocatalysis, water-splitting, green hydrogen

**Introduction.** The generation of green hydrogen from photocatalytic water splitting using sunlight and a semiconductor photocatalyst could provide a route for sustainable energy storage in the form of hydrogen. However, photocatalysts suffer from low efficiencies. $TiO_2$-P25 has become a benchmark catalyst in photocatalysis, despite its low efficiency as a consequence of its large bandgap, thus reducing the portion of the electromagnetic spectrum that a photocatalyst can absorb, as well as the high recombination rates and thus reducing the charge carriers that take part in the surface reactions.[1] Here, we show that $TiO_2$ can be modified using PGM nanoparticles to improve its efficiency via two phenomena: Schottky barrier formation and surface plasmonic resonance. A Schottky barrier created at the semiconductor-metal interface may act as an electron trap, prolonging the lifespan of the charge carriers. The photocatalyst's light absorption ability was investigated by varying nanoparticle morphology. [2]

**Experimental/Methodology.** Spherical, cubic and nanorod PGM nanoparticles (Pt, Pd and Ru) were loaded onto $TiO_2$ (P25 Degussa). The catalysts have been characterised using XRD, TEM, UV-VIS, TPR, and TPO. The photocatalytic activity was studied in a batch slurry photoreactor using UV-A, UV-C, and visible light. Furthermore, we present the role of a sacrificial agent and probe further into the catalyst-light relationship by varying light energy and intensity.

**Results.** The hydrogen production depends linearly on the number of photons (see Figure 1 (a)). The rate of $H_2$ formation increases upon the addition of PGMs, which is related to the metal work function and Schottky barrier.

The photo-catalytic water-splitting is often studied in the presence of a sacrificial agent (e.g. ethanol), which improves the rate of $H_2$ formation significantly (Figure 1( b) and (c))as ethanol acts as an electron donor reducing electron-hole recombination. Furthermore, we show the effect of nanoparticle morphology on the absorption ability of the photocatalyst using UV-VIS and reactor studies.

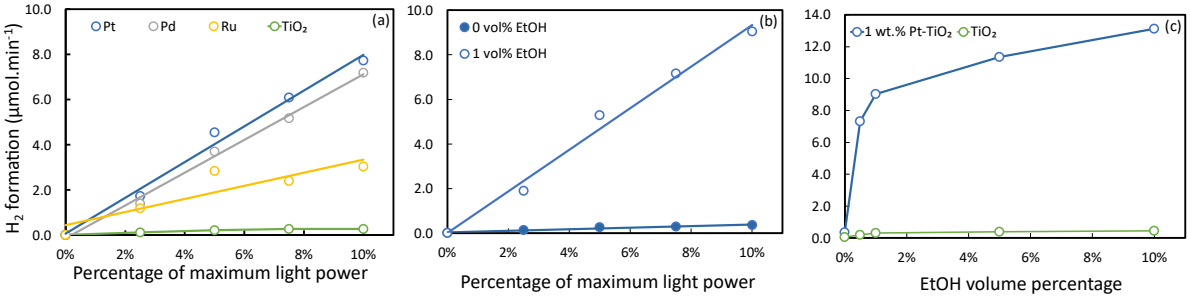

Figure 1: Rate of $H_2$ formation ras a function of percentage of maximum power for (a) various PGM loaded $TiO_2$ photocatalysts, (b) effect of sacrificial agent and (c) Rate of $H_2$ formation as a function vol. % of sacrificial agent

*muhammad.iqbal@tnuni.sk

**Keywords:** Heterojunction, Metal organic Frameworks (MOFs)

**Introduction.** $CuWO_4$, as a semiconductor-based photocatalyst with a moderate bandgap (2.2–2.4 eV), has been attracting considerable attention as a promising candidate for $H_2$ generation. Despite that, $CuWO_4$ does not show significant improvements in photocatalysis for hydrogen evolution reaction. A possible explanation is that the midgap states created by the empty Cu(3dx2-y2) could restrict the mobility of the carriers. Thus, $CuWO_4$ has to be modified, as a heterojunction to improve its electron transfer kinetics and properties [1]. Additionally, the heterojunctions between metal oxide-based semiconductors and metal-organic frameworks (MOFs) like Co-based ZIF-67 [2], $TiO_2$/MIL-101 [3], and ZnO/MIL-53 [4] have been used as photocatalysts due to their high ability of charge separation, greater surface area and light absorption. In the present work, we modified $CuWO_4$ nanoparticles with ZIF-8 to increase the surface area, broaden their light absorption region and inhibit the recombination of photogenerated electrons to these semiconductors, thus promoting their photocatalytic performance.

**Experimental/methodology.** $CuWO_4$ was prepared by co-precipitation method, while $CuWO_4$ hybrid composites were prepared by an in situ-growth method. XRD, SEM, FTIR, and XPS were used to inspect the structure.

**Results and discussion.** The ZIF-8/$CuWO_4$ hybrid structures were synthesized, as confirmed by XRD, FTIR (Figure 1 and 2), and XPS. The as-synthesized composites contain both $CuWO_4$ and ZIF-8 phases. Due to this, the band gap of ZIF-8 was reduced from 5.22 to 3.5 eV, as confirmed by DRS-UV-Vis spectroscopy (Figure 3 and 4). The minimum energy required to split water into $H_2$ and $O_2$ is 1.23 eV and four photons are needed for this reaction to occur. The ideal band gap of photocatalyst lies in between 2 to 3.5 eV for the effective absorption of light spectra, as the ZIF-8/$CuWO_4$ hybrid structures show similar band gap of 3.5 eV, therefore, the photocatalytic enhancement is expected.

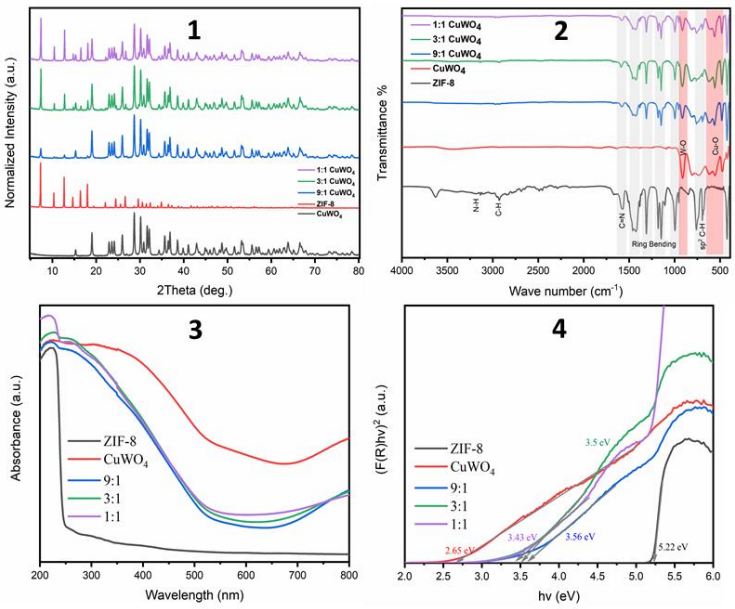

**Figure 1 XRD, 2 FTIR graphs, 3 Absorbance UV-Visible DRS, and 4 Kubelka-Munk Plot for pure ZIF-8, $CuWO_4$ and their hybrid structures**

# Photocatalytic Water Decontamination: Fe-C/g-$C_3N_4$ Catalyst in Action on Vltava River.

N. Ishak[1*], M. Šoóš[1], M. Grandcolas[2]

[1] *University of Chemistry and Technology, Technická 5, Prague, Czech Republic*

[2] *SINTEF Industry, Department of Sustainable Energy Technology, Forskningsveien 1, 0373 Oslo, Norway*

*Corresponding author*: ishakj@vscht.cz*

In this study, a photocatalyst composed of Fe-C/g-$C_3N_4$ was synthesized using a wet impregnation method and was evaluated for its effectiveness in decontaminating water from the Vltava River. The composite photocatalyst was activated through temperature treatment and was characterized using various techniques such as X-ray diffraction (XRD), transmission electron microscopy (TEM), Fourier Transform Infrared Spectroscopy (FTIR), thermal gravimetric analysis (TGA) and ultraviolet-visible spectroscopy (UV-Vis). The results showed that the catalyst was able to effectively remove bacteria from the water in few minutes under sunlight. The sample with the highest catalytic activity in degrading bacteria was identified. The optimal amount of catalyst in the medium was determined through experiments conducted under a solar simulator lamp for one hour. The reason behind the high activity of the Fe-C/g-$C_3N_4$ photocatalyst was also explored and it was found that the enhancement in the electrochemical properties was a result of the doping of iron and carbon, as well as heat treatment. The performance of the catalyst was also tested when it is embedded in an electrospun membrane and the results were compared to the case of the slurry application. Overall, this study suggests that Fe-C/g-$C_3N_4$ photocatalyst is a cost-effective, efficient and innovative method for green water decontamination, due to its high activity, low cost and non-toxicity.

# $MoS_2$ nanomaterials as efficient photocatalysts in Advanced Reduction Processes (ARPs)

Joanna Kisała

[1] *Institute Biology and Biotechnology, College of Natural Sciences, University of Rzeszow, Rzeszow, Poland*
[*] *jkisala@ur.edu.pl*

**Keywords:** photocatalysis, advanced reduction processes, reaction kinetic

**Introduction.** The major environmental challenge are organic compounds resistant to degradation under natural conditions. This group of compounds includes dyes, pesticides, pharmaceuticals, personal care products. One of the prominent goals of environmental studies has, therefore, been to degrade these substances to preferably harmless and easily disposable compounds. Although Advanced Oxidation Processes (AOP) are one of the widely used techniques for removing organic pollutants [1], they are not suitable in all cases (e.g. oxidative photodegradation of polyhalogenated compounds is kinetically unfavored [2]). Hence, reductive methods can be considered as an alternative degradation method [3]. In the present study, $MoS_2$ was examined as photocatalysts for two dyes degradation: methylene blue (MB) and bromophenol blue (BPB). The degradation processes were conducted under reductive conditions.

**Experimental/methodology.** A solution of dye (methylene blue MB, or bromophenol blue BPB) with suspended catalyst ($MoS_2$) was illuminated (power density 4.7 $mW \cdot cm^{-2}$) for 120 min. Analysis of the reaction progress was carried out by UV-Vis measurements of dyes decay and potentiometric measurements of an increase in bromide concentration. The reaction was conducted under reduction conditions with continuous argon flow (for oxygen removing) and in the presence of t-BuOH as a hydroxyl radical scavenger.

**Results and discussion.** The morphology and structure of catalyst were characterised by SEM, XRD, AFM, XPS spectroscopy, Raman spectroscopy, UV-Vis spectroscopy, and zeta potential measurements. The observed diffraction peaks in XRD spectrum revealed 2H phase of $MoS_2$ with average size of crystallite 50 nm. The estimated band gap 2.03 eV indicates good optical response to UV-Vis irradiation. The progress of photocatalytic degradation was monitored by recording changes in the dyes concentration. The substrate decay obeys the pseudo-first-order kinetics according to equation: $\ln C_t/C_0 = -k_{app}t$. The half-lives of decay ($t_{1/2}$) were 9.1 min and 17.3 min for BPB and MB, respectively. The apparent rate constant $k_{app}$ calculated from plots was $155.6 \times 10^{-3}$ $min^{-1}$ and $81.7 \times 10^{-3}$ $min^{-1}$ for BPB and MB, respectively. Observed for BPB debromination directly indicates the reducing pathway of BPB degradation. For establishing of degradation pathway, the kinetic simulations were performed with the KINETISCOPE™ stochastic kinetic simulation software. Based on the obtained kinetic results and simulations of the kinetics of the dyes degradation reaction, a suitable reaction pathway has been proposed.

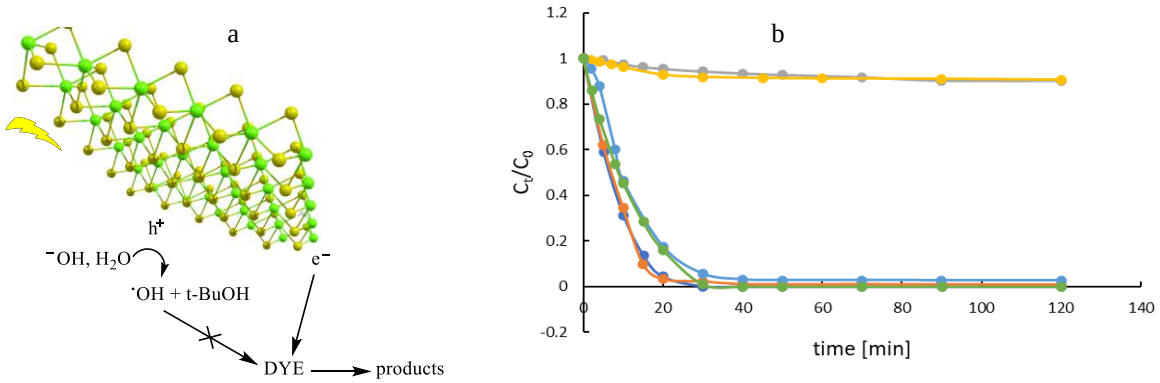

Figure 1. Schematic description of dye photocatalytic degradation (a); dyes decay in time in: photolytic process for MB (yellow), photolytic process for BPB (gray), degradation of MB (light blue), simulation of MB decay (light green), degradation of BPB (orange), simulation of BPB decay (blue) (b)

**Keywords:** textile microplastic, $TiO_2$ catalyst, photocatalysis, degradation

**Introduction:** The synthetic plastic industry is one of the fastest-growing industries in the world producing a wide range of products necessary for life. Textile industry is also among them and it is considered as one of the major sources of microplastic pollution. Textile microplastics are usually in the form of fibers, and their main source of release is their production and household washing. Consequently, microplastics (1 µm to 5 mm) end up in aquatic and terrestrial ecosystems and become one of the most serious environmental concerns. Its long persistence in the ecosystem threatens the health of humans, animals, etc. [1], [2].

The development of reliable technologies for removal of microplastic pollutants is receiving more attention nowadays, including physical, chemical, and biological treatment. Conventional processes are not effective, because thei removal is only physical separation from the water, and requires post-treatment for the complete degradation of microplastic pollutants. Advanced oxidation processes (AOPs) can completely remove of pollutants to non-hazardous molecules such as $CO_2$, $H_2O$, and mineral acids [3].

Heterogeneous photocatalysis is a method that uses light and catalyst to produce reactive oxygen species (ROS), known as radicals. Produced radicals have a high redox potential, e.g. hydroxyl radicals $E^\circ$ = 2.72 V, which can easily attack the molecular structure of various pollutants and completely convert hazardous organic pollutants into harmless products [4]. Furthermore, $TiO_2$-based photocatalysis can break bonds in plastics with the assistance of light.

**Experimental/methodology.** Photocatalytic degradation was performed on commercially available pure textile microplastic fibers such as polyethylene terephthalate (PET), polyamide (PA), and polypropylene (PP). Microplastic fibres were dispersed in an ultrapure aqueous suspension of $TiO_2$ catalyst. The photocatalytic tests were carried out using simulated solar light (300W Osram Ultra Vitalux bulb) as a source of irradiation. Microplastic fibres were characterised before and after photocatalytic treatment using a scanning electron microscope (SEM) and Raman spectroscopy in a range from 400 to 3300 $cm^{-1}$.

**Results and discussion.** The morphology of fiber's surface before and after photocatalytic treatments were analyzed. SEM analysis reveals that the surface of fibers is smooth before, while after the treatment under the simulated solar light in presence of $TiO_2$, is damaged. The deformations on the fibres are numerous and very obvious for PA fibres, and the less pronounced for PP microfibers. Further Raman analysis confirmed structural changes of plastics, which enable correlation between SEM and Raman methods. For future work, we expect to increase the rate of the degradation process with functionalization of $TiO_2$ nanocrystals.

**Keywords:** $CO_2$ reduction, $TiO_2$, photocatalysis, effect of pH, sol-gel, hydrothermal method

**Introduction.** The global warming and carbon dioxide emissions represent serious concerns for the developed countries. Efficient conversion of $CO_2$ into fuels would help solving two biggest societal issues, reduction of $CO_2$ emissions and upcoming fuel crisis. Photocatalytic reduction of $CO_2$ is one of the most investigated reaction, nonetheless, major breakthrough is still required. The most investigated material in photocatalysis is titanium dioxide without any doubt. The major disadvantage of $TiO_2$ is the relatively wide band gap of approximately 3.2 eV. This means only UV irradiation can generate electrons and holes, however, the trend in photocatalysis is to utilize visible light.

**Experimental/methodology.** A series of $TiO_2$ photocatalysts was prepared by various methods resulting in different phase composition. TiHT was prepared using hydrothermal method from $TiOSO_4$ and $NH_3$. TiSG sample was prepared by sol-gel method from titanium isopropoxide.

Photocatalytic tests were performed in a batch stirred photoreactor. Reaction mixture contained 100 ml of 0.2M NaOH with a photocatalyst (0.1 g) and was saturated by He or $CO_2$. An 8W Hg lamp ($\lambda_{max}$ = 254 nm) was used as the irradiation source. The gaseous samples were analyzed by a gas chromatograph (Shimadzu Tracera GC-2010Plus) equipped with BID (barrier discharge ionization detector). All of the measurements were reproducibly measured and three products were detected from photocatalytic reduction of $CO_2$ or during water splitting: $H_2$, $CH_4$ and CO.

**Results and discussion.** At pH = 7 the concentration of dissolved $CO_2$ (9744 mg/dm$^3$) is more than 100 times higher than at pH = 12.9 (84 mg/dm$^3$), but this fact is not crucial for the production of photocatalytic $CO_2$ reduction products. While higher CO yields were observed at pH = 7, the yields of $CH_4$ were higher at pH = 12.9. On the other hand, hydrogen generation is more than two times higher in case of photocatalytic reduction of $CO_2$ at pH = 7 (Fig.2).

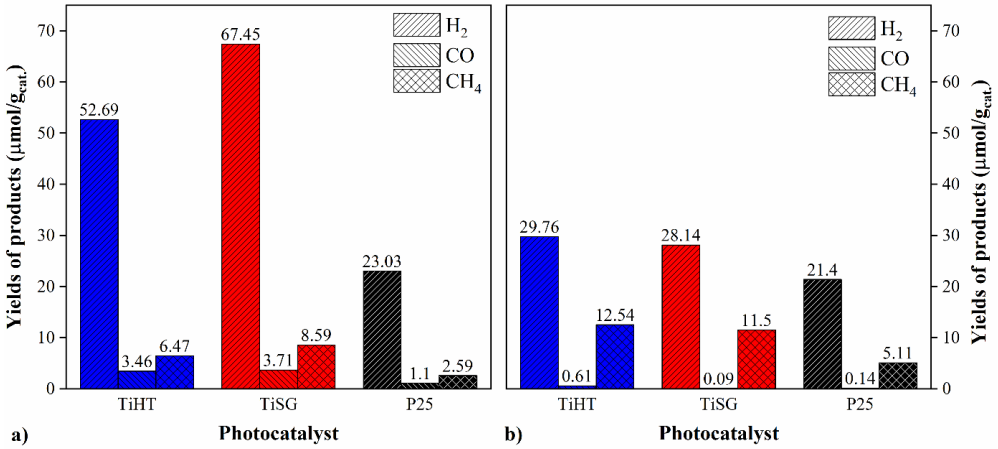

**Figure 1:** The results after 8 hours of 254 nm irradiation during photocatalytic reduction of $CO_2$ a) at pH = 7 and b) at pH = 12.9 over prepared $TiO_2$ photocatalysts and commercial $TiO_2$ P25.

**Keywords:** Carbon nitride, Photocatalytic degradation, Wastewater treatment

**Introduction.** The presence of hazardous and nonbiodegradable organic compounds poses a potential risk to ecosystems and human health. Among the different technologies, visible light photocatalysis technology is an effective way to degrade a wide range of stubborn organic contaminants in wastewater. Recently, graphitic carbon nitride (CN) as a low-cost, simple, and metal-free photocatalyst with a visible light response has shown noticeable activities [1,2].

**Experimental/methodology.** In this study, a metal-free S-doped g-CN (S-g-CN) was obtained by thermal polycondensation of melamine, cyanuric acid, and thiourea; afterward, the sulfur-doped sites in S-g-CN were efficiently converted to C-O by simple calcination under a static air atmosphere without any additive. To monitor the photocatalytic performance of prepared O-doped g-CN was examined by degradation of RB and TC under visible light irradiation.

**Results and discussion.** The nanosheet characteristic of the as-prepared sample was studied by HRTEM; **Fig. 1a** shows the structure of g-CN, indicating an ultrathin nanosheet architecture that is favorable for light harvesting. Other characterization results prove that fabricated O-CN photocatalyst exhibits excellent visible light harvesting, charge carrier transition, and electronic properties (not shown here). In addition, it shows the highest electron density at the CB edge, which makes it a strong reduction photocatalyst. O-CN indicated excellent photocatalytic activity in the degradation of RhB (12 mg $L^{-1}$) and TC (12 mg $L^{-1}$) under visible light irradiation after 15 and 60 min, respectively (**Fig. 1b & c**).

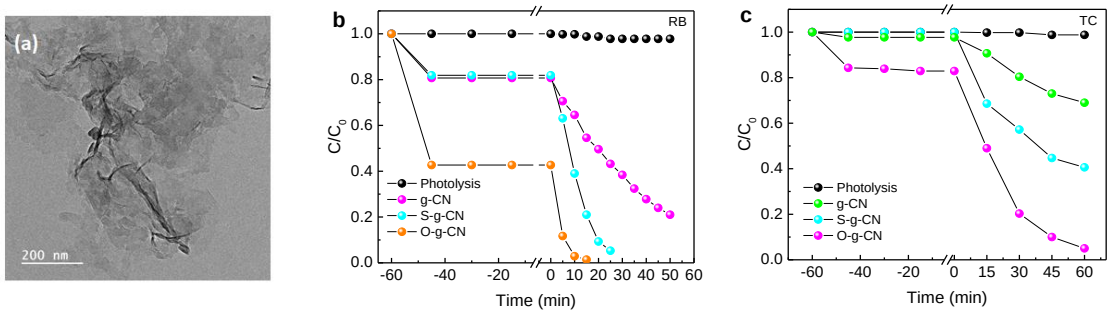

**Figure 1. TEM image of g-CN; photocatalytic degradation of (b) RhB, and (c) TC for fabricated samples.**

**Keywords**: Adsorption, Photocatalysis, Fenton, Iron, Composites

**Introduction**: Fenton-based and photocatalytic processes are ones of the most widely studied Advanced Oxidation Processes (AOPs) to achieve wastewater treatment[1]. Fe-based composites have been widely used for this purpose due its cost efficiency, easy synthesis and efficient removal of pollutants[2]. In addition, pollutants such as carcinogenic dyes, hazardous pharmaceutical products are persistent, thus being seriously alarming concern for the environment[3]. Therefore, it appears crucial to understand how different AOPs can be synergistically combined along with adsorption in Fe-based composites, so more efficient wastewater treatments can be designed.

**Methodology**: Fe-based composite (containing a carbon-based adsorbent) is synthesized using hydrothermal method for efficient removal of a model pollutant. The synthesized catalyst properties are studied using XRD, DRS, and SEM while their efficiency is investigated along with assessment of adsorption, photocatalysis, and Fenton contributions. In addition, the role of radicals including •OH are also assessed.

# Heterojunction semiconductors photocatalytic study

Ksenija Milošević, Davor Lončarević, Tihana Mudrinić, Jasmina Dostanić

*Institute of Chemistry, Technology, and Metallurgy, Department for Catalysis and Chemical Engineering, University of Belgrade, Belgrade, 11000 Serbia*

**Keywords:** photocatalysis, reaction mechanism, heterojunction, bandgap alignment

**Introduction.** Heterogeneous photocatalytic process has gained growing interest as an efficient method for environmental remediation and energy conversion by using a clean and renewable energy source. Photocatalysts are usually semiconductors that should fulfill key factors such as photogeneration of long-lifetime charge carriers, a suitable bandgap, a full range of sunlight utilization, sustainability, cost-effectiveness, high efficiency, and chemical and thermal stability [1]. To achieve these requirements, the main obstacles restricting efficient photoactivity, narrow light-response range and a high rate of charge carrier recombination, should be exceeded. Combining a semiconductor with a low valence band and a semiconductor with a high conduction band and adjusting a bandgap leads to the formation of heterojunction with improved charge separation, appropriate oxidation and reduction ability, and enhanced visible-light harvesting [2].

In our research, various binary heterojunction systems based on the wide-bandgap ($TiO_2$) and narrow-bandgap (g-$C_3N_4$, CuO, and $Co_2O_3$) photocatalysts were studied, with a thorough analysis of light harvesting, active species, and transport pathway of charge carriers, combined with the kinetics of the organic pollutants photodegradation.

**Experimental/methodology.** The morphological, optical, textural, and electrochemical properties of various photocatalysts were analyzed. The photocatalytic performance of the synthesized catalysts was tested in single and simultaneous systems using different organic pollutants.

**Results and discussion.** The synthesized photocatalysts displayed good adsorption capacity and enhanced visible-light photocatalytic performance in regard with neat photocatalyst. Formation of heterojunction between photocatalyst constituents brought to charge carriers transport pathway improvement and enhanced light harvesting. A radical scavenger study revealed the mechanism of interfacial interactions between photocatalyst constituents in single and multiple pollutant systems under solar and visible light irradiation, further indicating the type of heterojunction system (type II heterojunction or direct Z scheme). The type of heterojunction was found to be strongly influenced by the selection of combining photocatalyst constituents and their independent properties.

**Introduction**: Since the industrial revolution fossil fuels have driven economic growth and now**,** approximately 85% of global energy generation comes from combustion of coal, oil, or natural gas [1]. However, temperature increases due to rising atmospheric $CO_2$ concentrations arising from their use are projected to have many negative impacts, and therefore scientists are looking for methods to remove excess $CO_2$. One method is the artificial photosynthesis (AP) reaction. Reacting $CO_2$ with $H_2O$ to form CO or hydrocarbons using a sustainable energy source has become hugely desirable. The success of this process would contribute to the goal of creating a circular carbon economy and would ameliorate effects of fossil fuel use. Certain metals or conducting metal oxides can interact with UV or visible photons to give rise to a surface plasmon resonance, the oscillation of free electrons on the surface of a metal or metallic particle. These plasmons can decay *via* the generation of catalytically useful high energy "hot" electrons. Plasmonic nanostructures can act as co-catalysts with semiconductors, speeding up the transfer of excited electrons to acceptor molecules (either directly transferring "hot" electrons to an acceptor, or first injecting the electron into the CB of the semiconductor) and supressing exciton recombination, thereby increasing catalytic efficiency [2]. $RuO_2$, a plasmonic nanostructure, coupled with $TiO_2$, a UV-absorbing semiconductor, has shown to be active in the AP reaction, but neither component alone possessed the ability to both reduce $CO_2$ and oxidise $H_2O$ under visible light irradiation [3]. In this study particles of $RuO_2$ were deposited on the surface of GaP (a $CO_2$ reducing catalyst) and $Fe_2O_3$ (a $H_2O$ oxidising catalyst). The effect of the band edge positions of the semiconductors when coupled with $RuO_2$ in the AP reaction will be examined and used to help determine a mechanism of reaction.

**Experimental**: $RuO_2$, GaP, $Fe_2O_3$, and composites were prepared using hydrothermal syntheses. These were then characterised using XRD, FTIR, UV-Vis DRS, and $CO_2$-TPD. The presentation will also cover the reactivity of the materials in the AP reaction under batch conditions.

**Results:**

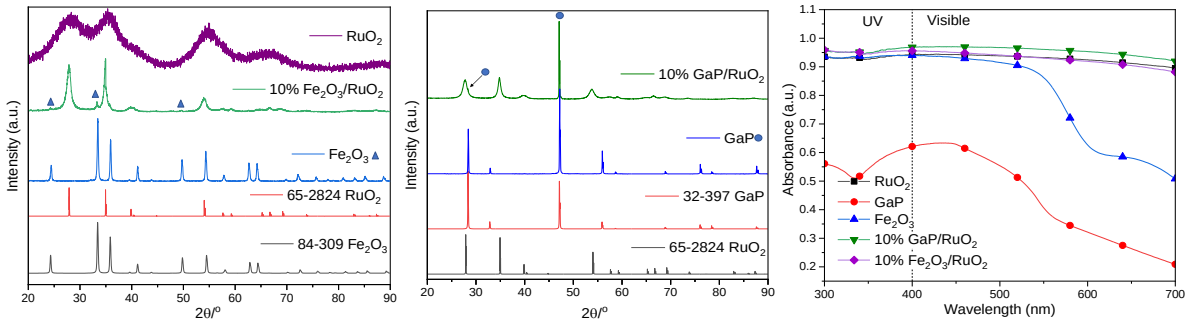

**Fig. 1: XRD profiles (left and centre), and UV-Vis DRS spectra (right) of all prepared materials.**

XRD shows GaP and $Fe_2O_3$ are present in the composites, providing a possibility for heterojunction formation at the relevant interfaces. As $RuO_2$ is a conductor, high absorbance values are observed across the UV-Vis spectrum. The composites' spectra show similar absorbance but also evidence of bandgaps in GaP and $Fe_2O_3$.

# 2D-3D $Mo_{1.33}C$-$TiO_2$ composites for photocatalytic hydrogen production

M. Nair,[1] A. C. Iacoban,[1] A. Kuncser,[1] M. Florea,[1] F. Neațu,[1] A. Mininni,[2] H. Badr,[2] M. W. Barsoum,[2] Ş. Neațu[1*]

[1]*National Institute of Materials Physics, Magurele, Romania*
[2]*Department of Material Science and Engineering, Drexel University, Philadelphia, PA, USA*
[*]*stefan.neatu@infim.ro*

**Introduction.** Humanity is facing one of the largest energy crises and environmental pollution problems in history. It is commonly acknowledged that the usage of fossil fuels has caused the planet's temperature to rise in recent years, and the future seems bleak [1]. Photocatalysis, which converts solar energy into clean energy such as hydrogen, is one of the most effective approaches to overcome these challenges [2]. As photocatalysts, only a few semiconductors have been developed so far and no semiconductor possesses all of the qualities required for successful photocatalyst (visible light absorption, photostability, low cost, and abundance), hence many methods for improving semiconductor photocatalyst efficiency have been developed [3]. The coupling of a suitable and powerful photon absorber (the semiconductor photocatalyst) with a material with high metallic conductivity (such as *i*-MXene) to perform the reaction at high conversions is thought to be an effective way of developing robust, safe, cost-effective, and efficient photocatalytic systems for water splitting [4]. Finding the right combination is difficult, but in this research line, the current study aims to develop *i*-MXene-based composites for photocatalytic hydrogen production.
**Experimental/methodology.** Several $Mo_{1.33}C/TiO_2$ composite materials were effectively produced in this study using an *in situ* solvothermal technique. The $Mo_{2/3}Y_{1/3}AlC$ *i*-MAX phase was used as a starting material for a chemical transformation that resulted in $Mo_{1.33}C$ *i*-MXene. This synthesis was carried out using numerous overextraction techniques with different synthesis parameters (reaction duration, HF solution concentration, etc.). This $Mo_{1.33}C$ *i*-MXene was then combined with $TiO_2$ nanoparticles to produce a composite material that exhibited improved photocatalytic activity. The phocatalytic studies were carried out in a cylindrical quartz reactor containing either MilliQ water (with no hole scavenger) or a water-methanol mixture (volumetric ratio of 4:1). A heatless illumination Xe light lamp system (MAX-303 from Asahi Spectra equipped with a UV-Vis (300-600 nm) mirror module) was employed as an irradiation source. In order to characterize these composites both before and after the reaction, a number of different techniques, including XRD, TEM, XPS, UV-Vis and Raman spectroscopies, were utilized in this study.
**Results and discussion.** The hydrogen production rates and the obtained apparent quantum yields (AQY) calculated at 365 nm are shown in Table 1. As seen, under specific experimental conditions, the best photocatalyst generates a hydrogen production rate of more than 1.2 mmols/gh.

**Table 1** The obtained hydrogen production rates under UV-Vis light irradiation

| Photocatalysts | AQY (%) | $H_2$ production rate (µmol/gh) |
|---|---|---|
| 0% $Mo_{1.33}C/TiO_2$ | 4.20 | 772 |
| 1% $Mo_{1.33}C/TiO_2$ | 4.88 | 897 |
| 3%-$M_{1.33}C/TiO_2$ | 5.56 | 1022 |
| 5% $Mo_{1.33}C/TiO_2$ | 6.81 | 1252 |

The obtained values are among the highest for *i*-MXene-based photocatalysts. The discoveries give up new possibilities for the creation of highly active noble metal-free materials for photocatalytic $H_2$ production.

**Keywords:** Carbon dots, Zinc Oxide, Nanoparticle, Photocatalyst, RR141 Dye

**Introduction**. Reactive Red 141 are the commercial names of the dye. Its empirical formula is $C_{52}H_{22}Na_8O_{26}S_8Cl_2N_{14}$ and is composed of two monochlorotriazine reactive groups. Reactive Red 141 (RR141) is a sulfonated, bright red color diazo reactive textile dye and is widely used for the dyeing processes in the textile industry. Sulfonated azo dyes have a negative aesthetic effect on the wastewater that is highly colored even at a low concentration of dye. The removal of the dye in natural water is urgently needed.

**Experimental / methodology :** Carbon dots (CDs) has been synthesis by hydrothermal mehod using the temperature of 180 °C for 4 hours from Coconut water. After that the CDs was mixed with ZnO for preparation of the composite using two different methods namly the hydrothermal and the precipitation methods. The sample was dried in the oven to become powder. The CDs/ZnO has been applied for removal of RR141 dye solution in wastewater.

**Result and Discussion** : The UV-light-driven photodegradation of reactive red 141 (RR141) by using the prpared photocatalyst was investigated.The lowering of RR141 concentration in the presence of with CDs/ZnO was found. The CDs/ZnO composite obtained from hydrothermal method showed higher performance than those obatied from bare CDs and CDs/ZnO composite obtained from precipiation method. The highest efficincy of about 90% was achieved with the greatest rate constant of about 0.020 $min^{-1}$. The degradation of other pollutants is under investigation. The recycling ability of the sample will be determined.

**Introduction.**

Most people spend between 70 to 90% of their time indoors. Additionally, many pollutants found in outdoor air are found in indoor air but at higher concentrations than outdoors. Indoor air quality problems of greatest concern at present are: passive exposure to tobacco smoke, formaldehyde exposure, nitrogen dioxide from gas-fuel cooking stoves, radon daughter exposure, and the diverse health problems encountered by workers in newer sealed office buildings [1]. Unlike other air purifiers which mostly trap particulate matter, photocatalysis is a promising new technology that can convert these indoor air pollutants into non-harmful products. For this purpose, an efficient composite photocatalyst, nitrogen (N) doped $TiO_2$/graphene oxide (GO) has been synthesized. $TiO_2$ nanoparticles are generally believed to be the most promising photocatalysts because of their non-toxicity, cheapness, long-term stability and high reactivity. Generally, there are three main approaches to improving the photocatalytic activity of $TiO_2$: band-gap tuning, minimizing charge carrier recombination, and absorbance of reactants on the surface of photocatalysts thereby promoting the forward reaction [2]. Nitrogen (N) doping shifts the valence band edge of $TiO_2$ and the combination of GO with $TiO_2$ serves the other two approaches of minimizing charge carrier recombination and absorbance of reactants. The increase in visible light activity was proposed by the creation of a sub-band level N2p orbital instead of the O2p orbital by nitrogen doping, thereby shifting the valence band edge. It was experimentally confirmed that the material has visible light activity. Graphene oxide has a 2D geometry that allows for excellent electron-transport properties and has a photoelectron reservoir due to its high conductivity. The photo-generated electrons from a $TiO_2$/graphene oxide interface can be more successfully accepted, stored and utilized in a redox reaction. The decreased electron–hole recombination and extended lifetime of electrons resulting from their separation are proposed as the key factor for improving the photocatalytic performance of $TiO_2$/graphene nanocomposites.

**Experimental/methodology.**

The commercial nanomaterials (titanium P25 and graphene oxide) were functionalized with different nitrogen and boron precursors. The nanocomposites were prepared using two approaches: (1) simple mixing and (a) with hydrazine hydrate. The prepared materials were characterized by complementary techniques. In order to do a screening of the catalytic activity of the materials it was performed photocatalytic experiments in water using a standard organic dye. The materials in powder form were immobilized in the support by different techniques: Wet infiltration, Dip coating and Spray coating.

**Results and discussion.** The material that present the best photocatalytic activity was the composite material (N-titanium dioxide/GO). A coating technique has been developed, having good photocatalytic activity and adhering well to the surface of the substrate. Even after 4 days of continuous operation, no material was removed from the support, it shows the robustness of the coating.

**Abstract:**
In this study, the photocatalytic activity, reaction kinetics, thermodynamics and modeling of commercial $TiO_2$-P25 and ZnO nanoparticles (NPs) for ibuprofen (IBU) photodegradation were examined using a batch reactor under ultraviolet (UV) irradiation. The reaction kinetics was modeled using first and second order rate equations, and the reaction mechanisms were identified. The photodegradation performance of both $TiO_2$ and ZnO NPs was further studied under varying reaction conditions including temperature (as shown in Figure 1), catalyst bulk density, and initial IBU concentration. The chemical and physical-diffusive aspects of the reaction were analyzed and the goodness of the kinetic models was evaluated. The results showed that the reaction rate for $TiO_2$ was of first order, while ZnO NPs followed second order kinetics with respect to IBU. The photodegradation mechanisms for $TiO_2$ and ZnO NPs were determined to be Langmuir-Hinshelwood and Eley-Rideal type, respectively. The thermodynamic parameters, including Gibbs free energy (ΔG°), enthalpy (ΔH°) and entropy (ΔS°) were assessed, indicating efficient photodegradation performance by these NPs. The reaction kinetics, mechanism, and model consistency with parameters combined with experimental data validation will be elaborated and discussed further during the presentation.

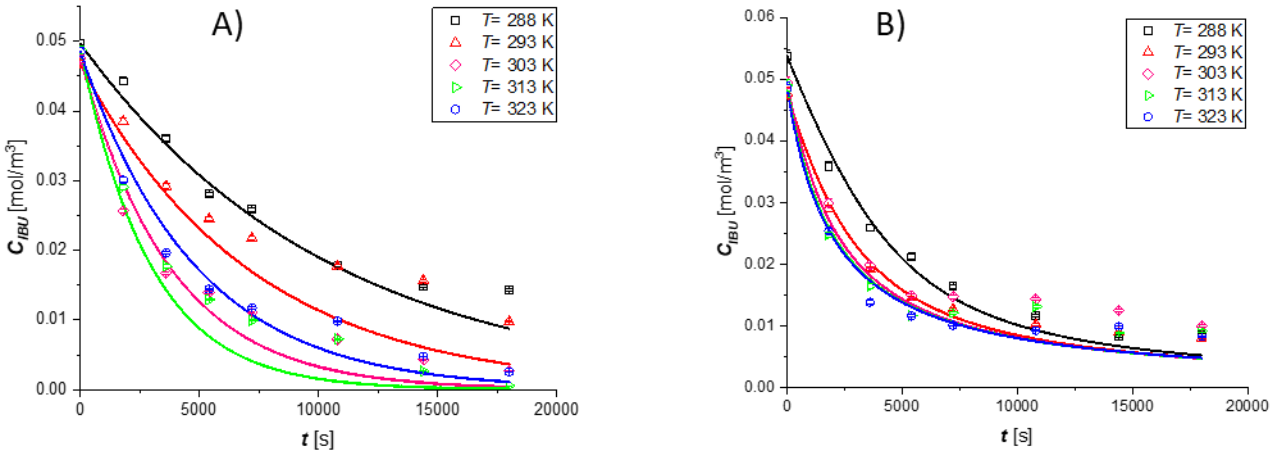

**Figure 1. Experimental results of the kinetic tests conducted at different temperatures. $C_{IBU,0}$ = 4·10$^{-2}$ mol/m$^3$, $\rho_B$ = 0.5 kg/m$^3$, $Q_{air}$ = 0.94·10$^{-6}$ m$^3$/s and $v$ = 750 rpm. Trends of the concentration profiles *vs* the reaction time for A) $TiO_2$ and B) ZnO.**

# Impact of the strength of Pd-perovskite interaction in Natural Gas Vehicle three-way catalysts: A kinetic approach

Y. Zheng, F. Dhainaut,. P. Granger*

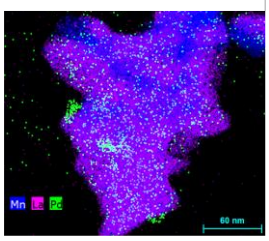
**Introduction.**



Natural gas fuelled engines are an alternative to gasoline and diesel engines less pollutant with emission particulate almost nil and lower greenhouse gas and $NO_x$ emissions. However, the complete removal of residual traces of methane, acting as greenhouse gas, remains an important challenge. The complete removal of $CH_4$ induces the installation of palladium-based Three-Way-Catalyst (TWC) running at higher temperature to activate methane. Highly loaded palladium catalysts can be developed to insure an acceptable conversion at moderate temperature and slow down detrimental effects of deactivation. An alternative consists in optimizing the nature of interaction between Pd and support exhibiting oxygen storage properties in order to create synergistic effects on the catalyst activity. Different methods, *e.g.* sequential vs. on pot methods, were implemented for the introduction of palladium onto the surface of $LaMnO_3$ perovskite support or inside the perovskite lattice respectively. The kinetics of methane combustion has been investigated on freshly-prepared samples and on aged samples at 750°C in wet conditions in order to understand the implication of the Pd-support interface on the kinetics, to evaluate the impact of subsequent deterioration induced by thermal ageing and/or water accumulation at the surface.

**Results and discussion.**

One pot method

Sequential method

TEM analysis revealed in all cases well-dispersed cationic $Pd^{n+}$ species predominantly stabilized in octahedral coordination of $LaMnO_3$ lattice according to a on pot method. In contrast, successive wet impregnation of the perovskite led to significant aggregation of palladium particles (look at the figures opposite). Aging in the presence of 10 vol.% $H_2O$ in air induced partial exsolution of palladium on the one pot sample which lead to the creation of strong interaction at the surface of $LaMnO_3$ avoiding extensive particle sintering. In contrast, PdO aggregates originally dispersed through impregnation weakly interact with the support and was found more sensitive to thermal sintering.

Kinetic measurements in the absence of water showed that the Pd-support interaction will govern the kinetics and can be related to a dual site mechanism which combines Pd and reactive oxygen species from the support. Such reaction mechanism has been compared especially on aged samples to a single site reaction mechanism involving only palladium. Based on this it was foung that significant particle Pd sintering on impregnation detriorates the interface and leads to a partial restoration of the single site mechanism whereas the dual site mechanism runs on the aged one pot sample.

Interestingly, further comparisons of both mechanisms when the reaction is performed in wet conditions show the suppression of the dual site mechanism irrespective of the method used for palladium deposition. Such changes have been explained by water hydrolysis of surface reactive oxygen species stabilizing into unreactive OH species. As a consequence, the Pd-support is deteriorated. A quantitative analysis based on the estimation of thermodynamic and kinetic parameter allow more extensive discussion especially on the adsorptive properties of Pd sites also perturbated.

# Palladium doped reduced graphene oxide-$TiO_2$ composites for enhanced visible-LED photocatalytic erythromycin degradation

**Introduction.** Heterogenous photocatalysis has demonstrated to be a promising option in water treatment, while nanotechnology opens a gate for the development of high-efficient and stable photocatalysts. Different carbon materials have been used to prepare $TiO_2$-based photocatalysts with enhanced catalytic properties, as well as noble metals (e.g., Ag, Au, Pt, Pd) acted as electron trapping sites promoting interfacial charge transfer processes in the resulting composites. In particular, the use of composites based on nanostructured $TiO_2$ and graphene oxide (GO) or reduced graphene oxide (rGO) is an interesting topic of research in photocatalysis, because an enhancement of the properties of the materials is expected to occur, due to a synergic interaction between both phases at the nanoscale [1,2] as well as to provide anchoring sites for noble-metal particles.

**Experimental/methodology.** Pd-doped rGO-$TiO_2$ composites were prepared by the sol-gel process and subsequently different post-treatments, such as thermal treatment in $N_2$ atmosphere and hydrothermal treatment were also carried out. The effect of the synthesis conditions on the properties of each material was studied and its photocatalytic activity was evaluated for the degradation of 10 mg $L^{-1}$ erythromycin A (Ery-A) solution under two different irradiation sources: simulated solarbox (SB) and a Solar-LED. Different aliquots were withdrawn, filtered and analyzed by UPLC-MS to determine the concentration of pollutant removed.

**Results and discussion.** The rGO-$TiO_2$ composites presented a good dispersion of the palladium on the material surface, even so a very small amount of metal (0.1 wt.%) was deposited. Pd nanoparticles were ranging 1-2 nm and a larger dispersion was achieved when rGO-$TiO_2$ was used as support in comparison with only $TiO_2$. XRD patterns exhibited the typical peaks associated to the anatase phase for all composites, but no signals were detected for Pd, which could be explained to their very small Pd-particle size. The materials obtained presented small values of BET surface area but considerable mesoporous volumes, which is very important for water treatment applications. Furthermore, the Pd-rGO-$TiO_2$ composites presented a narrowing band gap compared with the reference materials without Pd or rGO. The activity of the photocatalyst was determined by the different pre-treatment carried out and the type of irradiation source used. Thus, composites prepared by sol-gel method followed by a hydrothermal treatment achieved the total Ery-A degradation for 120 min under solar irradiation, while that prepared with thermal treatment achieved a Ery-A degradation of around 80 %. The activity of both materials was lower when a LED-visible was used, only a 50% being achieved at 300 min for Pd-rGO-$TiO_2$.

**Keywords:** photocatalysis, $N_2$ fixation, plasmonics, perovskites

**Introduction**

Amonia is proven to be one f the most synthetised chemicals in the world, having application in different fields, from pharmaceutical to agricolture; however, high temperatures and pressures (400 – 500 °C and 150 atm) make the Haber Bosch process rather energy – intensive and responsible for 3% of $CO_2$ global emissions [1]. Thus, finding new ways of producing ammonia in milder conditions is crucial to ensure a sustainable future. Plasmonic photocatalysis has proven to be a promising research field, as it benefits from localized surface plasmon resonance (LSPR); indeed, the collective movement of electrons can cause effective charge separation and accumulation, thus enhancing the catalytic performances. For this reason, catalyst design is crucial to ensure good light absorption, charge separation and $N_2$ activation [2]; perovskite – based materials are promising candidates for nitrogen fixation reaction, as for their tunability of structural, electronic, and functional properties [3]. Herein, we report $La_{0.9}Fe_{0.9}Cu_{0.1}O_3$ and $La_{0.9}Fe_{0.9}Ni_{0.1}O_3$ as possible systems for the plasmonic – assisted $NH_3$ synthesis using a commercial 100 W LED.

**Experimental/methodology**

$La_{0.9}Fe_{0.9}O_3$ and $La_{0.9}Fe_{0.9}Cu_{0.1}O_3$ and $La_{0.9}Fe_{0.9}Ni_{0.1}O_3$ were synthetized through a sol gel method, using metal nitrates as precursors and citric acid as complexing agent. Surface decoration was achieved through an exsolution process, treating Cu- and Ni-doped catalysts in 5%$H_2$/Ar at various temperatures and times. Structural analysis was achieved by means of XRD; morphological properties were probed using SEM and energy – dispersed X-ray spectrometry (EDX), while surface composition was observed through XPS. Specific surface area was evaluated using BET analysis; temperature programmed reduction (TPR) and desorption (TPD) were used to gain information about the active species and the adsorption properties of the catalysts. Catalytic tests were performed exposing 50 mg of catalyst to a 100 $cm^3$/min flux containing 2% $N_2$ and 6% $H_2$; a cost-effective, scalable approach was undertaken, using commercial 100 W LED lamp for 1 h to illuminate the system.

**Results and discussion**

Structural analysis pointed out that only the perovskitic phase was formed during the synthetic process, with no evidence of Fe impurities or Cu and Ni oxides; after the exsolution treatment, reflections of metallic Cu and Ni were observed in $La_{0.9}Fe_{0.9}Cu_{0.1}O_3$ and $La_{0.9}Fe_{0.9}Ni_{0.1}O_3$, respectively. A ≈10 $m^2$/g surface area was obtained for all the samples, with slight variations due to the insertion of dopants in the structure. XPS analysis confirmed the surface enrichment of Cu and Ni after exsolution; nanoparticles were observed during SEM measurements. Promising results were obtained in the catalytic reduction of nitrogen with hydrogen, achieving a good conversion at RT. Different conversions were observed at different temperatures, suggesting that more than one reaction mechanism may take place, depending on the electron excitation pathway. LSPR contribution to the catalytic activation of nitrogen was evaluated combining UV-VIS spectroscopy and the catalytic characterization.

# $H_2$ Production from the Photocatalytic Reforming of Ethylene Glycol

L. Roebuck[1*], H. Daly[1], C. Hardacre[1]

[1]*University of Manchester, Manchester, United Kingdom*
[*]*luke.roebuck@postgrad.manchester.ac.uk*

**Keywords:** Photocatalysis, Hydrogen, Ethylene Glycol, ATR-FTIR

**Introduction.**

Photocatalytic reforming (Photoreforming) for the production of $H_2$ has become an area of much interest in recent years due to it's potential for the production of clean hydrogen from either biomass or waste/pollutant sources by solar irradiation [1]. Photoreforming makes use of a photocatalyst for the conversion of an organic substrate and water into $H_2$ and $CO_2$. Organic substrates studied include lignocellulosic biomass, plastics, sugars, and alcohols among others. The reaction mechanisms however are complex and not well understood. In this work the photoreforming of ethylene glycol and propylene glycol are investigated. These molecules are interesting in themselves as they are present as pollutants and as waste materials in some industrial processes. However, as relatively simple molecules, their study also serves as a tool to better understand the fundamental reaction mechanisms in photoreforming for more complex substrates.

**Experimental/methodology.**

$Pt/TiO_2$ catalysts were prepared using the incipient wetness impregnation method. Photoreforming experiments were performed in an 80ml quartz reactor irradiated using a UV(λ=385nm) LED array. The reactions were performed under a constant flow of Ar gas which was also used to carry gaseous products for analysis by gas chromatography. Liquid phase products were analyzed post-reaction using HPLC. The adsorption of reactants and their surface reactions were investigated by in-situ using ATR-FTIR spectroscopy.

**Results and discussion.**

It was found that the $TiO_2$ polymorph used in $Pt/TiO_2$ photocatalysts has a significant effect on the photoreforming of ethylene glycol under UV irradiation. The anatase polymorph was found to produce more hydrogen than either rutile or mixed anatase:rutile phases. This is in contrast to much of the photocatalytic literature where mixed phase titania is preferred due to its enhanced separation of photogenerated charge carriers [2]. This effect was explained by a change in the reaction mechanism when even only small quantities of rutile phase is present in the photocatalyst. In Pt/anatase catalysts the major oxidation mechanism proceeds initially via the abstraction of α-hydrogens by radical species. On the other hand, in rutile or mixed phase catalysts, dissociative adsorption of the hydroxyl groups to form alkoxy intermediates is favoured. This mechanism leads to the formation of formaldehyde that accumulates in the liquid phase and prevents full oxidation to $CO_2$. Further work on propane-1,2-diol and propande-1,3-diol is ongoing to further probe this effect. Furthermore, it was found that surface-bound dicarboxylic acids such as terephthalic acid further enhances the hydrogen production and substrate conversion. Preliminary investigation indicates that water splitting is promoted by the free acid group of the terephthalic acid which aids proton transfer.

# Changes in photocatalytic behavior of g-$C_3N_4$/$TiO_2$ composites with varying the morphology of $TiO_2$

M. Roškarič[1*], G. Žerjav[1], J. Zavašnik[2], A. Pintar[1]

[1]*National Institute of Chemistry, Ljubljana, Slovenia*

**Keywords:** g-$C_3N_4$/$TiO_2$ photocatalysts, $TiO_2$ morphologies, heterogeneous photocatalysis, bisphenol A degradation, visible-light irradiation

**Introduction.** Heterogeneous photocatalysis is a hot topic in the field of waste-water remediation, because light of an appropriate energy can be utilized for the oxidative mineralization of water-dissolved organic pollutants [1]. The most commonly used photocatalyst, titanium dioxide ($TiO_2$), has two major drawbacks: (i) a wide band gap value ($E_{BG}$=3.0-3.2 eV), and (ii) high rate of the electron-hole pair recombination [2]. These drawbacks of $TiO_2$ can be overcome by using different $TiO_2$ polymorphs [2], doping $TiO_2$ with metals [3], depositing noble metals on $TiO_2$ surface [3], or combining $TiO_2$ with low band gap organic semiconductors like graphitic carbon nitride (g-$C_3N_4$, $E_{BG}$=2.6-2.7 eV, $S_{BET}$=16 $m^2$/g) [1], etc. Therefore, the aim of this study was to synthesize g-$C_3N_4$/$TiO_2$ composites using different $TiO_2$ morphologies and to study the influence of the selected $TiO_2$ morphology onto the electronic, optical and photocatalytic properties of the synthesized g-$C_3N_4$/$TiO_2$ composites.

**Experimental/methodology.** The synthesis of g-$C_3N_4$ from dicyandiamide was carried out as follows: end temperature 550°C, 300 °C/h, and 4 hours in air in a muffle furnace. Commercially available $TiO_2$ nanoparticles (DT-51, CristalACTiV™) represent the spherical-like $TiO_2$ (TNS) and were further used for the synthesis of amorphous $TiO_2$ nanorods (aTNR) by the synthesis procedure described in [2]. The crystalline $TiO_2$ nanorods (TNR) were obtained by the annealing of aTNR at 500 °C (120 °C/h) for 2 hours in air. For the formation of g-$C_3N_4$/$TiO_2$ composites, $TiO_2$ particles of different morphologies and g-$C_3N_4$ in a weight ratio 1:1 were ground in an agate mortar. The catalysts were denoted as g-$C_3N_4$/TNS ($S_{BET}$=57 $m^2$/g), g-$C_3N_4$/aTNR ($S_{BET}$=164 $m^2$/g) and g-$C_3N_4$/TNR ($S_{BET}$=57 $m^2$/g).

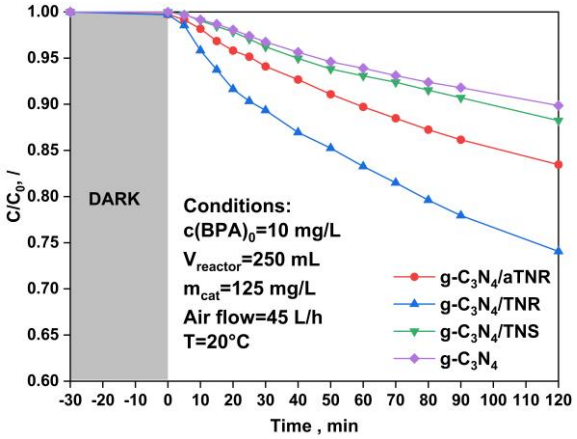

**Figure 1.** Photocatalytic degradation of aqueous BPA solution conducted in the presence of investigated catalysts under visible-light illumination.

**Results and discussion.** Combining $TiO_2$ and g-$C_3N_4$ significantly improved the initial low specific surface area of g-$C_3N_4$ and prolonged the "life-time" of charge carriers due to the injection of photogenerated electron from conduction band (CB) of g-$C_3N_4$ to CB of $TiO_2$. Additionally, the presence of g-$C_3N_4$ enables the utilization of visible light by the g-$C_3N_4$/$TiO_2$ composites for the charge carrier generation. From the results of photocatalytic oxidation runs of aqueous solution of bisphenol A (BPA) illustrated in Fig. 1, we can conclude that the g-$C_3N_4$/TNR composite exhibited the highest visible-light triggered photocatalytic activity toward the BPA degradation, which is due to the optimal balance between the specific surface area, the crystallinity of the selected $TiO_2$ morphology and optimal formation of the g-$C_3N_4$/$TiO_2$ heterojunction.

# Sono-photo hybrid catalytic process for the degradation of Tetracycline

S. Sajjadi and R. Klement

*Dept. of Functional Materials, FunGlass, Alexander Dubček University of Trenčín, Študentská 2, 911 50 Trenčín, Slovakia*

**Keywords:** Core-shell catalyst; Advanced oxidation processes; Bismuth tungstate; Indium sulfide; Tetracycline.

**Introduction.** Recently, combinations of various advanced oxidation processes (AOPs) have been applied to treat detrimental compounds from wastewater. Sonophotocatalysis can manifest the high degradation of a broad domain of contaminants [1]. Bismuth tungstate ($Bi_2WO_6$) is an n-type, narrow band gap (2.8–3.0 eV) semiconductor and has been considered a hopeful catalyst. Despite its high photocatalytic activity, pristine $Bi_2WO_6$ is not ideal due to photo-induced charge rapid recombination [2]. The indium sulfide ($In_2S_3$) semiconductor possesses a narrow band gap (1.8–2.3 eV), excellent visible light response, and a negative conduction band (CB) edge. However, its relatively slow carrier separation and migration kinetics make its catalytic performance unsatisfactory [3]. Additionally, magnetic supports could overcome the limitation of separation from the liquid phase, thus the catalyst could be effectively recycled by applying an external magnetic field [4]. Hence, in this study, the Z-scheme $In_2S_3/Bi_2WO_6/Fe_3O_4$ magnetic core-shell structure catalyst was prepared for the sonophotocatalytic degradation of tetracycline (TC).

**Experimental.** $In_2S_3$ microspheres, $Bi_2WO_6$ nanosheets, and $In_2S_3/Bi_2WO_6$ core-shell structures were prepared by the hydrothermal method. $In_2S_3/Bi_2WO_6$ core-shell structures were decorated with $Fe_3O_4$ by the co-precipitation method to achieve an $In_2S_3/Bi_2WO_6/Fe_3O_4$ magnetic core-shell catalyst. The prepared catalyst was characterized by SEM, EDX, DRS, XPS, and BET. In addition, the catalytic activity of the $In_2S_3/Bi_2WO_6/Fe_3O_4$ catalyst was investigated by sonophotocatalytic degradation of TC.

**Results and discussion.** The effects of $In_2S_3/Bi_2WO_6/Fe_3O_4$ and its components on the degradation efficiency of TC through sonophotocatalytic processes are shown in Figure 1. The 0.5 g/L of $In_2S_3/Bi_2WO_6/Fe_3O_4$ in solution with pH=6.5 and TC (10 mg/L) showed a high degradation efficiency of TC (94.7% within 60 min), under visible LED light (50 W) and ultrasound irradiation (140 W). This high catalytic activity of the $In_2S_3/Bi_2WO_6/Fe_3O_4$ core-shell catalyst was mainly attributed to the synergistic effects of the formed interfaces between the shell and core, which generate an electric field to facilitate charge transfer. Additionally, direct Z-scheme heterojunction inhibits $e^-$ and $h^+$ charge recombination and expands light absorption in the visible range. Furthermore, the results expressed the presence of synergy between the combined systems (sonocatalysis and photocatalysis). $In_2S_3/Bi_2WO_6/Fe_3O_4$ showed good reusability and stability.

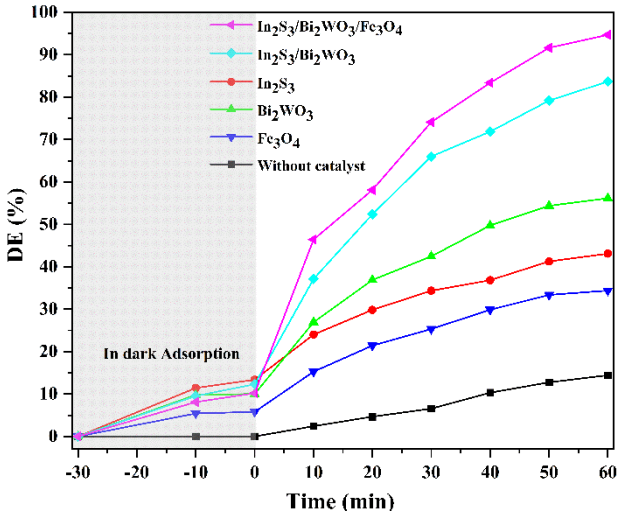

**Figure 1. The degradation of TC in the presence of $In_2S_3/Bi_2WO_6/Fe_3O_4$ and its components**

**Acknowledgment**

This study was carried out in the framework of the project FunGlass that has received funding from the European Union´s Horizon 2020 research and innovation programme under grant agreement No 739566.

**Keywords:** Bismuth/ molybdenum based photocatalyst, NMP, band gap, sulfate radical, PMS

**Introduction.** N-Methyl-2-pyrrolidone (NMP) is a cyclic amide that poses risks to human health, including impacts on the reproductive, liver, kidney, immunological, developmental, and central neurological systems (Li et al., 2018; Web reference-1). Therefore it is imperative to effectively remove the NMP from the water. Advanced oxidation processes (AOPs) offer a promising solution for the degradation of NMP. By forming heterojunction structures with semiconductors or metals, photocatalyst's activity can be significantly improved through increased charge separation, charge transfer, and lifespan of charge carriers (Hojamberdiev et al., 2013). This study investigates the use of bismuth (Bi) and molybdenum (Mo) based photocatalysts with peroxymonosulfate (PMS) for the efficient degradation of NMP.

**Experimental/methodology.** A modified hydrothermal technique was used to prepare the heterojunction $Bi_2MoO_6$ photocatalyst with varying bismuth amounts. The synthesized photocatalysts were characterized for structural and spectral characteristics using various techniques such as XRD, PL, SEM-EDX, UV-DRS and FT-IR. The NMP was degraded in a specially built photoreactor chamber during The photocatalytic studies. The NMP had an initial concentration of 10 mg/L, while the catalyst had a 15 mg/L concentration. Irradiation was performed with a set of three lamps (Philips) with an emission wavelength of 365 nm, arranged radially around the reactor. PMS was added to the reaction mixture with varying concentrations. A 100 µL sample was drawn using a syringe filter into an HPLC vial at a specified fluence interval, and 1mL methanol (HPLC grade) was added as a quencher. Initially, the experiments were conducted with only NMP and photocatalysts in the dark to observe the effect of UV irradiation.

**Results and discussion.** Well crystalline structure of the photocatalyst was observed through XRD. UV-DRS analysis showed that the synthesized photocatalyst was activated in UV-A spectral range. Negligible NMP degradation was observed under UV irradiation. With the addition of Bi2MoO6 photocatalyst under UV-irradiation, the degradation was improved to 45%. The addition of PMS in this reaction mixture significantly enhanced the NMP degradation to more than 90%. However, as the concentration of NMP was increased, the degradation was found to be reduced. This resulted because the radicals generated during the reaction was quenched by the intermediates and by-products formed during the degradation process. The various components of the water matrix had different effects on the degradation of NMP; some components improved the degradation, while others reduced the degradation of NMP.

**Keywords:** titanium dioxide, heterogeneous photocatalysis, gold nanoparticles, plasmonic metals

**Introduction.** The focus of research work in the field of heterogeneous photocatalyis for waste water treatment lies in the utilization of the semiconducting titanium dioxide ($TiO_2$) as the photocatalyst. The results show that $TiO_2$ is one of the best and versatile materials for photocatalysis, but it has a drawback of a wide band gap (3.2 eV). This can be overcome, for instance, by depositing plasmonic metal nanoparticles (e.g., Au) onto the surface of $TiO_2$, which in turn would enable harvesting of visible light and near-infrared radiation of the solar-light spectrum. $Au/TiO_2$ catalysts exhibit a strong visible-light absorption band at 500-600 nm due to the localized surface plasmon resonance (LSPR) effect exerted by Au particles [1,2]. Therefore, the aim of the present work was to synthesize $Au/TiO_2$ catalysts with different Au loadings and to investigate in detail their optical, electronic and morphological properties as well as to link them with their efficiency in generation of different reactive oxygen species (ROS).

**Experimental/methodology.** In the presented work, we used $TiO_2$ in the form of nanorods (TNR) prepared by hydrothermal synthesis procedure [1], onto which different weight loadings of Au nanoparticles (0.1, 0.4, 0.7 and 1.0 wt.%) were deposited by using the wet impregnation technique. The mixture was stirred for 21 hours, then dried at 80 °C and the obtained materials were calcined at 300 °C [3]. To evaluate the photocatalytic activity of investigated $Au/TiO_2$ catalysts, we performed a series of experiments to determine the oxidation pathway of the water-dissolved model organic pollutant bisphenol A (BPA). We further performed tests with 2,2-diphenyl-1-picrylhydrazyl (DPPH), 2,2´-azino-bis(3-ethylbenzothiazoline-6-sulfonic acid cation ($ABTS^{\bullet+}$) and coumarin (COUM), acting as radical scavengers, to measure the visible-light triggered generation rates of different ROS (i.e. superoxide anion and $OH^{\bullet}$ radicals).

**Results and discussion.** The results of SEM-EDX analysis show that the actual Au loading is the same as the nominal one in all investigated $Au/TiO_2$ catalysts. $N_2$ physisorption analysis revealed that the specific surface area, pore volume and pore diameter did not change after Au impregnation on TNR, which means that Au ensembles did not block the pores of TNR. The UV-Vis DR spectra of all prepared $Au/TiO_2$ catalysts show an absorption of light in the UV-light region (below 400 nm) due to the presence of $TiO_2$, and an absorption peak (hump) at around 550 nm due to the LSPR effect of Au clusters. XPS analysis shows that in all $Au/TiO_2$ samples gold was present in the metallic state. The lowest solid-state photoluminescene (PL) intensity, which also means the lowest recombination rate of charge carriers, was exhibited by the Au-1.0% sample, followed by Au-0.7%, Au-0.4%, and Au-0.1 % solids, respectively. The highest visible-light triggered BPA degradation rate was obtained in the presence of Au-1.0% catalyst, and the lowest one over the Au-0.1% solid. These findings are in very good agreement with the results of solid-state PL measurements. From the results of photocatalytic runs (BPA oxidation and ROS tests), we can conclude that the oxidation pathway of BPA degradation involves superoxide anion and hydroxyl radicals. It was further revealed that the formation of superoxide anion radicals (i.e. priority ROS to oxidize BPA) increases by increasing Au loading and decreasing Au particle size on the TNR support. $OH^{\bullet}$ radicals which were under visible-light illumination of $Au/TiO_2$ plasmonic catalysts produced exclusively via homolytic cleavage of $H_2O_2$ (the latter is produced by liquid-phase reactions involving superoxide anion radicals), play a secondary role in the reaction pathway of BPA oxidation; their formation strongly depends on metal-support interactions and is favoured in the presence of $Au/TiO_2$ solids with larger Au clusters on the TNR surface (i.e. Au-1.0% catalyst).

**Keywords:** $TiO_2$, water splitting, photoreforming, density functional theory.

**Introduction.** In the recent decades photocatalytic water splitting and alcohol photoreforming are frequently used methods for the conversion of sunlight to hydrogen energy due to its sustainability, environmental-safety, effectiveness and simplicity. Titanate based materials are the most studied photocatalysts combining the photo-activity of $TiO_2$ and good ion-exchange ability of layered titanates. Platinum (Pt) doping is considered as an effective approach for lowering the overpotential for hydrogen production and suppressing electron-hole recombination which results in improved photocatalytic activity. Alcohols are commonly used compounds in photoreforming process as hole scavengers which can lead to very selective, value-added oxidation products such as aldehydes, ketones, carboxylic acids, and esters. Photocatalytic reforming of primary and secondary alcohol includes α-H atom abstraction, followed by the formation of aldehydes or ketones, respectively. In contrast to primary and secondary alcohols, photoreforming of tertiary alcohols in the absence of an α-H leads to a C−C-bond cleavage [1,2]. In our research, prepared Pt doped titanate catalysts were studied for photocatalytic hydrogen production using 1-butanol, 2-butanol and tert-butanol. The theoretical calculations were used to further elucidate photoreforming mechanism of investigated alcohols.

**Experimental/methodology.** Pt doped titanate catalysts were synthesized via simple alkaline hydrothermal treatment, incipient wetness impregnation method and temperature programmed reduction. The physico-chemical properties of the prepared catalysts were investigated using various characterization techniques such as X-ray diffraction (XRD), scanning electron microscopy (SEM), $N_2$ physisorption, diffuse reflectance spectroscopy (DRS), temperature programmed desorption (TPD). The activities of the prepared Pt doped titanate catalysts were tested via photocatalytic water splitting/alcohol photoreforming for hydrogen production under simulated solar light irradiation. The theoretical evaluation using density functional theory (DFT) were performed in GPAW[1] with the projector augmented wave method (PAW) as implemented in the plane-wave approach.

**Results and discussion.** Photocatalytic hydrogen production efficiency of Pt doped titanate catalysts was related to highly active anatase crystal phase, preserved nanotubular structure and high specific surface area. The result showed that photocatalytic activity is strongly influenced by alcohol structure with the following order: 2-butanol > 1-butanol > tert-butanol, with obtained maximal hydrogen production rate of 7.5 mmol $g^{-1}$ $h^{-1}$, 5.3 mmol $g^{-1}$ $h^{-1}$ and 2 mmol $g^{-1}$ $h^{-1}$, respectively. Insights from this study showed that hydrogen production performance is a trade-off between adsorption/desorption rate of investigated alcohols and intermediates/products, as well as hole scavenging ability induced by stability of formed alcohol radical. The combination of theoretical calculation and experimental strategy was crucial for understanding the hole charge transport process and enhanced activity for hydrogen production of Pt doped titanate catalysts.

**Keywords:** photocatalyst, ZnO and Ag-ZnO, *Allium* test, chromosomal abnormalities

**Introduction.** Recently**,** photocatalysis is widely used for degradation of pollutants that are not readily degraded by conventional methods [1]. ZnO and Ag-ZnO were fabricated and then used as effective sunlight-active photocatalysts. The ZnO photocatalyst was very efficient in photodegradation on a wide range of antibiotics [2]. In addition, Ag-ZnO showed enhanced photocatalytic degradation of both antibiotics and reactive azo dyes [3]. Despite its effectiveness as a photocatalyst, some toxicities of ZnO were reported in microorganisms, algae, plants, and animals [4]. Additionally, cytotoxicity of Ag-ZnO was also reported for humans [5] because the chemical stabilities of ZnO [6] and Ag-ZnO [7] are high. Therefore, the potential threats of these photocatlysts need to be emphasized.

**Experimental/methodology.** The effects of ZnO and Ag-ZnO concentrations on elongation of onion roots and cell division in onion root tips were investigated. Onion bulbs were allowed to germinate on test tubes containing deionized water for 24 hours. Five maximum root lengths in each bulb were recorded. Then, elongating roots of onion bulbs were treated using solutions of ZnO and Ag-ZnO and deionized water as a control treatment. Four concentrations at 0, 50, 100 and 200 ppm of each photocatalyst were investigated. There were 6 bulbs for each treatment and the experiments were conducted under dim light and dark. Five maximum root lengths for each bulb were measured at an interval of 24 hours for 96 hours. Roots were cut after 96 hours and fixed in Carnoy's fixative solution and then preserved in 70% ethanol. Mitotic cell divisions in root tips were examined using light microscope.

**Results and discussion.** Similar effects of ZnO and Ag-ZnO were observed and the photocatalysts significantly ($p<0.05$) inhibited root growth at 50, 100 and 200 ppm. More reductions of root lengths occurred with increasing concentration of photocatalysts. However, there were significant differences in root growth under the concentrations of 50, 100 and 200 ppm. After 96 hours of ZnO treatments, root lengths in 0, 50, 100 and 200 ppm were 3.91, 1.05, 0.56 and 0.39 cm, respectively. Under the same period, the corresonding concentration of Ag-ZnO resulted in root lengths of 3.91, 0.79, 0.53 and 0.41 cm, respectively. Over a period of 96 hours, small root growth occurred under 50, 100 and 200 ppm of ZnO and Ag-ZnO indicating that the photocatalysts were not lethal for root growth. Over 96 hours at the same concentration, Ag-ZnO appeared to cause more reduction in root growth than ZnO suggesting that Ag-ZnO was more toxic than ZnO. Chromosome aberation, e.g. chromosome bridge, chromosome fragments and sticky chromosome were observed.

**Keywords:** ofloxacin, 5Ag-ZnO, photocatalyst, onion, root length and morphology, cell division

**Introduction.** Substantial amounts of antibiotic consumption of antibiotics [1] were inevitably accompanied by continuous secretion and release of the drugs to environments [2]. Ofloxacin(OFL), a second generation of fluoroquinolone antibiotics, is more effective than previous generation in treating various bacterial infections [3]. Due to the non-biodegradable nature of OFL, an effective degradation of the OFL is required before discharging the drug to the environment. Fabricated 5Ag-ZnO semiconductor is used as a photocatalyst to degrade OFL, producing OFL metabolites (OMs); nevertheless, OMs still need to be comprehensively investigated for their toxicity.

**Experimental/methodology.** Two experiments were undertaken. In experiment 1, OFL at a concentration of approximately 10 ppm, OMs containing OFL at a concentration of about 0.15 ppm and deionized water (DW) were assessed for their effects on the elongation of onion roots. Thirthy six onion (*Allium cepa*) bulbs with uniform root growth under DW for 24 hours were used in these experiments. Maximum root lengths were determined for these bulbs. Three groups of 12 onion bulbs were assigned to DW, OFL and OMs treatments, respectively. Maximum root lengths were measured at 24, 48 and 72 hours after applying the treatments. All procedures in experiment 1 were used in experiment 2; however, in this case the growth of onion roots was allowed for 24 hours only prior to taking measurement of maximum root growth. All roots in each bulb were cut and fixed in Carnoy's fixative solution and then transferred to 70% ethanol. Preserved root samples were used to examine cell divisions in root meristematic tissues using a light microscope.

**Results and discussion.** In experiment 1, abnormal root growths occurred under OMs while normal root growths were observed under DW and OFL. There were no significant differences in maximum root length between DW and OFL treatments over 72 hours and maximun root lengths at 72 hours for DW and OFL were 3.35 ± 0.88 and 3.80 ± 1.09 cm, respectively. However, maximum root lengths treated with OMs were significantly lower ($P<0.05$) than those treated with DW or OFL and maximum root length at 72 hours for the treatment was 1.55 ± 0.42 cm. Crochet root were predominantly presented in onion treated with OMs. In experiment 2, the maximum root lengths were not significantly different between DW and OFL treatments and the lengths were 3.37 ± 0.56 and 3.30 ± 0.45 cm. However, maximum root lengths of 1.93 ± 0.41 cm by OM treatment were significantly lower ($P<0.05$) than those by either DW or OFL treatment. Normal cell division occurred in DW and OFL treatments while aberration of cell division was observed in OMs treatment. Two experiments indicate that OFL is not harmful to onion roots. Although OMs is not lethal to onion root growth, the metabolites exhibit some adverse effects.

**Keywords:** $CO_2$ reduction, $CH_4$, Photocatalytic, $TiO_2$

Global warming caused by the greenhouse effect, which seriously threatens the safety of human life. In the process of photocatalytic reduction of $CO_2$, photocatalysts convert solar energy into chemical energy, and then reduce $CO_2$ into valuable compounds, such as CO, $CH_4$, $CH_3OH$ or other hydrocarbons, thus providing an environment-friendly solution that can promote the recycling of $CO_2$ and the production of sustainable renewable energy.

A well-designed photocatalyst with excellent activity and selectivity is crucial for photocatalytic $CO_2$ conversion and utilization. $TiO_2$ is one of the most promising photocatalysts. However, its excessive surface oxidation potential and insufficient surface active sites inhibit its activity and photocatalytic $CO_2$ reduction selectivity.

In this work, $TiO_2$ nanoparticles were successfully prepared by sol-gel method, and the separation and migration efficiency of photogenerated carriers was greatly improved by noble metal Pd modification, thereby greatly improving the photocatalytic $CO_2$ reduction performance and making the selectivity of $CO_2$ photocatalytic reduction of $CH_4$ up to 100%.

# Evaluation of photocatalytic particles deposition techniques to fibrous membranes for pollutant degradation

Z. Vilamova[1*], M. J. Sampaio[2], L. Svoboda[1], J. Bednar[1], Z. Simonova[1], R. Dvorsky[1], C.G. Silva[2] and J. L. Faria[2]

[2] *Laboratory of Separation and Reaction Engineering, Laboratory of Catalysis and Materials, Department of Chemical Engineering, Faculty of Engineering of the University of Porto, Portugal*

[*] *zuzana.vilamova@vsb.cz*

**Introduction.**

In recent times, fibrous membranes have developed a crucial role in the filtration of pollutants from water [1] or air [2]. Unfortunately, if the filter membrane is used for several hours or days, it leads to a gradually increasing concentration of pollutants on the membrane surface. However, this contamination can be effectively eliminated by the presence of photocatalytic submicroparticles as part of the fibrous membrane. Titanium dioxide and zinc oxide photocatalysts can be found as part of filters for wastewater [2] or air [1] treatment, but their high band gap energy and toxic properties [3] limit their use. However, graphitic carbon nitride (g-$C_3N_4$) proved its antibacterial properties while maintaining its non-toxic character [4]. It is a semiconducting metal-free photocatalyst, whose easy synthesis, low band gap energy (2.7 eV), easy functionalization, and high physicochemical stability predispose it to be used in the photodegradation of organic pollutants [4] and pathogenic microorganisms [4].

**Experimental/methodology.**

The Nanospider NS 1WS500U (Elmarco, Czech Republic) equipment was used for membrane preparations. The neat PVB (Mowital 60BHH) solution was stirred over-night at room temperature in an isopropyl alcohol solution to final 8 wt% concentration, than electrospun at 21 °C, 36.5 % humidity; the distance was set at 20 cm; high voltage was set at 55 kV; substrate-shift set at 5 mm/min. PVB_blend was prepared by electrospinning method as well. PVB+g-$C_3N_4$ (8:1) blend was prepared in an isopropyl alcohol to final 8 wt% PVB concentration. The experiment was performed at same conditions as PVB_neat. The PVB_thermal membrane was prepared as follow: 1 g of g-$C_3N_4$ was dispersed in aquatic environment (100 ml), then neat membrane (PVB_neat) was added to this solution and heated for 24 hours at 40 ºC in oven and label as PVB_thermal. Last membrane was prepared by combination of blend and thermal methods.

**Results and discussion.**

Polyvinylbutyral (PVB) fibrous membranes were prepared by the electrospinning method, and their photocatalytic activities were tested by degradation of phenol. The blend method is the most widely used. Active particles are added to the polymer solution prior to the electrospinning process. This approach seems logical and effective. Unfortunately, this method led to particle encapsulation by a polymer within the fiber and to a decrease in photocatalytic activity ($k = 0.00115\ min^{-1}$). Another method is called thermal treatment. This method led to the attachment of the particle to the fiber surface, allowing its significantly more effective surface action ($k = 0.00176\ min^{-1}$). However, the thermal method caused changes in the fiber size distribution. Using a combination of the methods mentioned above, the last membrane was prepared and tested with the highest photocatalytic activity ($k = 0.00281\ min^{-1}$). However, electrons and holes of active g-$C_3N_4$ caused rapid polymer degradation.

**Keywords:** Sulfamethoxazole, Graphene-like biochar, Iodine, photodegradation, simulated sunlight

**Introduction.**

Sulfamethoxazole (SMX) is an antibiotic widely used in the treatment of human and animal diseases. It has been detected in wastewater effluent and aqueous environment. Owing to a long half-life of 85-100 days, a long-term accumulation in the ecosystem causing drug resistance was found [1]. Titanium dioxide is one of the commonly used photocatalysts, which possesses advantages of non-toxicity, low cost, and high photochemical stability. However, its high energy gap makes it impossible to apply to visible light. Doping non-metal elements into $TiO_2$ is an efficient solution way to shorten the energy gap of photocatalyst. The non-metal elements of N, C, S, I, B, F, and P are often used as doppants. Among which, iodine ($I^{5+}$) and $Ti^{4+}$ have similar ionic radii to introduce the I5p orbital slightly higher than the valence band of $TiO_2$, resulting in red-shift of the chracteristics wavelength of photocatalyst [2,3]. The graphene-like biochar prepared from wasted Lanyu podocarp (B) possesses high conductivity to increasing photodegradation, and ecocomical value enhancement for agricultural wastes.

**Experimental/methodology.**

The B/I-$TiO_2$ photocatalyst was synthesized by sol-gel and hydrothermal method and SMX was ptotodefraded under simulated sunlight. The surface characteristics of graphene-like biochar, including specific surface area, graphitization, lattice arrangement, surface charge, were characteristized. In this study, the doping amount of iodine and graphene-like biochar, the pH value, free radical identification, and the useful life of B/I-$TiO_2$ photocatalyst were investigated.

**Results and discussion.**

It was found that the disordered structure could be transformed into a graphite microcrystalline structure through hydrothermal activation treatment. Prolonging the hydrothermal time helps to shrink the graphite-like d-spacing of graphene biochar and improving the degree of graphitization of graphene-like biochar. At pyrolysis temperature of 700 ℃ and 900 ℃, a long-term hydrothermal activation time of 6 hours will reduce the total pore volume, decreasing the specific surface area from 1036 and 947 $m^2/g$ to 825 and 88 $m^2/g$, respectively.

The doppants of iodine and graphene-like biochar can effectively shorten the energy gap of $TiO_2$ from 3.2 to 2.91eV and red-shift the absorbance wavelength to 426 nm, which build a good environmrnt to degrade SMX under a visible light. Moreover, the excited electrons was guided into graphene-like biochar, which good crystallinity could delay the recombination of electron/hole pairs and enhance the efficiency of photodegradation.

Results showed that the removal rate of SMX by 5LB700H2I1T photocatalyst is 40% with a reaction rate constant ($k_d$) of $1.2\times10^{-3}$ $min^{-1}$under a pH value of 7, including the adsorption efficiency of 14%, and photodegradation efficiency of 26%. The 5LB700H2I1T is positively charged and could easily attract $SMX^-$ to generate an electrostatic effect, thereby improving the adsorption and photocatalytic degradation performance. The adsorption removal efficiency of SMX is positively correlated with the doping amount of graphene-like biochar. After three-time cycle of photodegradation test, the removal efficiency of SMX only decreased by 2%. A good reusability and high stability of prepared B/I-$TiO_2$ photocatalysts were verified.

# Influence of Schottky barrier height on the photo/thermal catalytic activity of $TiO_2$+Pt catalysts

G. Žerjav[1*], A. Pintar[1]

[1]*National Institute of Chemistry, Ljubljana, Slovenia*
[*]*gregor.zerjav@ki.si*

**Keywords:** plasmonic noble metal, visible-light illumination, Schottky barrier height, photothermal catalysis

**Introduction.** The plasmonic properties of noble metals (Au, Ag, Pt, etc.) can trigger the photocatalytic activity of the wide band-gap semiconductor $TiO_2$ under visible-light illumination [1,2]. In this case noble metals, if illuminated with light with wavelength equal or greater than their surface plasmon resonance, generate "hot electrons". The generated "hot electrons" are further injected into the conduction band of $TiO_2$. The efficiency of the plasmon induced "hot electron" injection is influenced by the height of the Schottky barrier (SB) at the junction between the noble metal and the $TiO_2$ support [1,2]. The aims of the present study were (i) to investigate in detail how the optical, electronic and catalytic properties of $TiO_2$+Pt catalysts with 1 wt.% Pt loading depend on the textural and morphological properties of the $TiO_2$ support, (ii) to use the X-ray photoelectron spectroscopy (XPS) technique to determine the height of SB (SBH), and (iii) to investigate the multifunctional use of the prepared $TiO_2$+Pt catalysts by using the same material as a photo, thermal and photothermal catalyst in various environmental cleaning applications.

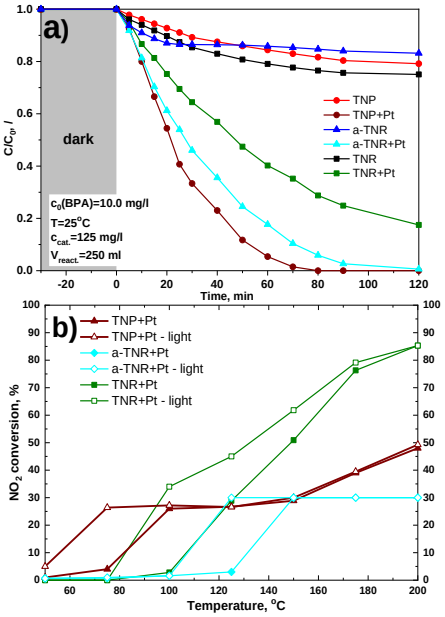

**Figure 1.** (a) Photocatalytic degradation of aqueous BPA conducted in the presence of investigated catalysts under visible-light illumination. (b) $NO_2$ conversion vs. temperature curves (solid symbols) and visible-light assisted $NO_2$ conversion vs. temperature curves (open symbols) over prepared $TiO_2$+Pt catalysts.

**Experimental/methodology.** $TiO_2$+Pt plasmonic solids with 1 wt.% Pt and different $TiO_2$ supports (anatase nanoparticles (TNP, $S_{BET}$=86 $m^2/g$), polycrystalline nanorods (a-TNR, $S_{BET}$=352 $m^2/g$) and single-crystal anatase nanorods (TNR, $S_{BET}$=105 $m^2/g$)) were synthesized by the wet impregnation technique. The ability of the prepared $TiO_2$+Pt materials to be used as a photocatalyst for the waste water treatment was tested in a batch slurry reactor under visible-light illumination using water-dissolved bisphenol A (BPA) as a model organic pollutant. In addition, the prepared solids were examined in a catalytic model reaction to evaluate the activity during $NO_x$ reduction in the presence of $H_2$ as a reducing agent, in order to conceptually demonstrate an alternative approach for low-temperature $NO_x$ abatement that was further enhanced/upgraded by photocatalysis where visible-light illumination was employed.

**Results and discussion.** Due to different charges of the $TiO_2$ support surfaces, Pt ensembles with different sizes, crystallinities and degrees of interaction with the $TiO_2$ supports were formed during the catalyst preparation procedures. The SBH were 0.38 eV for a-TNR+Pt, 0.41 eV for TNP+Pt, and 0.50 eV for TNR+Pt samples, respectively. Low visible-light triggered photocatalytic activity of TNR+Pt catalyst toward oxidation of water-dissolved BPA is attributed to its high SBH and active site degradation due to adsorption of BPA and/or BPA products (Fig. 1a). On the other hand, the highest photothermal catalytic $H_2$ assisted $NO_2$ reduction rate was exhibited by the TNR+Pt sample (Fig. 1b) that can be ascribed to a narrow particle size distribution of small Pt ensembles, the absence of the Pt catalyzed reduction of the TNR support at higher temperatures, and lower rate of re-injection of "hot electrons" from the TNR support to Pt ensembles.

# CdS-chitosan nanocomposite for efficient visible light-driven photocatalysis.

Ladpeace Mbonnjwa[1], Sive Nosenga[1], Phindile B. Khoza[1]*
University of KwaZulu Natal, Durban, South Africa
*khozap2@ukzn.ac.za

**Introduction:** As the global population increases and resource-intensive economic development continues, many countries, particularly South Africa, are failing to meet the accelerating water demand. Heterogeneous photocatalysis appears as an emerging destructive technology among the new oxidation methods or advanced oxidation processes.[1] This technology leads to the mineralization of most of the organic pollutants. In this study, CdS nanoparticles were synthesized using the thermal decomposition method, in which the single molecular precursor was decomposed at high temperatures in the presence of a capping agent (TOPO or HDD) to produce monodispersed nanoparticles.[2] The capped CdS nanoparticles were immobilized onto chitosan microbeads for better recyclability and re-usability.The composite of CdS-chitosan was used as a photocatalyst in the degradation of rhodamine-B in an aqueous system.

**Experimental:** The physical, morphology, and spectroscopic properties of the synthesized CdS, chitosan and CdS/chitosan composites were characterized using the X-ray diffraction spectroscopy (XRD), Fourier transforms infrared spectroscopy (FTIR), Brunauer-Emmett-Teller method (BET), scanning electron microscopy, energy dispersive X-ray mapping (SEM-EDX-mapping), transmission electron microscopy (TEM) with high resolution-transmission electron microscopy (HR-TEM) and UV–Vis, photoluminescence spectroscopy (PL).

**Discussion:** The composite showed superior photocatalytic performance, nearly seven times higher than the individual components. The high photocatalytic efficiency of the composites may be attributed to the role played by the significantly improved surface area and the occurrence of high photoinduced charge separation, as revealed by the morphological and opto-spectroscopic characterization of the synthesized composites, and photocatalysis experimental data. Furthermore, the composites exhibited excellent recyclability and stability, making it potential candidates for use in environmental remediation.

# Photocatalytic degradation of micropollutants using $TiO_2$ on carbon foam

D. Lokhat[1*], E. Kadwa[1], N. Keswa[1], N. Ntshangase, M. Carsky[1]

[1]*School of Engineering, University of KwaZulu-Natal, Durban, South Africa*
[*]*lokhat@ukzn.ac.za*

**Keywords:** carbon foam, photocatalyst, micropollutant

**Introduction.** Photocatalysis has been extensively studied as a relatively simple and effective means of degrading micropollutants in water. It is a technique which requires a light source and a material capable of generating free radicals in the reaction medium. Titanium dioxide ($TiO_2$), a semiconductor material, is a highly effective photocatalytic material. There have been numerous research studies dedicated to the improvement of photocatalytic activity of $TiO_2$. Furthermore, as a means of avoiding the problems of separation and recovery of the $TiO_2$ particles, the immobilization of the active component on a support material has also been intensively studied [1]. Amongst the different substrates proposed, carbon foam is a relatively low cost and robust support structure for the immobilization of $TiO_2$. It has favourable electron transport characteristics and exhibits superior adsorption capability (particularly important for the low concentration of certain micropollutants) which together results in higher photocatalytic activity [2].

**Experimental/methodology.** In this study, samples of $TiO_2$ on carbon foam were produced, and the materials were tested as a photocatalyst for the degradation of an organic dye (rhodamine B, which serves as a model micropollutant) in water. The carbon foam was activated with potassium hydroxide before being loaded with the titanium dioxide precursor and calcined. Four different catalysts were prepared, which included activated and unactivated samples, and samples calcined at different temperatures (400-600 °C). The photocatalytic activity of the catalyst was determined through batch studies using a cylindrical glass reactor equipped with a UV lamp.

**Results and discussion.** The activated carbon foam support gave a photocatalyst with the highest level of anatase $TiO_2$, which is more effective than the rutile and brokite phases which were detected in the unactivated carbon foam samples. Then percentage removal of dye (by both degradation and adsorption) was the highest in the activated photocatalyst (18.3%). This compared very well to the percentage removal of unsupported $TiO_2$ (18.5%). The unactivated photocatalyst performed relatively poor, with only 5-8% removal of dye. The activated $TiO_2$-carbon catalyst was effective for the degradation of rhodamine B dye.

# Fabrication of Bioinspired $TiO_2$-CdS Core-Shell Structure for Long-term Stability Hydrogen Evolution Photocatalyst

Jihyun Lee, Azizar Ghufran Aulia, Jongwook Hong, Beom Jin Kim*

*Department of Chemistry, University of Ulsan, Ulsan, 44610, Korea*

**Keywords:** bioinspired, photocatalyst, high stability, type-II, hydrogen evolution reaction

**Introduction.**

Artificial photosynthesis, the process of converting solar energy into chemical energy, offers a viable solution to address the greenhouse effect and the fossil fuel crisis. In this study, an innovative $TiO_2$-CdS core-shell structure of nanorods was developed as a photocatalyst to enhance photocatalytic efficiency. A bioinspired approach was employed, wherein CdS nanorods were individually encapsulated with a biologically functionalizable $TiO_2$ layer using a catalytic peptide inspired Nature. This bioinspired approach and compatible reaction conditions enabled the encapsulated CdS nanorods to maintain their stability and original shapes, distinguishing them from conventional $TiO_2$/CdS photocatalysts. The in-situ decoration of $TiO_2$ nanoparticles on the surfaces of the CdS nanorods ensured a close contact between the two components. This close connection between CdS and $TiO_2$, along with the favorable type II heterojunction, promoted effective separation of charge carriers and preserved robust redox properties.

**Experimental/methodology.**

To synthesize CdS nanorods $CdCl_2 \cdot 2.5H_2O$ and $CH_4N_2S$ were mixed with ethylenediamine and then introduced into the autoclave for 48 hours. Next, CdS nanorods were dispersed in ethanol, and 11-mercaptoundecanoic acid was added. The solution was sonicated for 30 minutes and then heated for one hour. The mixture was centrifuged, and the resulting precipitate CdS-MUA were rinsed with Tris-HCl Buffer before dissolved in peptide. The mixture was then centrifuged for 5 minutes. The collected CdS NPS were immersed in TiBALDH. The peptide deposition and $TiO_2$ formation cycle was performed several times to create thicker $TiO_2$ shells. Finally, the prepared samples were calcined for 3 hours.

**Results and discussion.**

As a result, a significant enhancement in the photocatalytic hydrogen ($H_2$) evolution reaction and stability over 20 hours was achieved. The $H_2$ yield rate of the $TiO_2$-CdS composite reached 3209 $\mu mol\ g^{-1}\ h^{-1}$, which is 6 and 422 times higher than that of pure CdS and $TiO_2$, respectively. Additionally, when compared to conventional methods, the photocatalytic activity was four times greater. This research offers a novel perspective on the development of type-II scheme photocatalytic systems with optimal performance characteristics.

**Keywords:** Copper, Electrochemical Detection, Plasmon

**Introduction.**

The unique plasmonic properties of metallic nanoparticle catalysts have placed them in a privileged spot among other materials in nanoscience. Plasmonic materials developed so far are typically made of gold and silver. The relative high cost of gold and silver hinders the commercialization of plasmonic materials. Hence, it is significant to search for low-cost and earth-abundant materials for plasmonic applications. Copper (Cu) is much less expensive than gold, and its nanostructures have been proposed for a number of applications within photonics, catalysis, nanothermometry, biosensing or nanomedicine. In this study, facile and one pot-synthesis of Cu NDs was fabricated by Galvanic replacement reaction through immersing the aluminum (Al) foil in the copper sulfate solution at room temperature for 1 h. The dendrite-like Cu nanostructure on Al foil was further functioned as SERS substrate and PEC H2O2 sensor without enzyme under the LSPR-mediated effect.

**Experimental/methodology.**

The schematic growth of Cu NDs on Al foil was fabricated via a Galvanic replacement reaction, as shown in Fig. 1a. Typically, 12.5 mM $CuSO_4$ was dissolved in 25 mM HCl aqueous solution. An Al foil (1×2 $cm^2$) was washed using diluted hydrochloric acid and then rinsed with distilled water three times. After being dried by flowing nitrogen gas, the Al foil was immersed in the $CuSO_4$ solution. Red copper metallic particles formed on the Al foil in a few minutes with effervescence, and Cu NDs were produced on the surface of Al foil for 1 hour.

**Results and discussion.**

In order to probe the SERS detection limit of Cu NDs/Al foil substrate, the samples were immersed into the different concentration of 4-MBA solutions. The results show the Raman spectra from the leaf-like Cu nanostructures with 4-MBA concentrations varied from $1\times10^{-1}$ to $1\times 10^{-7}$ M. Obviously the signals gradually decrease with decreasing the 4-MBA concentration. We could clearly observe 4-MBA Raman signals when a solution with a concentration as low as 0.1 μM was used. Finally, the EF value was calculated to be about $10^6$. The enhancement factor as high as $7\times10^6$ revealed the 3D Cu NDs on Al foil could be used as effective SERS substrate in trace detection.

To further verify the LSPR-enhanced H2O2 reaction on Cu NDs/Al foil electrode, the effect of excitation intensity and wavelength on the electrocatalytic performance was studied. The results shows that the plasma-enhanced H2O2 reduction current of Cu NDs increases significantly with an illumination intensity of a 450 nm light source and is linearly dependent. Importantly, this linear dependence can rule out the effect of photo-thermal heating and prove to be a characteristic of hot charge carriers related to photochemical reactions, revealing more production of hot charge carriers at a higher illumination intensity. In addition, the excitation wavelength-dependent steady-state currents of H2O2 reduction on the Cu NDs electrode at -0.4 V were measured to probe the LSPR-accelerated effect. The steady state current varies significantly with five separate wavelengths, showing a red-shift trend to the LSPR spectrum of Cu NDs. This shift corresponds to the increase of the refractive index around Cu NDs, in relation with optical changes involving the formation and structuring of complexes. Except for the red-shift, it almost overlaps with the plasma excitation peak of Cu NDs, indicating that LSPR excitation should be the main factor leading to the observed increase in current. Therefore, we attribute the dramatic enhancement in cathodic current of H2O2 electro-reduction to the LSPR effect of the Cu NDs.

# Treatment of flue / exhaust gases

# Catalyst Adhesion Enhancement Technology for Metallic Honeycomb Substrates for Energy and Environmental Applications Using Special Coating Techniques

J.-H. Choi[1*], G. Kim[1], H. Jeong[1]

[1] *Korea Institute of Materials Science, Changwon, Gyeongnam 51508, Republic of Korea*

**Keywords:** catalyst adhesion, metallic honeycomb substrate, powder spray coating, intermediate layer

**Introduction.** Wash-coating methods have been widely used to coat environmental catalysts on ceramic and metallic honeycomb substrates. Adhesion strength of conventional wash-coated catalysts on metallic substrates, however, might not be enough especially for exhaust gas after-treatment applications demanding high mechanical durability. The wash-coated layer of ceramic-based catalysts on the metallic surface tends to be easily detached because bonding property between ceramic and metallic materials is basically not good. Herein, a special ceramic powder spray coating (PSC) method and some other techinques were adopted to greatly enhance the adhesion strength of catalysts on metal honeycomb substrates for energy and environmental applications.

**Experimental/methodology.** Honeycomb metallic monolith catalysts were prepared using the powder spray coating and conventional wash-coating techniques and their catalyst adhesion strength and performance were compared using an in-house lab bench system. The PSC technique was applied to form oxide-based intermediate layer [1] or to directly coat catalyst powders on the substrates. Some other techniques such as substrate andizing [2] and pack cementation [3] were also used to form the oxide intermediate layers on metallic substrates.

**Results and discussion.** The powder spray coating technique without using any binding material was successfully applied to form the dense intermediate layer with well-adhered interface and rough surface without pore or crack on metallic honeycomb substrates [1]. Metallic monolith catalysts with the intermediate layer showed much better washcoat adhesion property than those without the intermediate layer even with high washcoat loading. De-NOx conversion efficiency of the metallic monolith catalysts having the intermediate layer was much higher than those without the layer after the ultrasonic vibration test to evaluate the adhesion property [1]. The intermediate layer formation, therefore, could considerably increase the washcoat adhesion strength of metallic monolith catalysts to enhance their long-term mechanical stability. Monolith catalysts having a Fe-ZSM5 layer directly coated on stainless steel sheets using the PSC method also showed super-strong adhesion property and high NOx removal performance comparable to that of wash-coated catalysts for both standard and fast $NH_3$-SCR reactions.

**Keywords:** nanoparticles, microfluidics, microreactors

**Introduction.** Metallic palladium and palladium-based nanoparticles have been extensively studied in a wide range of catalytic applications, including their use in air pollution remediation catalysts in the automotive industry[1,2]. However, the relationships between their catalytic activity and size and composition remains unknown due to the dynamic structure of the nanoparticles under catalytic conditions.
This work demonstrates the continuous synthesis of palladium-based nanoparticles with controllable sizes and a narrow size distribution using continuous flow microreactors for catalytic applications. This new method enables for the first time, the elucidation of size-activity relationships, decoupling size and supports effects. In addition, the easy scale-up of the method can lead to a new way of designing and manufacturing catalysts.

**Experimental/methodology.** Flow microreactors are used for the continuous synthesis of Pd nanoparticles from palladium nitrate precursors and sodium borohydride. The reactants were injected using syringe pumps at a controlled flow rate and both reactants molar concentrations were kept constant. In this study, the 3D configuration of microreactors enables continuous colloidal synthesis of palladium oxide nanoparticles through hydrolysis and palladium nanoparticles through reduction methods. The combination of laminar flow in the microreactors (characterised by low Reynolds numbers) and the promotion of transitional flows (i.e. Langragian turbulence) through 3D configurations leads to a narrow residence times which is translated into narrow size distributions even in the absence of steric capping ligands.[3]

**Results and discussion.** This study investigates the effect of different palladium precursors on the rate of reaction and stability during the synthesis. Palladium oxide (PdO) nanoparticles of sub 5 nm size and metallic palladium nanoparticles with tunable sizes below 10 nm are synthesised. The results reveal the higher instability of the Pd nanoparticles with respect to PdO counterparts in the absence of capping ligands. In this work, we demonstrate that manipulation of initial precursor speciation can greatly affect the stability of resulting nanoparticles and allowing their synthesis in the absence of in-situ capping ligands and stabilisers.
Tunable sizes of these Pd-based nanoparticles are synthesised and deposited onto ceria supports in order to be used as model catalysts for three-way catalysis. The variation in nanoparticles size of active metal affects the number of uncoordinated sites available for the reactions to occur and the different species of Pd-based nanoparticles present on the surface affect the dynamic behaviour and mechanism of the reaction. The synthesised materials will be tested for their catalytic activity and compared against benchmark catalysts.

**Keywords:** full dispersion, atomic arrangement, ensemble, single-atom, three-way catalysis

**Introduction.** The single-atom catalysts (SACs), in which all the metal atoms are isolated on the support with 100% dispersion, have received much attention due to unique catalytic performace [1]. However, SACs cannot catalyze propane or propylene oxidation requiring metal ensemble sites to cleave C-C bonds [2]. Thus, atomically dispersed catalysts with ensemble sites are highly desired. In this work, we prepare metal (Pt, Pd, and Rh) ensemble catalysts (ESCs) with 100% dispersion and use them for three-way catalysis.

**Experimental/methodology.** Commercial γ-alumina was activated by pre-reduction ($rAl_2O_3$) to create coordinatively unsaturated $Al^{3+}_{penta}$ sites [3]. Ceria species were impregnated to the $rAl_2O_3$, and then defective ceria nanoparticles were formed on the $Al^{3+}_{penta}$ sites ($CeO_2$-$rAl_2O_3$) with many $Ce^{3+}$ sites. Then, metal species (Pt, Pd, and Rh) were impregnated slowly on the defective ceria at 40 °C, resulting in ESCs.

**Results and discussion.** The ESCs had 100% dispersion as confirmed by CO and $H_2$ chemisorption. The diffuse reflectance infrared Fourier-transform (DRIFT), extended X-ray absorption fine structure (EXAFS), and high angle-annular dark field scanning transmission electron microscopy (HAADF-STEM) results clearly showed the atomically dispersed metal ensemble structure. When the ESCs and SACs were employed to three-way catalysis, the ESCs showed excellent low-temperature activity for the oxidation of CO, $C_3H_6$, and $C_3H_8$ and the reduction of NO (Figure 1). However, the SACs showed poor activity for the simultaneous reaction due to competitive adsorption by unreacted hydrocarbons. The ESCs showed outstanding durability against hydrothermal aging at 900 °C for 24 h, long-term reaction for 420 h, and recycle tests.

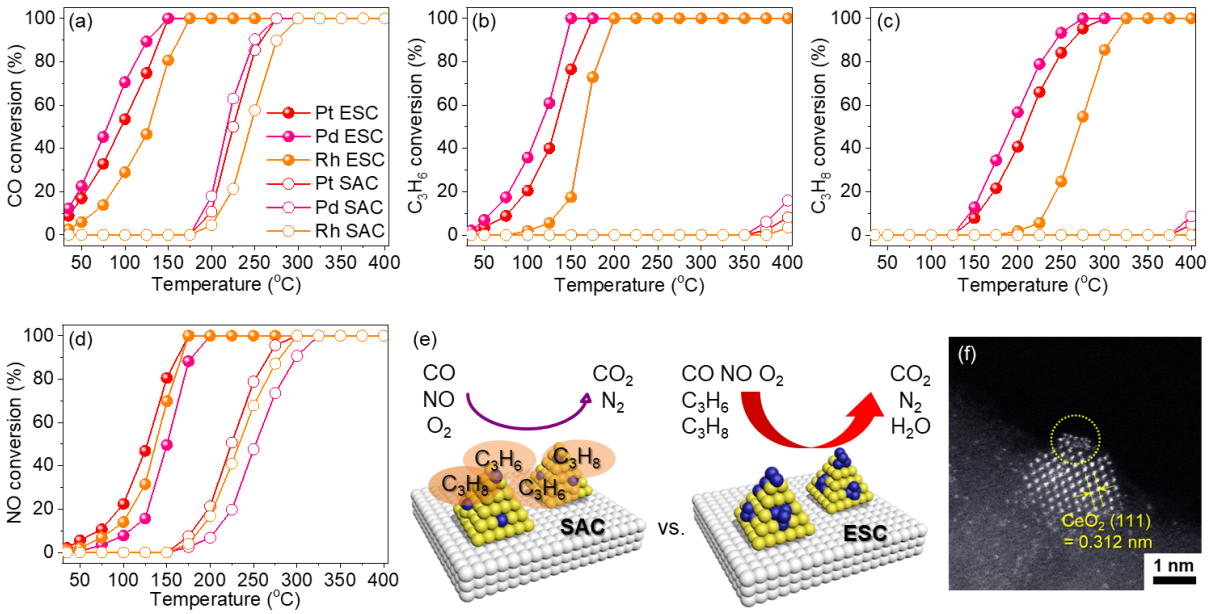

**Figure 1. Catalytic performance of ESCs and SACs for a three-way catalysis: (a) CO conversion, (b) $C_3H_6$ conversion, (c) $C_3H_8$ conversion, and (d) NO conversion. (e) Schematic comparison of SAC and ESC. (f) STEM image of Pt ESC.**

[*]*oliver.kroecher@psi.ch*

**Introduction.** Methane from biomass and $CO_2$ is considered as one the most promising fuels for a future sustainable energy system. However, the use of methane as fuel in internal combustion engines is associated with the emission of considerable amounts of unburned methane with a GWP of 27.9 compared to $CO_2$. Efficient catalysts for methane emission control are mainly based on palladium that suffer from high light-off temperatures that are often above the actual exhaust gas temperatures. We have recently shown that short reducing pulses (SRP) strongly enhance the methane oxidation activity of Pd-based zeolite catalysts [1]. In this study, we have expanded this concept of oxygen oscillations to more practice-relevant Pd-based catalysts and three-way-catalysts (TWC) under both lean and stoichiometric conditions, by combining lab reactor tests, operando spectroscopy and engine test rig experiments.
**Experimental/methodology.** 2 wt % $Pd/Al_2O_3$ [2] and $Pd\text{-}Rh/Al_2O_3$ were prepared as model catalysts by wet impregnation, followed by calcination at 500 °C for 2 h. 1.6. wt% $Pd/Al_2O_3$ doped with La [3], a commercial Pd/Rh TWC [4,5] as well as Pd, Pt-Rh, Pd-Rh and Pt-Pd-Rh on alumina and ceria-zirconia coated on ceramic monoliths were provided by Umicore [6]. Powder as well as monolith catalyst tests were conducted in suitable model gas reactors in the laboratory equipped with fast gas dosage switching and FTIR as well as MS gas analytics. Selected model catalysts were characterized ICP-OES, $N_2$ physisorption, SEM/EDX, TEM, in situ DRIFTS, XRD, operando XANES and in situ XPS. The large catalyst samples from Umicore were also tested on a heavy-duty 4-cylinder natural gas engine under stoichiometric conditions.
**Results and discussion.** Under lean operating conditions, methane was oxidized by oxygen in the steady-state. By applying SRP, the activity of $Pd/Al_2O_3$ was enhanced by activation of the steam refoming (SR) reaction associated with a significant drop in the apparent activation energy. Fit of time-resolved operando XAS data using kinetic models of oxidation revealed that only moderately active PdO existed under static operation, while during SRP operation highly active $PdO_x$ species were formed and maintained by the presence of metallic Pd. A practical range of Pd oxidation degree with 25–65% Pd was found to be optimal to preserve high $CH_4$ conversion [2]. Under stoichiometric operating conditions, periodic lean-rich switches not only improved methane oxidation but also NO reduction over $Pd/Al_2O_3$ as model TWC [3]. The effect of $O_2$ pulses on the methane conversion could be calculated and predicted reliably. The results found in the laboratory over $Pd/Al_2O_3$ under TWC conditions could be confirmed at the engine test rig with a commercial Pd-Rh catalyst [4]. Whereas direct oxidation was the only $CH_4$ conversion pathway in steady-state, the high conversion under transient conditions was due to SR. During oscillations a characteristic “W” shape of the methane concentration profile was found that could be explained by different reaction regimes linked to catalyst oxidation and adsorbed surface carbonaceous species [5]. Among the different PGM combinations Pd-Rh proved to be best suited, since it kept SR active for longer time after transition from lean to rich [6].

**Introduction.** Supported Pd catalysts are considered amongst the most active in several catalytic processes, in particular for environmental catalytic applications (e.g., methane/CO oxidation, hydro-dehalogenation) [1]. Despite their high activity the use of these catalysts may be limited on the long run by the high price, especially with the expected increase of their demand in several applications [1]. Therefore, development of strategies to rationalize the use of active Pd species and a enhancing their stability under reaction conditions is indispensable. This can be achieved by stabilization of small Pd nanostructures (single atoms, clusters, 2D-rafts) on oxide surfaces. Recently, we showed that sol-gel prepared $CeO_2$-$TiO_2$ supports are good candidates for stabilizing highly dispersed Cu atoms with the big advantage of enhancing the Ce3+ /Ce4+ redox shuttle [2]. In this work we employed a structurally optimized $CeO_2$-$TiO_2$ supports to prepare $Pd/CeO_2$-$TiO_2$ catalysts with different Pd nanostructures achieved by controlled variation of Pd loading and preparation method. Herein, we aim at understanding the interplay of different Pd nanostructures with support redox properties and their influence on the catalytic activity in CO oxidation under a kinetically controlled regime. A multitude of characterization methods, including in-situ/operando spectroscopic techniques have been applied.

**Experimental/methodology.** $Pd/CeO_2$-$TiO_2$ catalysts with different Pd loadings were synthesized using a one-step sol-gel method (details in Ref.[2]) or using wetness impregnation for comparison. Catalytic activity measurements were done in a fixed-bed flow reactor (1% CO, 1% $O_2$, He balance). Catalysts were characterized using surface/bulk sensitive methods including, $N_2$ adsorption, X-ray diffraction, temperature programmed reduction ($H_2$-TPR), near ambient-pressure X-ray photoelectron spectroscopy (NAP-XPS), and X-ray absorption spectroscopy (XANES/EXAFS) at Pd K-edge (SAMBA beamline, Soleil Synchrotrone).

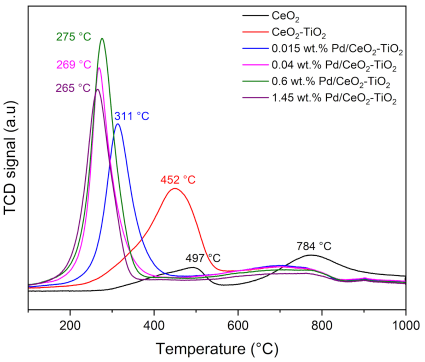

**Figure.** 1 $H_2$-TPR profiles of bare support and the Pd supported on $CeO_2$-$TiO_2$.

**Results and discussion.** The Pd mass-normalized activity/turnover frequencies (TOFs) of $Pd/CeO_2$-$TiO_2$ with trace amount of Pd (0.1 wt.% - to ensure atomically dispersed Pd according to previous work [2]) display essentially a parabolic dependence of temperature between 80 and 250 °C, with the rate increasing continuously with increasing temperature. Comparison of TOF values at different temperatures for Pd single-atom (Pd-SAC) versus Pd-cluster based catalysts show a complex-structure reactivity pattern and interplay of support reducibility and Pd nanostructure (i.e., Pd-SAC or Pd Cluster). This is represented by tendency for higher activity for Pd-SAC at higher temperatures, and in contrast higher activity for Pd-cluster catalysts at lower temperatures. $H_2$-TPR showed a shift in $CeO_2$ surface reduction temperature to lower temperature (**Fig. 1**) on increasing the loading of Pd (i.e., increasing Pd cluster size). In agreement with $H_2$-TPR, NAP-XPS demonstrated that the presence of Pd on the surface of highly dispersed ceria nanoparticles as small clusters or single atoms promotes the $Ce^{4+}/Ce^{3+}$ redox couple, leading to higher tendency for O-vacancy defects formation[3]. These findings shall be discussed together with detailed XANES/EXAFS results to highlight the complex structure-reactivity relationships of supported Pd catalysts under reaction conditions in an interplay with redox properties of carrying $CeO_2$-$TiO_2$ support.

**Keywords:** exhaust gas aftertreatment, reaction kinetics, diffusion, SpaciMS

**Introduction**

Catalytic particulate filter is a multifunctional device combining catalytic converter with particulate filter. It consists of parallel channels that are alternately plugged at one end [1]. The gas is forced to pass through the porous wall between the channels and the soot particles remain trapped [2]. A catalytically active layer is deposited on and/or inside the filter wall [3]. Its spatial distribution and microstructure influence conversion of gaseous pollutants, pressure drop as well as filtration efficiency [1,2,3].

**Experimental**

Three catalytic filters were prepared by vacuum deposition of different Pt/γ-$Al_2O_3$ (0.5% wt.) catalyst slurries on Corning cordierite filter substrate (300 cpsi, wall thickness 200 um, mean pore size 25 µm). The first sample was coated with $d_{90}$ = 0.3 µm catalyst particles forming a thin layer inside wall pores. The second sample was coated with $d_{90}$ = 20 µm slurry that remained mainly on top of the wall. The third sample combined both catalyst locations. All the samples possessed the same total catalyst loading. Tests on all samples included temperature programmed oxidation of CO and octane. The samples were tested as clean, soot-loaded and regenerated. Mercury intrusion porosimetry (MIP), scanning electron microscopy (SEM) and X-ray tomography (XRT) were used to check the structure of catalytic layers. The samples were fouled with 35 nm or 100 nm soot particles and regenerated at 700 °C. Not only the outlet concentrations were measured but also the profiles inside the filter were studied. To do this, two thin capillaries were inserted into the sample, one in the inlet channel and another in in the outlet channel, and the concentration profiles were measured by the SpaciMS technique [4]. The outlet gas composition was analyzed by FTIR MKS 2030 HS and the pressure drop was monitored by a differential pressure sensor.

**Results and discussion**

The experiments focused on higher gas flow rates that, in addition to catalytic activity, reveal the extent of transport limitations [5]. The measured concentration profiles show that CO and octane slip is distributed uniformly along the entire channel and the samples do not show any non-uniformity of the catalytic layer that would cause a local increase in concentration. The slip is therefore caused by a diffusion limitation at the level of the catalyst microstructure and diminishes at lower flow rates. The samples loaded with soot show somewhat higher slip of unreacted octane, which suggests that soot may act as an additional barrier for reactant diffusion to catalytic centers. The impact of accumulated soot on activity of the individual samples is compared and suitable catalyst microstructures are identified.

**Keywords:** Methane oxidation, Palladium oxide, Catalyst deactivation, Water inhibition

**Introduction**

Catalysts for complete methane oxidation suffer from water-induced deactivation due to the high concentrations of steam in the exhaust from natural gas-fired large engines. It is commonly accepted that water deactivate the surface through covering the active sites with hydroxyl groups.[1] Here we show through a series of $CH_4$-TPR and activation measurements that the deactivation takes place by two distinguishable pathways. A reversible deactivation due to surface coverage (inhibition) and an irreversible deactivation due to a structural change in the palladium oxide.

**Experimental/methodology.**

Palladium oxide (3 wt% Pd) on a modified alumina support was tested in a dedicated catalytic setup fitted with water injection (0-20 vol% water) and methane detector (FID) and with temperature and pressure control (up to 5 bar) during methane oxidation. The catalyst can be repeatedly regenerated to 100% of the original activity using reduction pulses of 1000 ppm methane in nitrogen.[2] $CH_4$-TPR data was obtained using the same setup as for catalyst testing.

**Results and discussion.**

Figure 1: Methane oxidation (1000 ppm $CH_4$, 10 % $O_2$, 5 % $H_2O$) of a palladium on alumina catalysts showing the two distinct types of deactivation.

The deactivation profile for both types of deactivation was investigated under a series of different reaction conditions: Temperature, methane concentration, water content, pressure. It is shown that the irreversible deactivation is only taking place when the catalyst is converting methane. The $CH_4$-TPR performed with and without water reveals a significant shift of the reduction temperature of palladium oxide after the irreversible deactivation.

We show how the rate of deactivation of the catalyst depend on both the water and methane concentration with comparable reaction orders.

On the basis of the results a deactivation model is proposed and we present spectroscopic evidence to suggest the identity of the structural transition taking place during the irreversible deactivation.

**Keywords:** three-way catalysis, palladium, platinum, ceria

**Introduction.** In the field of automotive exhaust treatment and three-way catalysis continuous innovation is needed to meet the increasingly stringent legislative standards that aim to limit emissions from cars with internal combustion engines. Since modern three-way catalysts already operate efficiently at elevated operating temperatures, the focus of current research has shifted towards improving the low-temperature activity of such catalysts and thereby decreasing emissions during the cold start phase of the engine. (1) This is especially important in hybrid vehicles, where the catalyst cools down while driving on battery power. Promising catalysts for low-temperature exhaust aftertreatment are $Pd/CeO_2$ and $Pt/CeO_2$ catalysts in which the active metal is highly, possibly atomically dispersed. (2) One of the main reasons why these highly dispersed catalysts are not yet commercially used in three-way catalysis is their limited stability at the high peak temperatures (>1000°C) that can be reached inside a catalytic converter.

**Experimental/methodology.** In this work, flame-spray pyrolysis (FSP) is used to synthesize ceria nanoparticles containing highly dispersed Pd and Pt. FSP allows for a high degree of control over the ceria particle size in the range of 5 nm to 15 nm with good reproducibility and scalability (Figure 1a). These FSP-made $Pd/CeO_2$ and $Pt/CeO_2$ catalysts are then subjected to high temperature hydrothermal conditions as well as realistic aging conditions in a simulated exhaust gas with periodic switches between oxidizing (lean) and reducing (rich) atmospheres. As-synthesized and treated samples are compared in terms of their metal and ceria particle sizes, oxidation states, reducibility and catalytic performance.

**Results and discussion.** Even though there is significant sintering of the ceria support, hydrothermal treatment has little impact on the metal oxidation state or dispersion of the metal, as evidenced by EXAFS and XPS measurements. Still, hydrothermally treated samples show a lower catalytic activity in CO oxida-tion. In catalysts aged under realistic conditions, significant sintering of Pd and Pt and the emergence of a metallic phase is observed (Figure 1d). A combined XANES/XRD operando study on $Pd/CeO_2$ showed that such metallic Pd particles form already at 500°C in the CO oxidation reaction under rich conditions, but redisperse under lean conditions (Figures 1b and 1c). These results highlight the significant and complex changes occurring during catalyst aging and show the importance of testing aged materials in addition to fresh catalysts.

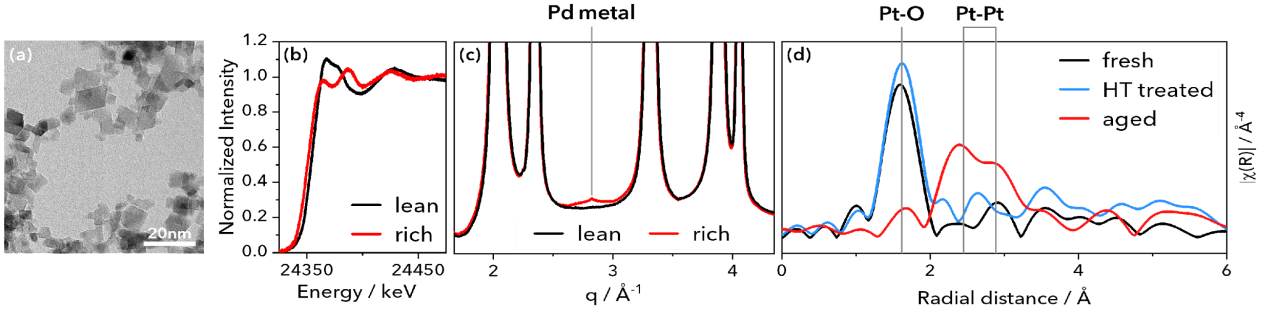

**Figure 1** – (a) TEM image of an as-synthesized $Pd/CeO_2$ catalyst. Formation of metallic Pd particles during CO oxidation under rich (excess CO) conditions at 500°C as evidenced by (b) operando Pd K-edge XANES and (c) operando XRD. (d) Ex situ EXAFS of fresh, hydrothermally (HT) treated and aged $Pt/CeO_2$ catalysts.

# Intra-catalyst $CH_4$-oxidation pathways of three-way catalysts and implications on $NO_x$-conversion profiles for a natural gas vehicle exhaust under lambda modulation

William Partridge[1*], Dhruba J. Deka[1], Calvin Thomas[1], Josh Pihl[1]

**Introduction.** Natural gas (NG) is an attractive alternative to other fossil fuels for internal-combustion engines [1]. NG engines produce little soot and have lower $NO_x$ and $CO_2$ emissions than diesel engines. Stoichiometric NG engines operate under varying air-to-fuel ratio or lambda (λ) modulation (also known as lean-rich cycling) which creates dynamic exhaust-gas conditions. Three-way catalysts (TWC) are used to control NG engine emissions such as $CH_4$, CO and $NO_x$, and their performance can change depending on the modulation-induced compositional changes of the exhaust gas. Understanding how the $CH_4$ conversion pathways vary along the catalyst and through the λ cycle, how it effects $NO_x$ conversion, and the impact of catlyst formulation is relevant to formulating NG-vehicles after-treatment strategies[2].

**Experimental/methodology.** Monolith TWC samples with two different oxygen storage materials were used: reference $Pd/Al_2O_3$-$CeZrO_x$ and PGM-$Mn_{0.5}Fe_{2.5}O_4$. Intra-catalyst Fast-SpaciMS [2] resolved reaction transients along the catalyst flow channel. Lambda-modulation was achieved by dithering the $O_2$ concentration between Lean (high-$O_2$) and Rich (low-$O_2$) at various λ centers, frequencies, and amplitudes. The TWC was operated at 350°C-500°C and with a feed stream containing 0.42% $CH_4$, 0.45% CO, 0.15% $H_2$, 0.10% NO, 9.5% $CO_2$, 18.5% $H_2O$ and varying $O_2$ flowing at 40,000/h space velocity.

**Results and discussion.** We performed $O_2$, $CH_4$, $H_2$ and NO measurements at various intra-catalyst locations across a wide range of λ-modulation parameters, and Fig. 1a-b shows the $O_2$ and $CH_4$ profiles at a representative condition (amplitude 0.10, λ-center 1, frequency 0.25Hz, temperature 500°C). In the Rich phase, $CH_4$ steam reforming (SRM) and partial oxidation (POM) area rapidly activated, OSC is consumed, and Pd sites are reduced. In the Lean phase, SRM and POM turn off as the catalyst is reoxidized. Maximum $CH_4$ conversion occurs around the Rich-Lean transition. At late-Rich times (2s, Fig.1(c) intra-catalyst spatial profile), $H_2$ is produced from SMR and POM. The $NO_x$ conversion follows $CH_4$ conversion indicating its dependance on SMR and POM products. At late-Lean times (Fig.1d) SRM, POM and $NO_x$ conversion are only active in the catalyst back. The extent of total oxidation, SRM and POM differed for the spinel catalyst. The dominant $CH_4$ conversion routes involved SRM and POM for the reference TWC, but surface metallic PGM or oxygen vacancies the spinel-TWC. For both catalysts, λ modulation creates a back-to-front and front-to-back progression of these reactions and catalyst oxidation states through the Rich-Lean λ cycle. This study shows previously unknown dynamic reactions and catalyst oxidation-state waves. Understanding the impact of λ modulation on catalyst performance and the various reaction-zone dynamics will enable control strategies to co-optimize engine efficiency and emissions.

**Keywords:** $NH_3$-SCR, Cu-SSZ-13, Reaction Mechanism

**Introduction.**
Zeolites containing Cu or Fe exhibit high catalytic activity in $NH_3$-SCR, which is essentially controlled by the nature and nuclearity of the metallic active centers. A comprehansive insight into the SCR reaction mechanism can be obtained from synergy between catalytic studies combined and spectroscopic analysis of the reaction intermediates when isotopically enriched reactants are used, and interpretation of the results is ascertained by DFT modelling combined with ab initio thermodynamic simulations.

**Experimental/methodology.**
Two types of catalysts of various copper speciation, obtained by impregnation of CHA zeolite with $CuCl_2$ (i-CuSSZ-13) and via one pot synthesis (o-CuSSZ-13), and characterized by SEM/TEM/EDX, MAS-NMR, IR, EPR, and NH3-TPD techniques, were selected as model systems. Their isotopic studies were performaed in TPSR and sready state mode.

***Results and discussion.***

The isotopic in $O_2/^{15}NH_3$-SCR, $^{18}O_2/NH_3$-SCR and $^{18}O_2/^{15}NH_3$-SCR profiles provided direct evidence that at $T$ < 200 °C the standard SCR reaction occurs alone, whereas at $T$ > 200 °C it is accompanied by ubiquitous intrazoelite oxidation of $NH_3$ (i-AMO), which involves $Cu^{2+}$–$O^{2-}$–$Cu^{2+}$ and $Cu^{2+}$ centers**.** The i-AMO reaction is triggered by temporal excess of $NH_3$ with respect to NO, caused by release of ammonia stored in the zeolite cages with the increasing temperature. For the i-CuSSZ-13 sample, $^{16}O^{18}O$ production was related to the presence of segregated CuO clusters, revealing that the dissociation of $O_2$ above 400 °C with formation of peroxy species trigger external $NH_3$ oxidation (e-AMO). The COS 2D and rapid scan IR and EPR studies along with the constructed 2D thermodynamic diagrams derived from the DFT/FPT modelling alllowed for distinguishing three temperature regions of the SCR/AMO reactions, corresponding to $NH_3$-reach, lean and dry conditions. and the main processes of each stage were identified. For conceptualization of the SCR reaction, a 2D diagram of stoichiometry, oxidation state and charge compatibility, where the NO and $NH_3$ reactants and the kye SCR/AMO intermediates are ordered as a function of their oxidation state and the O/H(N) ratio was constructed. The diagram reveals the principal stoichiometry, charge and oxidation state requirements between the reactants and intermediates, and principal modes of their regulation (via $OH^-$ reductive elimination, and $H^+/e^-$ or $H^+$ transfer), for straightforward turnover of the SCR/AMO reactions. The observed in situ oxidation of excessive $NH_3$ (i-AMO) in the region of high conversion suggests benefits for the main SCR process from the dynamic adjustment of the ammonia dose at low temperatures, rather than continuously supplying $NH_3$ at a constant level. This should not only limit the ammonia slip, but also reduce its waste due to considerable unproductive, yet pervasive, oxidation (i-AMO).

[*]*grunwaldt@kit.edu*

**Introduction.**
Oxygenates as renewable fuels generated by conversion of atmospheric $CO_2$ with renewable hydrogen are promising candidates for achieving carbon neutrality. Furthermore, their combustion leads to the same efficiency as obtained with state-of-the-art diesel engines while less soot formation is observed. Nevertheless, a catalytic after-treatment system is still required, including a $NO_x$ removal catalyst. Due to the incomplete combustion of alternative fuels such as biomethane and oxymethylene ethers (OME), emissions of several hazardous compounds are expected. Herein, formaldehyde (HCHO) is a problematic pollutant since its complete suppression over a standard oxidation catalyst is hardly possible due to external diffusion limitations [1]. Hence, uncovering the influence of HCHO on the $NH_3$-SCR activity of the $NO_x$ removal system is highly important. In addition, it gives a new insight into the copper species involved.

**Experimental/methodology.**
A series of Cu-SSZ-13 catalysts with different Cu:Si:Al ratios were prepared similarly as in our earlier work [2, 3]. The resulting powders were coated on cordierite monolith cores (400 cpsi) by dip-coating. Catalytic tests were performed in a stainless-steel reactor from 150-550 °C using a model gas mixture of 0350 ppm NO, 0-350 ppm $NH_3$, 0-80 ppm HCHO, 10 % $O_2$, 12 % $H_2O$ in $N_2$ at a gas hourly space velocity of 100,000 $h^{-1}$. The gas composition was monitored by a MKS FTIR instrument. Additionally, detailed *ex situ* and *in situ/operando* characterization was conducted to elucidate the relations between catalyst structure, measured activity and byproduct formation.

**Results and discussion.**
When studying the impact of formaldehyde on the $NO_x$ conversion activity of Cu-SSZ-13, a major drop in the low temperature SCR activity was observed [4]. Furthermore, the conversion of formaldehyde leads to different products depending on the catalyst composition, including the formation of highly toxic HCN emissions. Though, careful tuning of the Cu:Si:Al ratio shows the potential to significantly decrease the HCN emissions. Spatially resolved *operando* XAS measurements performed at the Cu K edge during $NO_x$ removal uncovered a clear impact of formaldehyde presence on the $Cu^{2+}/Cu^{+}$ redox behavior. The obtained results reveal crucial and new mechanistic insights involved in HCN formation as a function of gas mixture, temperature and catalyst composition and at the same time give additional insights into the $NH_3$-SCR mechanism itself.

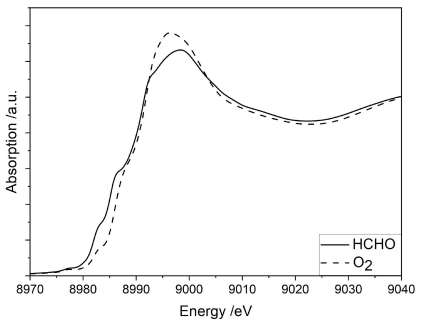

**Figure 1: XANES spectra of Cu-SSZ-13 in the presence of HCHO (solid line) and in air (dashed line).**

**Keywords:** emissions control, environmental catalysis

**Introduction.** Cu-SSZ-13 is widely used as a $NO_x$ reduction catalyst in diesel engine after-treatment systems. However, sulfur, a common component in diesel fuel and oil, can lead to catalyst deactivation. Literature has shown that the relative amounts of Cu sites identified as Z2Cu and ZCuOH lead to different S poisoning extents (1-3) and those relative Cu site amounts can be influenced by mild hydrothermal aging (4,5). Based on these findings, one approach proposed to protect a Cu-SSZ-13 catalyst from sulfur poisoning is to decrease the amount of ZCuOH in favor of more Z2Cu sites, via mild hydrothermal aging.

**Experimental/methodology.** The Cu-SSZ-13 catalyst was provided by Cummins Inc. and came as a honeycomb monolith structure with a cell density of 300 cells/in$^2$ (cpsi). Selective catalytic reduction (SCR) experiments were conducted before and after mild hydrothermal aging and sulfur exposure. The samples were also characterized using $NH_3$ temperature programmed desorption (TPD) and oxidation (TPO), CO, NO and $SO_2$ oxidation, CO titration, NO + $NH_3$ titration and diffuse reflectance infrared Fourier transform spectroscopy (DRIFTS).

**Results and discussion.** SCR of $NO_x$ by $NH_3$ over the Cu-SSZ-13 sample used can be inhibited by sulfur poisoning. In terms of the commonly identified Cu species in this formulation, literature (1-3) and our own data suggest that a sample with more Z2Cu relative to ZCuOH is less susceptible to sulfur poisoning under some conditions. Furthermore, the catalyst with more ZCuOH appears to be, in general, a better oxidation catalyst. Mild hydrothermal aging induces the migration of the Cu from ZCuOH to Z2Cu and at the same time leads to decreased CO, NO, $NH_3$ and $SO_2$ oxidation conversions. DRIFTS also correlates the change in $NH_3$ oxidation to a change in relative ZCuOH amounts. Our results describe a correlation between the extent of sulfur poisoning to the catalyst's oxidation ability. The results after different sulfur treatments, such as $SO_3$ exposure, and higher temperature and higher $O_2$ concentration during $SO_2$ exposure, all suggest a mechanism where surface $SO_2$ oxidation leads to more deactivation. This therefore implies that the extent of poisoning is dependent on the oxidation activity of the different Cu species, not solely on their relative amounts.

The above results demonstrate that surface oxidation of $SO_2$, or the presence of $SO_3$, leads to more significant catalytic SCR deactivation. And as mentioned above, literature suggests that different Cu species are more or less prone to S poisoning (1-3). We used density functional theory (DFT) and probe reaction experiments to characterize Cu amounts and types, with emphasis on ion-exchanged Cu and multinuclear Cu species. Our results show that multinuclear Cu species are particularly prone to S poisoning, and that the extents of regeneration after exposure are also dependent on S exposure conditions. Overall, the talk will focus on how Cu speciation influences the extent of S poisoning, and which species are more prone to forming stable S-bound species.

**Introduction.** Cu exchanged chabazite (CHA) catalysts are applied for selective catalytic reduction of NOx by ammonia ($NH_3$-SCR) in diesel exhausts. A limitation for application of Cu-CHA is its sensitivity to $SO_2$ [1]. $SO_2$ reacts predominantly with $[Cu_2^{II}(NH_3)_4O_2]^{2+}$ complexes, formed upon activation of $O_2$ in the $NH_3$-SCR reaction cycle [2,3]. The reaction of $SO_2$ with $[Cu_2^{II}(NH_3)_4O_2]^{2+}$ leads to reduction of some $Cu^{II}$ to $Cu^{I}$, in the absence of $O_2$ [3]. In this work, we show that the uptake of $SO_2$ is enhanced when $O_2$ and $H_2O$ are present, and leads to a stronger deactivation of the Cu-CHA catalysts.

**Experimental.** All measurements were done in a quartz U-tube reactor, connected to a FTIR spectrometer for analysis of the gas composition at the reactor outlet. A series of Cu-CHA catalyst samples (Si/Al ratio 6.7; 3.2 wt% Cu, 10 mg sample size) was pretreated with different methods to form framework bound $Cu^{I}$ and $Cu^{II}$, mobile $[Cu^{I}(NH_3)_2]^{+}$ and the $[Cu_2^{II}(NH_3)_4O_2]^{2+}$ complex. After the pretreatment, the catalyst was exposed to 100 ppm $SO_2$, or dry 100 ppm $SO_2$/10% $O_2$, or 100 ppm $SO_2$/10% $O_2$/5% $H_2O$ mixtures at 200°C for 45 min. The S/Cu ratios were calculated from the measured $SO_2$ uptakes. To evaluate the deactivation, we express the rate constants for $NH_3$-SCR at 200 °C after $SO_2$ exposure as a percentage of the rate constants for the fresh catalysts. For the $[Cu_2^{II}(NH_3)_4O_2]^{2+}$ complex, the $SO_2$ exposure and activity measurement cycle was repeated 6 times, to achieve a high deactivation and follow deactivation rates.

**Results and discussion.** Figure 1a shows the deactivation with the S/Cu ratios after the first cycle (black points) for different Cu species in absence and presence of $O_2$ and $H_2O$. In absence of $O_2$ and $H_2O$, the $SO_2$ uptake for the $[Cu_2^{II}(NH_3)_4O_2]^{2+}$ complex (star point) is higher, compared to the other Cu species species (green dash circle), in agreement with earlier XAQ and $SO_2$-TPD results [3]. Addition of $O_2$ and $H_2O$ leads to a higher uptake of $SO_2$ up to a S/Cu ratio of about 0.6. The deactivation follows the same trend. The loss of activity is about 1.5-2 times the S/Cu ratio, indicating that a smaller amount of sulfur in the catalyst results in a strong deactivation. This effect is even stronger in the repeated cycles with the $[Cu_2^{II}(NH_3)_4O_2]^{2+}$ complex, where a small S/Cu ratio of 0.3 results in a 82% reduction of the activity. (Red dash line in Figure 1a). This does not follow the same trend as adding $O_2$ and $H_2O$, indicating that the S/Cu ratio alone is not sufficient to characterize the deactivation. Figure 1-b shows the deactivation and $SO_2$ uptake with repeated $SO_2$ exposure with and without $O_2$ and $H_2O$. The presence of $O_2$ and $H_2O$ accelerates the $SO_2$ uptake and enhances the deactivation, but in all cases the S/Cu ratio saturates, and some residual activity remains.

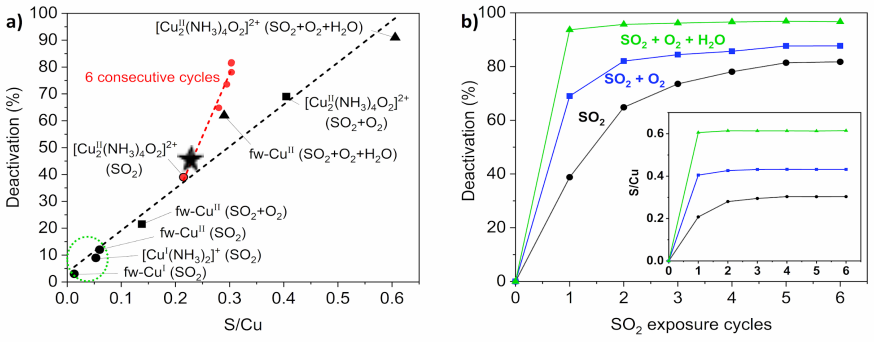

Figure 1- a) Deactivation meaurements versus S/Cu ratios for different Cu species and conditions at 200 °C, b) Measured deactivation and $SO_2$ uptake (S/Cu ratio) in repeated $SO_2$ exposure cycles at 200 °C.

**Introduction.** Emission control of NOx (NO and $NO_2$) is an important task for an industrial chemical process that relies on thermal energy produced by the combustion of fossil fuels. For stationary deNOx systems such as those in coal-fired power plants and waste treatment plants, selective catalytic reduction (SCR) has been used with ammonia as a reducing reagent to convert harmful NOx to harmless $N_2$ and $H_2O$ [1]. Although the stationary deNOx systems have been successfully established, a conventional catalyst needs a high temperature (>300°C) for $NH_3$-SCR to proceed. DeNOx catalysts can be moved to the latter part of the system to avoid deactivation if the deNOx catalyst works at a low temperature (~150°C) since the downstream gas is usually cooled down to 100-150°C. We have reported a bulk $V_2O_5$ and W substituted $V_2O_5$ catalyst for low-temperature $NH_3$-SCR (<150°C) under a wet atmosphere [1-3]. In this study, we report a new catalyst for low-temperature de-NOx catalyst based on topotactic material $Na-V_2O_5$.

**Experimental/methodology.** To obtain $Na-V_2O_5$, $NH_4VO_3$, $NaNO_3$ and oxalic acid were dissolved in water, and then the solution was heated overnight to evaporate the water on a hotplate. Finally, the resulting solid was calcined at 300°C for 4 h.

**Results and discussion.** The structure of $Na-V_2O_5$ obtained from the XRD pattern is shown in Fig 1, and the structure of $Na-V_2O_5$ differs from orthorhombic $V_2O_5$ and $W-V_2O_5$ (Fig. 1a) in that it has a monoclinic crystal structure (Fig. 1b). The reaction rate was calculated at 150°C (Fig. 1c). $Na-V_2O_5$ was more active than the previously reported $W-V_2O_5$, $V_2O_5$, and $V/W-TiO_2$, which simulates industrial catalysts, and maintained high activity in the presence of 10% water. In the presentation, we will discuss the activity caused by the catalyst structure.

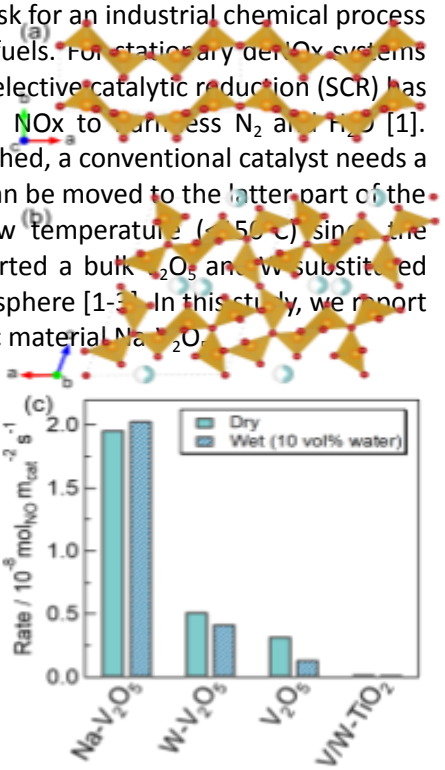

**Fig. 1 Structure model of $V_2O_5$, $W-V_2O_5$ (a), and $Na-V_2O_5$ (b), and the comparison of reaction rate in $NH_3$-SCR at 150°C.**

**Keywords:** Cu-zeolite, $NH_3$-SCR, Cu redox, Cu reduction, Cu oxidation, transient kinetic analysis

**Introduction.**

$NH_3$-SCR on Cu-zeolite (CHA) catalysts is considered the best available technology to control nitrogen oxides (NOx) emissions from vehicles [1,2]. Recently, great attention has been paid to the low-temperature (LT, ≤250°C) reaction mechanism. Cu sites are involved in a redox process, cycling between $Cu^{2+}$ to $Cu^{+}$ in the reduction (RHC) and $Cu^{+}$ to $Cu^{2+}$ in the oxidation (OHC) half-cycles. Nevertheless, a fully consistent kinetic description of the catalytic redox scheme is still debated [1-4]. Herein, RHC and OHC kinetics are independently assessed and then combined to predict the closure of the LT STD-SCR redox mechanism.

**Experimental/methodology.**

Tests were run over a model Cu-CHA catalyst (powders, 32 mg, Cu loading =1.8% w/w, SAR =25) at low temperature (150-200°C) in the presence of 2% v/v $H_2O$. Three main protocols were executed: i) isothermal oxidation of a fully reduced catalyst with $O_2$; ii) isothermal reduction of a fully oxidized catalyst with NO=$NH_3$=500 ppm; iii) $O_2$ feed step changes going from Standard-SCR (STD, NO+$NH_3$+$O_2$) to pure reduction (NO+$NH_3$) conditions, and vice versa. The experimental data were fitted according to a transient integral PFR model of the test reactor (cascade of 20 CSTRs) assuming: a) the RHC rate to be 1st and 2nd order in the NO concentration and the $Cu^{2+}$ fraction, respectively [2]; b) the OHC rate to be 1st and 2nd order in the $O_2$ partial pressure ($P_{O2}$) and in the reduced Cu fraction, respectively.

**Results and discussion.**

By protocol (i) we monitored the temporal evolution of the $Cu^{2+}$ fraction during Cu-oxidation (Figure 1A). Notably, $O_2$ alone was able to fully re-oxidize the catalyst after 1h at low temperature. The OHC data were nicely fitted by the assumed 2nd order redox kinetic model in $Cu^{+}$, confirming the oxidation half-cycle to be a dual-site mechanism with $O_2$ as the sole oxidant and an inconsequential role for NO [1]. Concerning the RHC, results from protocol (ii) confirmed the ability of NO+$NH_3$ to completely reduce $Cu^{2+}$ sites to $Cu^{+}$ producing $N_2$ according to a $Cu^{2+}$:NO:$N_2$=1:1:1 stoichiometry (Figure 1B). Again, the accuracy of the fit confirmed the 2nd order dependence of the reduction rate on the $Cu^{2+}$ fraction [2]. These results emphasize the dominance of dinuclear Cu species in the redox mechanism of low-T Standard SCR. Once OHC and RHC were independently investigated, the estimated rate constants were used to directly predict the Standard SCR profiles from protocol (iii). Notably, the model was able to predict not only the steady state deNOx activity, but also the bed-average $Cu^{2+}$ fraction at STD-SCR conditions, as well as the monotonic transient behavior of the NO/$N_2$ concentrations profiles (Figure 1C). The present results provide a stoichiometrically and kinetically consistent closure of the Cu redox cycle (with an overall NO:Cu=1:1 stoichiometry) in the STD-SCR chemistry and offer new insights into the LT $NH_3$-SCR mechanism over Cu-CHA.

**Keywords:** Cu-zeolite, $NH_3$-SCR, redox mechanism, SAR effect

**Introduction.** $NH_3$-SCR (Selective Catalytic Reduction) over Cu-exchanged zeolite catalysts is considered the leading technology able to control the emission of nitrogen oxides (NOx) from Diesel engine exhausts [1,2]. Despite the high number of publications related to this topic, the low temperature mechanism (≤250°C) of the Standard SCR reaction is still highly debated [1-3]. Nowadays, there is a general consensus about the involvement of Cu in a cyclic redox mechanism, with its oxidation state varying from $Cu^{II}$ to $Cu^{I}$ and from $Cu^{I}$ to $Cu^{II}$ in the reduction (RHC) and oxidation half-cycles (OHC), respectively [1-3]. However, a clear understanding of the effects of the catalyst formulation (*e.g.*, $SiO_2/Al_2O_3$ ratio, SAR, and Cu loading) and of the gas feed composition (*e.g.*, NO, $NH_3$, $O_2$ and $H_2O$ concentrations) on the SCR redox chemistry is still lacking. Herein, based on transient experiments and a kinetic modelling approach, we provide fundamental insights into the low-T Standard SCR mechanism, mainly focusing on the effects of SAR and $H_2O$.

**Experimental/methodology.** The study was performed over two model Cu-CHA catalysts (32 mg of powder) with same Cu loading (1.77% w/w) and different SAR (13 and 25). Dry and wet conditions (0-2% v/v $H_2O$) were investigated in a low T-range (150-200°C) according to three main protocols: i) isothermal reduction of a fully preoxidized catalyst with 500+500 ppm of $NO+NH_3$; ii) isothermal oxidation of a fully prereduced catalyst with 8% v/v of $O_2$ as the sole oxidant; iii) $O_2$ feed step changes from pure reduction ($NO+NH_3$) to Standard SCR ($O_2+NO+NH_3$) conditions, and vice versa. The collected data were further analyzed according to a transient integral model of the test flow reactor (cascade of 20 CSTRs) based on the following assumptions: i) $1^{st}$ and $2^{nd}$ order dependence of RHC rate on NO concentration and oxidized Cu fraction; $1^{st}$ and $2^{nd}$ order dependence of the OHC rate on $O_2$ concentration and reduced Cu fraction.

**Results and discussion.** According to protocols (i) and (ii), we confirmed on both samples: i) the ability of $NO+NH_3$ to completely reduce $Cu^{II}$ sites; ii) $Cu^{I}$ sites to be fully oxidized by $O_2$ as the sole oxidant. In addition, the good match between model and experimental profiles confirmed the accuracy of the assumed reaction pathways and kinetics of both RHC and OHC. Furthermore, the independently estimated RHC and OHC kinetic constants were able to successfully predict both NOx conversion and bed-average $Cu^{II}$ fraction observed from protocol (iii) at STD-SCR steady-state. To evaluate the effect of SAR, the estimated rate constants ($k_{RHC}$ and $k_{OHC}$) were compared in terms of Arrhenius plots over the two samples. For the sake of simplicity, only results for wet conditions are here described. In particular: i) higher $k_{RHC}$ and apparent activation energy ($E_{act}^{RHC}$) were estimated over SAR13; ii) the opposite trend was observed for OHC, with $k_{OHC}$ values and activation energy ($E_{act}^{OHC}$) higher on SAR25. Notably, $H_2O$ showed the same kinetic effects of SAR, promoting OHC but inhibiting RHC [3], hence suggesting a possible correlation between SAR and $H_2O$ effects: due to the less *hydrophilic* nature of the high-SAR zeolite, $H_2O$ would be able to interact more intensely with the Cu cations, thus enhancing the OHC promotion as well as the RHC inhibition.

**Introduction.**

Nitric acid is one of the most widely produced commodity in the world with approximal 60 million of tonnes produce annually [1] [2]. The production of nitric acid is coupled with the formation of nitrogen oxide and $N_2O$ which is the third most impacting greenhouse gas (GHG) after $CO_2$ and $CH_4$. A catalytic abatement system is required to treat the flue gas of a nitric acid production plant, which is currently implemented using various catalytic systems. Fe-exchanged zeolites catalysts are currently the state of art catalysts which could achieve both $NO_x$ and $N_2O$ abatement. Many Fe zeolites have been explored, such as Ferrierite (FER), ZSM5 and BEA [3]. In this contribution, a comparison was made between fresh and aged Fe-FER and Fe-ZSM5 industrial catalysts, both supplied by ALSYS, in order to study the catalyst at the end of its operating life. Fe-FER catalyst is a proprietary catalyst of CASALE and ALSYS and it is used in nitric acid plants [4]. Field and laboratory results have shown that Fe-FER might allow customers to benefit from high catalytic activity and stability to lower catalyst turnover.

**Experimental/methodology.**

Commercial extruded catalysts were prepared on an industrial scale by ALSYS. The catalysts show a uniform cylindrical shape with a diameter close to 2 mm. Fe-FER and Fe-ZSM5 were subjected to a simulated accelerated ageing procedure, developed to model specific catalytic ageing, to study catalytic behavior at the end of the catalyst's life. Particular attention was devoted to the $N_2O$ abatement. In fact, the catalytic tests were performed under relevant industrial in an Inconel reactor (de$N_2O$ reaction condition: NO 70 ppm, $NO_2$ 30 ppm, $N_2O$ 900 ppm, $O_2$ 3.0%, $H_2O$ 0.3% and $N_2$ balance; de$NO_x$ condition: NO 325 ppm, $NO_2$ 325 ppm $N_2O$ 40 ppm, $NH_3$ 650 ppm, $O_2$ 3.0%, $H_2O$ 0.3% and $N_2$ balance.). A very high spatial velocity was used to highlight the differences in catalytic activity between the catalysts tested. Ageing treatments were carried out for 150 h at two temperatures (600 and 700°C) with 12% $O_2$ and 6% $H_2O$. The detector used was FT-IR coupled with a lambda probe for oxygen measurement.

**Results and discussion.**

Focusing on the fresh catalyst, the results show the higher catalytic activity of Fe-FER compared to Fe-ZSM5 for both $NO_x$ and $N_2O$ abatement. The superior catalytic activity of Fe-FER for $N_2O$ abatement becomes particularly significant after the ageing procedure, where a different catalytic behaviour is observed. The results of the laboratory were used to analyse the impact of tertiary abatement catalyst on the nitric acid process performance, in terms of abatement system design and stack emissions. In addition, the study will contribute to the understanding of catalyst performance during the Start Of Run and End Of Run which are essential aspects for reducing overall emissions ($NO_x$ and $N_2O$), achieving a more efficient process and minimising abatement system costs. The global GHG emissions over tertiary catalyst lifetime were evaluated for a typical nitric acid dual plant. The total catalyst volume used for emissions mitigation has been estimated for both catalysts considering the different deactivation behavior tested in laboratory. The reactor design based on Casale proprietary axial-radial gas flow through catalyst beds is shown as robust technology able to reduce overall installed catalyst volume by 5 – 10% with pressure drop across catalyst bed of 90 – 150 mBar and homogeneous gas distribution in the catalyst bed.

# Insight into the Effects of Dopants (Fe, Al) on Catalytic Performance and $SO_2$ Tolerance of $MnO_x$ Catalysts for Low-Temperature $NH_3$-SCR of $NO_x$

H. Li[1], L. Schill[1], R. Fehmann[1], A. Riisager[1*]

[1]*Centre for Catalysis and Sustainable Chemistry, Department of Chemistry, Technical University of Denmark, 2800 Kgs. Lyngby, Denmark*
[*]*ar@kemi.dtu.dk*

**Introduction.** Mn-based catalysts have attracted significant attention as alternatives to vanadium-tungsten-titania (VWT) catalysts in the selective catalytic reduction of $NO_x$ with $NH_3$ ($NH_3$-SCR), due to their excellent low temperature (LT) activity and environmental benignity. However, pure $MnO_x$ catalysts suffer from a narrow active temperature window, undesirable $NH_3$ oxidation at relatively high temperature (>200 °C) and high sensitivity to $H_2O$ and $SO_2$ [1,2]. In this work, the effects of co-metals (Fe and Al) as well as synthesis method on the catalytic performance, $SO_2$ resistance and regenarability of $MnO_x$ catalysts were systematically studied.

**Experimental/methodology.** $MnFeO_x$ and $MnAlO_x$ were prepared by both the citric acid method (CA) and by a novel solvothermal method (H) and characterized by transmission electron microscopy (TEM) and temperature programmed reduction of $H_2$ ($H_2$-TPR). $NH_3$-SCR activity was tested in a fixed-bed quartz reactor at a weight hourly space velocity (WHSV) of 240,000 mL/(g·h) using a feed gas containing 600 ppm NO, 600 ppm $NH_3$, 4.5 vol.% $O_2$, 25 ppm $SO_2$ (when used), 2.5 vol.% $H_2O$ (when used) and $N_2$ as the balance. S-poisoned samples were obtained by pre-treating catalysts with 100 ppm $SO_2$, 4.5 vol.% $O_2$ at 150 °C for 6 h. Catalyst regeneration was performed by heating in air at 400 °C for 2 h.

**Results and discussion.** $MnFeO_x$-H catalyst with a hybrid structure of nanoparticle and nanotube (Fig. 1a) showed better $H_2O$ and $SO_2$ resistance than $MnFeO_x$-CA catalyst (Fig. 1b). The influence of Fe and Al on the performance of $MnO_x$ catalyst was studied next (Fig. 1c). The $NO_x$ conversion of $MnFeO_x$-H was ≥ 90 % at 100 to 250 °C, which is a wider temperature window than that of $MnAlO_x$ (150-250 °C). The $NO_x$ conversion over both S-poisoned catalysts decreased significantly at low temperatures. However, $MnFeO_x$-H-S exhibited a higher $NO_x$ conversion than $MnAlO_x$-H-S. After thermal regeneration, the activity of $MnFeO_x$-H-R was well recovered, which could reach 80% at 200 °C much higher than that of $MnAlO_x$-H-R (40%). Above all, $MnFeO_x$-H exhibited better LT activity, stronger $SO_2$ resistance and better thermal regeneration than $MnAlO_x$-H. $H_2$-TPR results (Fig. 1d) showed that the Fe doped catalysts were reduced at lower temperatures than Al doped counterparts, which could be due to the coordination between Mn and Fe through the redox cycles of $Mn^{4+}/Mn^{3+}/Mn^{2+}$ and $Fe^{3+}/Fe^{2+}$. Especially after regeneration, the coordination between Mn and Fe could help more $Mn^{2+}$ to recover to $Mn^{4+}$ and $Mn^{3+}$, resulting in a better performance than $MnAlO_x$-H-R.

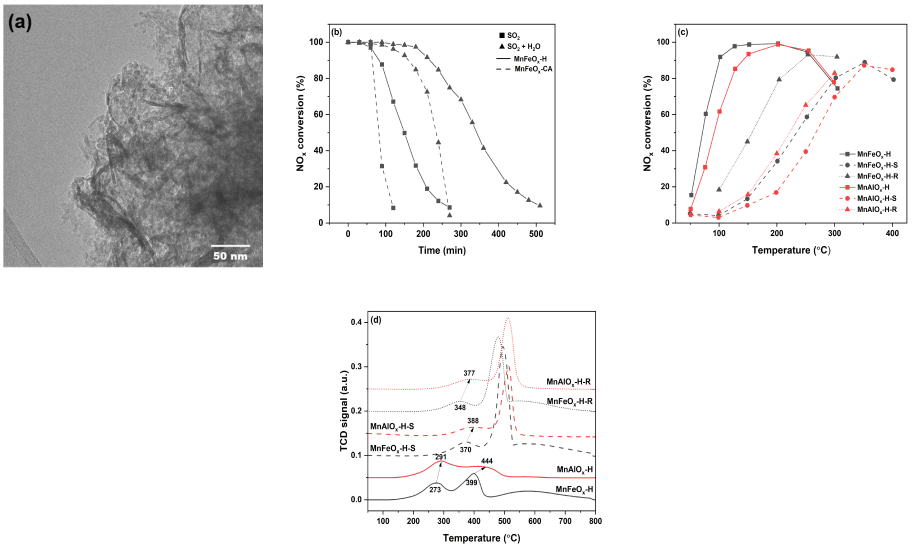

**Fig 1. (a) TEM image of $MnFeO_x$-H catalyst, (b) $SO_2$ and $H_2O$ tests of $MnFeO_x$-H and $MnFeO_x$-CA, (c) $NO_x$ conversion of $MnFeO_x$-H, $MnAlO_x$-H and derived catalysts, (d) $H_2$-TPR of catalysts**

**Keywords:** Fe-zeolite, NOx, Speciation

**Introduction.** The abatement of NOx and $N_2O$ emissions from Diesel vehicles, due to increasingly strict regulations, represents an important challenge for the automotive sector**.** Whereas Cu/CHA catalysts are extensively employed for $NH_3$ SCR, Fe/CHA are now being investigated for their greater $N_2O$ abatement activity and higher selectivity at high temperatures, compared to copper chabazites. While there is general agreement on the redox nature of $NH_3$-SCR mechanism, in which Fe ions cycle between $Fe^{2+}$ and $Fe^{3+}$, the discussion on the nature of the active species and their role in the ammonia SCR chemistry is still open. The presence of different iron species in the catalyst complicates the rationalization of the results obtained with characterizations techniques (ex. UV-vis, Mossbauer) [1]. Transient response methods are here innovatively proposed as an additional methodology to improve the understanding of Fe/CHA catalysts. Specifically, given the important role of $NO_2$ in the SCR chemistry over Fe zeolites, we study the interaction between $NO_2$ and the Fe/CHA catalysts.

**Experimental/methodology.** Three Fe/CHA samples (Fe loading: 1%, 1.5 % and 3.0% w/w) are investigated. In the tests He is the carrier gas (GHSV=266250 Ncc/(h*gcat)) and the species concentrations are measured by an FT-IR gas analyzer and a Mass spectrometer. Two protocols are used: I) $NO_2$ adsorption + TPD: After a pre-oxidation with 8% $O_2$ v/v, 1 h at 550°C, $NO_2$ adsorption is performed at 150 °C (500 ppm of $NO_2$) then a Temperature Programmed Desorption is run (15°C/min, 150°C to 550°C), II) NO+$NH_3$ reduction: after a pre-oxidation step, 500ppm of NO and of $NH_3$ are fed to the catalyst at 330°C. NO+$NH_3$ reduction tests, succesfully employed for Cu/CHA [2], are performed in this study to investigate the oxidation state of the catalyst: firstly, after a pre-oxidation step at 550°C with 8% $O_2$ v/v; secondly, after preoxidation with 8% $O_2$ v/v and 500ppm of $NO_2$. It has been highlighted in previous works that $NO_2$ plays an important role in the SCR chemistry of Fe zeolites, since it is responsible for the greater activity of the Fast SCR with respect to the Standard SCR and is considered involved in the re-oxidation of isolated iron sites [1]. To investigate this aspect and elucidate the relation between the different Fe active species and their interaction with $NO_2$ the evolution of NO and $N_2$ during NO+$NH_3$ reduction tests is observed.

**Results and discussion.** The results show that the amount of released $NO_2$ during the TPD is proportional to the amount of Fe in the sample, in fact a ratio $NO_{2\ ads}/Fe_{load}$ of 2 between the amount of $NO_2$ adsorbed on the catalyst and the total amount of iron present in the sample is observed. Moreover, comparing the NO+$NH_3$ reduction tests performed for each sample, it is evident how the pretreatment with $O_2$ + $NO_2$ at 550°C leads to higher NO consumption/$N_2$ production, which can be rationalized as an increase in the oxidation state of the catalyst. Notably, the observed higher NO consumption cannot be due to the presence of $NO_2$ either in the gas mixture or prestored onto the catalyst surface, since the nitrogen dioxide is only fed during the pre-oxidation step at high temperature. A possible explanation for the stronger initial oxidation (i.e., with $O_2$ only or $O_2$+$NO_2$) is that $NO_2$ activates specific Fe species (e.g., isolated iron sites [1]) which cannot be oxidized in its absence.

**Keywords:** Ce based OSMs, Time-resolved Energy dispersive EXAFS, Emission control catalysis

**Introduction.** Oxygen releasing and storage are occurred by Ce(III)-Ce(IV) redox. Since oxygen storage reaction is very fast and real-time measurement is difficult by gas phase anlysis, real kinetic results for OSC are still lacking. Here we provide a general strategy for OSC kinetic study by probing changes of Ce(III)-Ce(IV) via an operando energy dispersive EXAFS during Oxygen realseing process. In addition, this research reaveled the relation between doping metal and Ce based support which will make it possible for us to develop OSMs for low temperature applications and to design efficient catalysts for other oxidation reaction.

**Experimental/methodology.** Energy dispersive EXAFS was used to monitoring the oxidation state changing of Ce by time resolution of 2 seconds. Non-monochromatic X-ray by bent crystal (polychromator crystal) was focused on the beginning part of sample near the inlet and then diverged towards a position sensitive detector where beam position is correlated to energy. FReLoN detector was used to detect the diverged beam after the sample. Ce L3-edge was measured simultaneously. Pure $Ce_{0.5}Zr_{0.5}O_2$ (CZ); 0.6wt%Cu/$Ce_{0.5}Zr_{0.5}O_2$ (Cu-CZ) and 1wt%Pd/$Ce_{0.5}Zr_{0.5}O_2$ (Pd-CZ) were measured with temperature from 373K to 623K.

**Results and discussion.** With 1wt% of Cu disperied on CZ, the reduction depth and rate was improved. The activation energy of Ce reduction for CZ is twice as much as Pd-CZ and almost four times more than Cu-CZ which is only 36.58 kJ/mol. Due to the unique $[Cu(I)O_2]^{3-}$ generated during redcution, the reductio ability of the Ce was enhenced sigenificantly[1], which means higher oxygen storage capacity can be achieved. The reaction pathway was changed with Cu doping, this also gives one detailed explaination for the metal-support interaction in emission control catalysis .

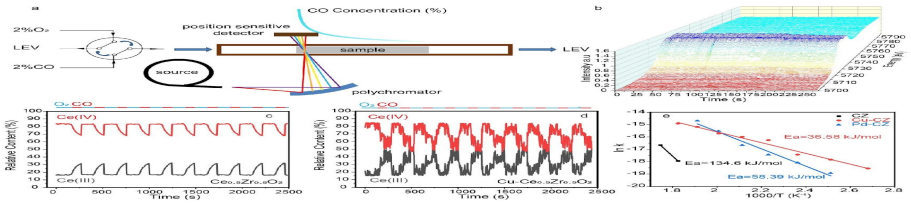

**Figure 1. a Scheme of the experiment setup. b Evolution of Ce L3 edge XANES for CZ during fast gas switch. c,d Relative content for Ce during fast gas switch for CZ and Cu-CZ. e Arrhenius plot for CZ; Cu-CZ and Pd-CZ.**

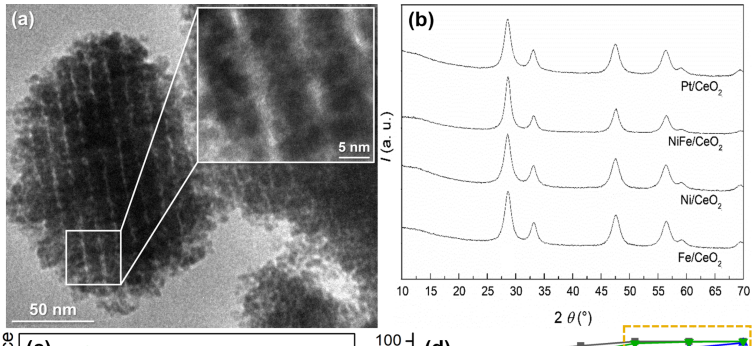
**Keywords:** CO oxidation, active supports, nanostructured ceria, bi-metal catalysts.



**Introduction.** Air pollution has become one of the main environmental issues in the modern society. While for transportation very restrictive limitations on emission are already present, for industrial ones are expected to be adopted in few years, especially for CO emissions that will need to be cut below 500 ppm [1]. Pt-based catalysts are already largely employed for CO oxidation [2]; however, economical aspects cannot be neglected anymore. For such reason, we designed a ceria-supported catalyst based on more affordable metallic active phase, namely Fe, Ni, and Fe-Ni mixed phase [3].

**Experimental.** Soft-templated (CTAB) and hard-templated (SBA-15) ceria [4] were prepared and active metal phases were deposited by incipient wetness impregnation method, aiming to 5 $\%_{mol.}$; then, the materials were calcined in air at 600 °C for 3 h. The catalysts were then thoroughly characterized (BET, XRD, SEM, HR-TEM, EDX, ICP-MS, Raman, CO@FT-IR at 77 K) and then tested for CO oxidation.

**Results and discussion.** From preliminary catalytic screemning, we observed an extremely high activity of Pt catalyst (as expected), slightly lower for Ni catalyst, and almost no catalytic activity for the Fe one. Interestingly, Fe-Ni sample displayed activity close to Pt (> 99%, fulfilling the 500 ppm requirement) in the T range of our interest (300-400 °C), especially when supported on hard-templated ceria. Indeed, the growth inside SBA-15 channels gave 30% larger surface area to the support than CTAB did. XRD did not show any sign of NPs formation; Raman and CO@FT-IR spectroscopies evidenced the insertion of $Ni^{2+}$ isolated species inside superficial defective sites of ceria supports. Such effect was enhanced by the presence of Fe, enhancing the exposure of Ni sites. Finally, the Fe-Ni hard-templated catalyst was tested in real conditions [5] for several days, maintaining a CO conversion > 97%. The slight deactivation was probed with CO@FT-IR and identified in the formation of a small fraction of Ni NPs.

[*] *Corresponding author. Email: yongdan.li@aalto.fi (Y. Li)*

**Keywords:** NO direct decomposition; Perovskite; $BaCoO_3$; $CeO_2$ morphology; Reaction mechanism

**1. Introduction.** Nitrogen oxides ($NO_x$), emitted in the flue gas from stationary sources, is extremely toxic to human health and environment via forming acid rain, photochemical smog, and ozone layer depletion. Currently, several technologies have been proposed for $NO_x$ abatement, such as selective catalytic reduction (SCR) with ammonia, selective non-catalytic reduction and $NO_x$ storage and reduction, and etc. [1]. Among these technologies, NO direct decomposition ($2NO \rightarrow N_2 + O_2$) has been regarded as the most attractive pathway for NO removal due to its eco-friendly and no requirement of reductants [2,3]. However, its practical application is hampered by low activity and low $O_2$ resistance of the catalysts. Moreover, the research on distinct structure-activity relationship and detailed reaction mechanism with/no $O_2$ for NO direct decomposition are still unclear, and the design of high-performance catalyst is another bottleneck that restricts this technology.

**2. Experimental/methodology.** The $BaCoO_3/CeO_2$ catalyst samples were prepared with an excess impregnation method. The three samples by using different morphology of $CeO_2$ support, are referred to as $BaCoO_3/CeO_2$-particles (BCP), $BaCoO_3/CeO_2$-sphere (BCS), and $BaCoO_3/CeO_2$-rod (BCR). The XRD, $N_2$-BET, HRTEM, SEM+EDX, XPS, $H_2$-TPR, $O_2$/NO-TPD, *In situ* DRIFT and isotopic ($^{18}O_2$) exchange experiments were performed to investigate the structure-activity relationship and reaction pathways.

**3. Results and discussion.** The activity, NO conversion to $N_2$ at 800 °C follows an order $BaCoO_3/CeO_2$-r (78.8%) > $BaCoO_3/CeO_2$-s (75.9%) > $BaCoO_3/CeO_2$-p (56.9%)> $BaCoO_3$ (8.6%) at a space velocity 1 g·s/cm$^3$. The $BaCoO_3/CeO_2$-r exhibts high tolerance to $O_2$ and high stability with conversion decrease from 78.8% to 74.6%, 60.0% and 50.0% at 800 °C with 1, 5 and 10 vol% $O_2$, respectively. The high redox activity, higher active oxygen mobility and NO adsorption capability ensures the high activity, while the high surface area (31.29 m$^2$/g) and uniform distribution of active sites on the surface also promote the performance. Such superior catalytic activity and $O_2$ tolerance of BCR are attributed to the strong proveskite-support interaction (PSI) on the oxide phases interface. In situ DRIFT and $^{18}O^2$ isotopic transient exchange experiments reveal that the rate-determining step is the formation of $N_2O$*.

**Introduction.** Mn-based oxides are promising catalysts for the selective catalytic reduction (SCR) of NOx with NH3 at temperatures below 200 °C [1]. There is a general agreement that combining Mn with another metal oxide, such as CeOx improves catalytic activity. However, to date, there is an unsettling debate on the role of Ce as Mn promoter on the SCR reaction. To solve this, here we have systematically studied the effect Ce by preparing, characterizing, and testing around 30 catalysts aiming for a well-controlled homogeneous dispersion of the metal oxides.

**Experimental/methodology.** A series of individual, binary and ternary materials with different molar concentrations were prepared by a controlled co-precipitation method. Several characterization techniques were used, such as X-ray diffraction, $N_2$ physisorption at 77 K, elemental composition by inductive coupled plasma spectrometry, temperature-programmed reduction with $H_2$ and temperature-programmed desorption of $NH_3$, high-resolution X-ray photoelectron spectroscopy, X-ray absorption spectroscopy and annular dark-field scanning transmission electron microscopy in conjunction with electron energy-loss spectroscopy. The catalytic activity measurements in the $NH_3$-SCR reaction were carried out in a commercial PID reactor at conditions close to a real lean-burn diesel engine.

**Results and discussion.** Characterization strongly confirms that the synthetic route renders an amorphous and homogeneous distribution of all the metal atoms in the ternary Mn, Ce and Ti mixed oxides. This is also corroborated by high-resolution electron microscopy (figure 1a). XPS also confirms that surface and bulk compositions match. $H_2$-TPR suggest an interaction of Mn species with Ce, which increases the reduction temperature of Mn. The catalytic activity of the samples was measured at low temperature (150 °C). When activity was surface-area normalized, a clear linear dependency with the amount of Mn is observed in the binary Mn-Ti samples. The ternary Mn-Ce-Ti has also a pseudolinear correlation with the Mn content but with a lower slope (Figure 1b). We inferred that MnOx species in the binary Mn-Ti catalysts are more active than in the Mn-Ce-Ti catalysts and that Ce is just an structural promotor, increasing catalyst surface area. On the other hand, addition of Ce is increasing $N_2$ selectivity as it suppresses second step oxidation and thus $N_2O$ formation by a dilution effect on the MnOx active sites [2] (see figure 1c and d) The latter still makes Ce an attractive additive for Mn-Ti systems.

**Figure 1.** a) Elemental mapping of a selected Mn-Ce-Ti catalyst in high magnification showing a homogeneous distribution of the different metal oxides. b) Surface-specific activities for the NO reduction at 150 °C plotted as a function of the Mn content on the catalysts. The blue dots correspond to the ternary Mn-Ce-Ti catalysts. The red dots are from the binary Mn-Ti and the individual Mn catalysts. c) Surface-specific $N_2O$ rates at 150 °C as a function of the Mn surface density. d) Schematic representation of the reaction mechanism in a Mn-Ce-Ti ternary catalyst in which a well-mixed amorphous structure promotes the spacing of MnOx species and therefore reduces the formation of $N_2O$.

**Keywords:** NOx, $NH_3$, Water-gas-shift reaction

**Introduction.** NOx emitted from combustor of power plant and mobile sources is known to be environmental pollutants. Selective catalytic reduction of NOx to $N_2$ by $NH_3$ has been investigated promising way to reduce NOx emission. We have been proposed that NOx should be converted to valuable materials rather than $N_2$ production.

We reported that Pt catalysts supported on $TiO_2$ showed high activity for NO to $NH_3$ reaction using CO + $H_2O$ as reductant in the previous study[1]. Intermediate species of water gas shift reaction (WGS), such as formate, were involved in $NH_3$ formation on the NO-CO-$H_2O$ reaction. Considering this finding, the catalysts having WGS activity would have a capacity to form $NH_3$ in NO-CO-$H_2O$ reaction. $Cu/CeO_2$ is reported to show high activity for WGS reaction, we employed $Cu/CeO_2$ for $NH_3$ formation on NO-CO-$H_2O$ reaction in this study[2].

**Experimental/methodology.** Copper catalysts were prepared by means of incipient wetness method. After 1, 3, 5, 10, 20 and 40wt% Cu loading, the sample was calcined at 773 K for 4 h, and then reduced under 10 vol%$H_2/N_2$ at 673 K for 1 hour. Catalytic activity test was performed using a fixed bed flow reactor. Sample was used 0.15 g. The concentration of NO-CO-$H_2O$ reaction were 1000 ppm NO, 3000 ppm CO and 1% $H_2O$.

**Results and discussion.** Temperature dependence of Catalytic activity of 5wt% $Cu/CeO_2$ for the NO-CO-$H_2O$ are shown in Fig. For NO-CO-$H_2O$ reaction, NO conversion increased with increasing temperature, and then reached 100 % above 473 K. NO conversions to $NH_3$ were 68% and 83% at 423 and 473K, respectively. Above 473 K, NO conversion to $NH_3$ were in the range of 80-85%. $N_2$+$N_2O$ concentrations were lower than 44 ppm, which was corresponding to NO conversion to $N_2$+$N_2O$ of 4%, at all temperature measured. NO conversion to $NH_3$ on $Pt/TiO_2$ at 423 K was 61%, so that $Cu/CeO_2$ exhibited almost 10% higher value. Almost same $NH_3$ formation as $Pt/TiO_2$ was succeeded without using the precious metal.

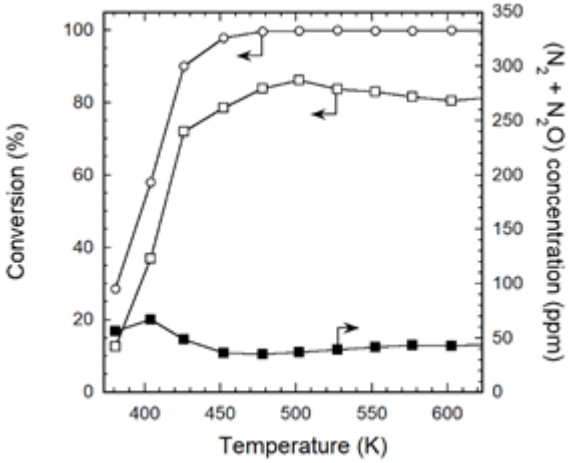

Fig. Catalytic activity of 5wt%$Cu/CeO_2$ catalyst under NO-CO-$H_2O$, (circle) NO conversion, (square) NO conversion to $NH_3$, (filled square) $N_2$ and $N_2O$ concentrationtables

**Keywords:** exhaust gas aftertreatment, selective catalytic reduction, $NO_x$, reaction kinetics

**Introduction**

Selective catalytic reduction of nitrogen oxides (SCR) using Cu ion exchanged into SSZ-13 zeolite, Cu/SSZ13, is the current standard technology for diesel engine exhaust NO emissions reduction. The active species start as ion-exchanged Cu, with 2 such sites often described, $Z_2Cu$ and ZCuOH, where Z represents a zeolite Al site. However, a distribution of sites exists, including these two ion-exchanged Cu types, solvated Cu, as well as multinuclear Cu and CuO nanoparticles. Each of these plays a different role in desired and undesired reactions. The site distribution evolves with time on stream and reaction conditions, and therefore the model must evolve also. This means including rate laws for changes in active site concentrations as a function of reaction environment conditions.

**Experimental methods**

A commercial Cu-SSZ-13 SCR honeycomb monolith provided by Cummins Inc. was employed in the experiments. The migration of Cu species during hydrothermal aging, as well as the change in Cu distribution on low-temperature and high-temperature $NH_3$ oxidation and SCR reaction mechanisms are considered. The impact of sulfur oxides ($SO_2$ and $SO_3$) on the transformation processes is also investigated. Characterization techniques include $H_2$ temperature-programmed reduction ($H_2$TPR), NO+$NH_3$-TPR, $NH_3$ temperature-programmed desorption ($NH_3$-TPD), CO titration, and diffuse reflectance infrared Fourier transform spectroscopy (DRIFTS) are used to characterize and quantify catalyst site densities. Based on the experimental data, kinetic equations for transformation rates for individual site types are expressed as functions of actual site concentration, gas composition and temperature.

**Results and discussion**

Cu migration occurs both from the ZCuOH to the $Z_2Cu$ position, and from both ion-exchanged positions to agglomerated Cu particles. For the former, “mild” hydrothermal aging (HTA) conditions lead to such a transition. Changes in $Z_2Cu$ and ZCuOH site numbers have been correlated to changes in Brönsted acid sites, as $Z_2Cu$ requires 2 Al sites whereas ZCuOH only 1. The total amount of $NH_3$ desorbed remains constant, as does the total amount of ion-exchanged Cu measured in a separate experiment. But there is a shift in $NH_3$ desorbing at low versus high temperature, away from the high temperature associated with the Brönsted acid sites in the zeolite, to the lower temperature associated with the Lewis acid Cu site. The loss in Brönsted acid site number correlates directly to the amount of ZCuOH that transformed to $Z_2Cu$. In terms of Cu agglomeration into particles, higher temperatures induce this loss in SCR active species through the zeolite structure collapsing and Cu dissociation from the zeolite framework positions and subsequent agglomeration.

# $NO_x$ adsorption and stability on Pd/SSZ-13 low-T adsorbers: mechanistic pathways investigated by *Operando* FTIR spectroscopy

Y. Hamid[1], R. Matarrese[1], S. Morandi[2], L. Castoldi[1], L. Lietti[1*]

[1]*Politecnico di Milano, Dept. of Energy, Milano, Italy*

**Keywords:** Pd-doped zeolites, Cold-start, NOx adsorbers, PNA, Pd, SSZ-13, Operando FT – IR Spectroscopy.

**Introduction.** Significant amounts of $NO_x$ are emitted during vehicle cold-start, since after-treatment devices like SCR and/or LNT systems are inactive at low temperature [1,2]. A possible solution is the adoption of low temperature $NO_x$ adsorbers, the so-called Passive NOx Adsorbers (PNAs) that utilize their ability to temporarily store $NO_x$ at low temperature (<150 °C) and release at higher temperature. The use of Pd-promoted zeolites has been suggested, which however must be optimized in view of the high cost of the active Pd component. Goal of this study is to deepen mechanistic aspects related to the low-T adsorption/desorption of $NO_x$ and to envisage by means of *Operando* FT- IR Spectroscopy and microreactor studies the role of species like CO, HC, $O_2$ and $H_2O$ on the performance of catalyst .

**Experimental/methodology.** An home-made Pd-doped chabazite sample (Pd loading 1% w/w), calcined at 750°C has been considered in this study. $NO_x$ adsorption experiments were conducted both in a microreactor apparatus and in an *operando* FT-IR apparatus at different temperatures; the thermal stability of the $NO_x$ stored species has been investigated by temperature programmed desorption (TPD). Experiments have been done in presence/absence of CO, $C_3H_6$, $H_2O$ and $O_2$.

**Results and discussion.** Catalyst characterization indicates the presence of isolated Pd species (with oxidation states +1 and +2) and (minor) PdO particles as well. Upon $NO_x$ adsorption the formation of $Pd^{n+}$ nitrosyls , in the form of anhydrous or hydrated complexes depending on the adsorption temperature (bands in the range 1750-1850 $cm^{-1}$) is observed, involving $Pd^{2+}$ to $Pd^{+}$ sites. Nitrosyls formation is accompanied by $NO_2$ evolution, and possibly by the reduction of $Pd^{2+}$ to $Pd^{+}$. Bands related to monodentate and bidentate nitrates (1330 and 1457 $cm^{-1}$) were apparent as well when adsorption is carried out at low temperatures. Upon heating the sample (see Fig. 1a as example), hydrated nitrosyls transform into anhydrous nitrosyls (bands at 1810 and 1850 $cm^{-1}$) below 200°C, and desorption of water is observed. Nitrates also decompose at these temperatures. Anhydrous nitrosyls show much higher thermal stability and decompose above 300°C (Fig. 1c). When CO is present in the feed, Pd-carbonyls and -nitrosyls are formed, but the displacement of carbonyls by nitrosyls is observed. However CO reduces the Pd sites and modify the NO adsorption. Similar effects have been observed in the case of $C_3H_6$, although in this case the hydrocarbon molecule is not easily displaced by NO.

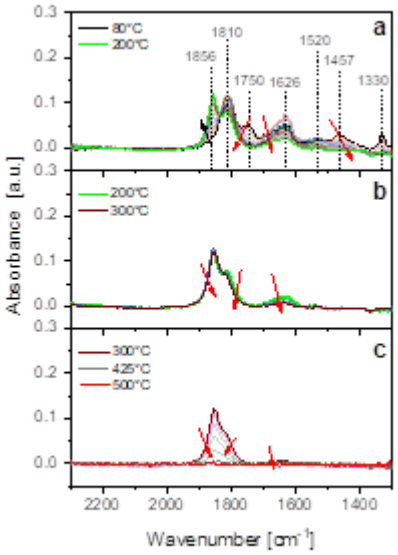

**Fig 1. FTIR spectra recorded upon heating the Pd/SSZ-13 sample after NO adsorption at 80°C in the presence of $O_2$ and $H_2O$**

The impact of $O_2$ and $H_2O$ on the pathways involved in NOx adsorption/desorption have also been analyzed. Oxygen alone has a minor effect on the catalyst's adsorption capacity and on the stability of the nitrosyls, while water slightly modifies the NO storage capacity but greatly modifies the thermal stability of the adsorbed species.

**Keywords:** SCR, catalyst deactivation, phosphorous

**Introduction.** Emission of nitrogen oxides ($NO_x$) is regarded as a major source of atmospheric pollution and must be kept at a minimum. Selective catalytic reduction (SCR) catalysts are commonly used for $NO_x$ emission reduction but with the increase in bio-based fuels for engines and in incineration processes, phosphorus contamination is more common compared to processes utilizing fossil-based fuels. In this work we have studied commercial $V_2O_5$-$WO_3$/$TiO_2$ monolith catalysts that have been exposed to bio-based fuel during incineration for two different periods of time in a commercial system.

**Experimental/methodology.** In this study we have performed characterization of a fresh unused monolith sample and compared it with samples collected from the monoliths used in a commerical plant for different time on streams utilising a range of methods: Temperature programmed desorption of ammonia ($NH_3$-TPD), X-ray photoelectron spectroscopy (XPS) and activity measurements.

**Results and discussion.** Samples were extracted from the used monoliths and the most significant finding regarding impurity elements was the increasing amount of phosphorous with time on stream, together with a lower activity regarding NOx conversion. Other elements showed a rather small or insignificant change with use for these samples. The phosphorous species were found to be of the phosphate types and the Brønsted site density and apparent strength was similar to the native catalyst. XPS data indicate that the oxidation state of V has changed in contrast to W, which remained the same. A lock of V into an oxidation state of +IV, not suited for the operating red-ox cycles, is detrimental to activity. Figure 1 shows the concentration of elements measured by EDS profiles of the cross section of the catalyst monolith walls.

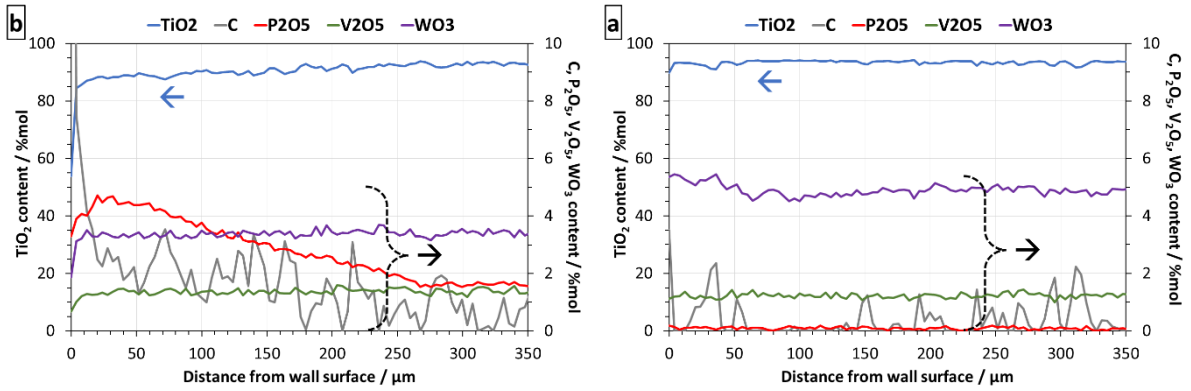

Figure 1: EDS composition profiles for the catalyst material as well as carbon and phosphorous, from edge to centre of the catalyst monolith wall; a) fresh catalyst and b) used catalyst.

**Introduction**

To reach EU climate targets, the steel and iron production sectors are looking to decrease their $CO_2$ emissions by up to 90% by 2050. The INITIATE project aims to demonstrate how residual carbon-rich gases, such as blast furnace gas (BFG) and basic oxygen furnace gas (BOFG), from the steel sector can become a valuable feedstock for the chemical sector, leading to a cost-efficient decarbonisation of the steel industry.[1] The demonstration includes the continuous production of $N_2$+$H_2$ and $CO_2$ streams (i.e., a feedstock for the ammonia and urea industries), reducing the overall carbon footprint. The project aims at a 30% decrease of primary energy use, a 40% decrease of raw material demand and up to 90% reduction in the direct $CO_2$ emissions. The INITIATE project takes all necessary steps to provide the basis for the roll-out of a 1st commercial size demonstrator at 50 kt/y urea on the basis of BOFG.

**Experimental/methodology**

The design of the pilot plant, which will be constructed at the partner SWERIM's site in Lulea, Sweden, is nearing completion. The pilot will take BFG and BOFG from the SSAB steel plant next-door, decarbonise it, tune the $H_2/N_2$ ratio of the intermediate product and produce $NH_3$ at TRL-7 scale. For the novel concept of BOFG to ammonia, the functional materials (i.e., water gas shift (WGS) catalyst to produce hydrogen from BOFG; materials for the removal of sulphur species and CO + $CO_2$ to purify the hydrogen stream for ammonia production) are currently being defined and evaluated at lab-scale.

**Results and discussion**

In the INITIATE project, the WGS section is an essential part of the technology where CO-rich gases are converted to hydrogen and $CO_2$. We have demonstrated previously the suitability of the iron-based HTWGS catalyst for the production of hydrogen from BFG streams.[2] An advanced split-flow WGS configuration will be deployed to produce hydrogen from industrial residual gases from the iron and steel industry at pilot plant scale. This WGS concept allows to optimise the steam requirement, contributing to minimise the energy penalty associated with the novel $CO_2$ removal.[3] An important aspect is the identification and quantification of the contaminants present in the BFG and BOFG, as it influences the functional materials choice and pilot lay-out. In parallel to a literature review, extensive contaminant measurement campaigns were performed at SSAB for BOFG. This resulted in a detailed overview of the type and level of contaminants that may be expected and the definition of the pilot clean-up section upstream the ammonia loop. The findings emphasise the need for tailored investigations per site as the gas composition can vary significantly.

# Aging of Three-Way Catalysts for Biogas Fuelled Heavy-Duty Trucks

Anders Ersson[1]*, Samuel af Ugglas[1,2], Maximilian Kempe[1,2], Moa Sundén[1], and Henrik Kusar[2]

[1]*Scania CV AB, Södertälje (Sweden)*
[2] *Department of Chemical Engineering, KTH – Royal Institute of Technology, Stockholm, (Sweden)*

**Keywords:** Three-way catalysts, biogas, heavy transport, aging

**Introduction.** Biogas as fuel for heavy transport have become a very good alternative to conventional diesel. The biogas, which can be produced from a large variety of wastes, is considered a very beneficial biofuels from a greenhouse gas perspective [1]. The biogas is most commonly used as a fuel in Otto type engines where three way catalysts, TWC, is the preferred exhaust treatment solution. Even though TWC:s have been around for a long time for gasoline cars. The use for heavy-duty trucks and the use of gaseous fuels, mainly consisting of methane puts new demands on the TWC catalysts. For example the unburnt methane from the fuel is much more difficult to oxidize compared to the unburnt hydrocarbons from gasoline engines [2].

The TWC in heavy trucks have significantly higher demands on life lengths compared to gasoline fuelled passenger cars, which increases the demand for high resilience towards aging for TWC used in heavy duty applications.

In the present study catalyst samples subjected to accelerated hydrothermal aging were compared to aged catalysts samples from real life vehicles. The material properties as well as the catalytic activity were used for the comparison.

**Experimental/methodology.** Seven catalytic samples were retrieved from a fresh, commercially available three-way catalyst. Six of the samples were aged in a gas-flow reactor where the $O_2$ concentration, temperature, and time were changed. The activity of the aged and fresh catalyst samples were evaluated in a synthetic catalytic activity test reactor (SCAT) at different static light-off conditions. The results were compared to a number of aged samples from actual trucks.

**Results and discussion.** The main objectives of the study was to compared accelerated hydrothermal aging in labscale environment with the aging of real field TWC samples. The study have shown that the lab-scale aging affected both the $CH_4$ oxidation and the reduction of the $NO_X$ with tests of field age samples. The ongoing work will compare these results with the result for several field aged samples from biogas fuelled heavy duty trucks.

# The Effect of Various Renewable Fuels on Diesel Particulate Filter Performance

S. af Ugglas[1,2*], A. Ersson[1], L. J. Pettersson[2], H. Kusar[2]

[1]*Scania CV AB, Södertälje, Sweden*
[2]*KTH Royal Institute of Technology Chemical Engineering, Stockholm, Sweden*
[*]*samuel.af.ugglas@scania.com*

**Introduction**

The use of fuels derived from renewable sources is increasing in the pursuit of reducing the impact on climate and fossil dependency of the transport sector [1]. However, the use of biofuels changes the composition of the exhaust gases and can introduce impurities posing new challenges to the exhaust aftertreatment system [2]. Alkali metals present in the exhaust are known to poison the automotive catalysts and also form ash with other properties compared to lubricant-derived ash which further impacts the performance of the diesel particulate filter [3, 4].

**Experimental**

Catalytic diesel particulate filters have been collected from heavy-duty vehicles running on various renewable fuels and blends. Evaluation of the catalytic activity towards NO and HC oxidation was performed with a gas flow reactor connected to a continuous gas analysis equipment. Assessment of the aging is performed by correlating the physicochemical properties to the catalytic performance of the samples.

**Results and discussion**

Chemical poisons can be found in various degree for all samples. While the level of poisons appears to be less dependent of kilometers driven, the amount of Na and K are strongly correlated to the composition of the fuel used during operation. Assessment of the samples indicates excessive aging of the samples with higher alkali metal content leading to a decrease in the catalytic activity.

# Doped Ceria Catalysts for NOx Storage and Reduction

O. Hamill[1], A. Goguet[1], N. Collis[2], P. Millington[2], J. Collier[2], L. Mantarosie[2], N. Artioli[*]

**Keywords:** Doped Ceria, NOx Reduction, Emission Control

**Introduction:**

The new Euro 7 protocol, proposed by the Commission on 26th October 2022, concerning emissions of lean-burn engines, presents a need for further optimisation of existing after-treatment technologies. It reveals a 35% reduction to the NOx emission limit for cars and vans, compared to Euro 6 [1]. A well-known technology employed to reduce NOx to clean emissions in light-duty vehicles is the Lean NOx Trap (LNT). LNTs employ catalysts consisting of PGMs supported on ceria ($CeO_2$) or other mixed oxides. Ceria's redox property makes it an attractive selection, as well as its ability to store $NO_x$ at low temp (<300 ˚C), especially when Pt is present. Storage properties of ceria can be further enhanced by doping. Dopants reportedly allow ceria to function better at low temperature (<300 ˚C), and to reduce the PGM loading required to achieve the same conversion efficiencies. [2] The RE metals Sm, Pr and Nd have been employed as dopants on $CeO_2$ for LNT applications to increase surface oxygen content, oxygen vacancies, defect densities, and cause changes to the Pt-ceria interaction. These structural changes can allow for higher NSC during lean operation and enhanced activation during rich purge. [3] Sm, Pr and Nd doped catalysts (10 wt.%) were synthesised on a range of ceria based catalysts with different Pt loadings (0-1 wt.%). Morphological changes observed through dopant addition has been investigated and related to catalytic performance increases.

**Experimental/methodology:**

NOx Storage Capacity experiments were carried out in a fixed bed reactor (tot. flow 200 Ncc/min, 40mg cat). Initial activation and cleaning ran from RT to 450˚C flowing 0.4% $H_2$ in Ar. Storage conditions consisted of 5% $O_2$, 400ppm NO, balanced with Ar. For $H_2$-TPR experiments; catalysts were pretreated to 500°C for 1hr in 10% $O_2$/He (35ml/min). $H_2$ consumption was measured from 0-1000°C in 5%$H_2$/Ar (35ml/min) at 10˚C/min.

**Results and discussion:**

NSC experiments were performed to assess the differences in $NO_x$ storage capabilities at low temperatures (150-300˚C), on a range of doped ceria and Pt-ceria samples (Figure 1). It is observed that, at 150˚C, the NSC increases by 15% and 40% compared to that of the bare support, upon doping with Sm and Pr, respectively. To understand the dopant effect on NOx storage and oxidation capability, $H_2$-TPR experiments were also performed. Figure 2 shows reduction profiles of the four supports. Ceria shows the expected $H_2$ consumption peaks: from ~200-600 $^0$C and >700 $^0$C related to surface and bulk reductions of $CeO_2$, respectively. Upon 10wt.% addition of Sm, Pr and Nd, more intense peaks of reduction are observed between 250-450˚C along with a continuous $H_2$ consumption section between 600-700˚C possibly indicating a mixed phase reduction.

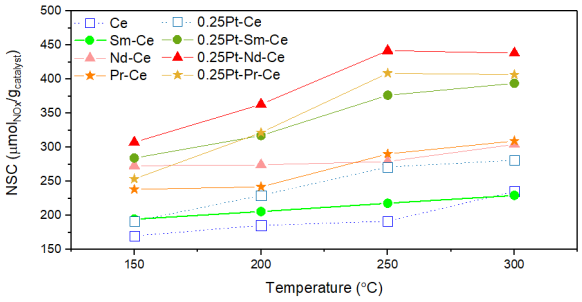

Figure 1. NSC experiments *(Ce = Ceria)

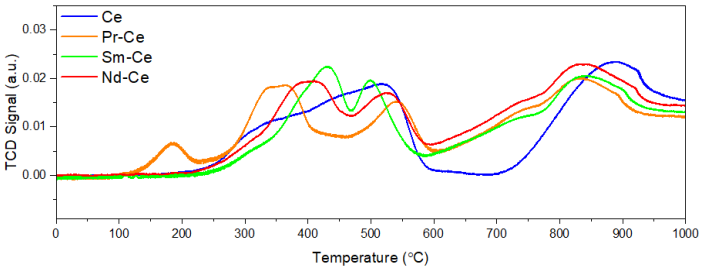

Figure 2. $H_2$-TPR experiments *(Ce = Ceria)

Many other characterisation techniques have also been used to study catalyst modification with doping. XPS highlighted an increase in surface O content present on the doped samples. Raman spectroscopy investigations showed higher defect densities on doped surface. EELS imaging illustrated partial separation of Pt at the $CeO_2$ surface caused by Sm doping which affects the Pt-Ce bonding. These studied effects may help explain the greater catalytic performances of the doped catalysts to remove NOx at low temperatures.

# Interaction between Sorbent and Metal Catalyst in a Dual Functional Material for the Direct Air Capture & Conversion of $CO_2$

Freek Karaçoban, Tomas van Haasterecht, Harry Bitter
*Wageningen University, Wageningen, The Netherlands*

**Keywords:** Direct air capture, Carbon dioxide, Dual functional material, Potassium carbonate, Ruthenium

**Introduction.**

To combat climate change, approaches to capture and convert $CO_2$ are developed. One of these is dual functional materials (DFMs) that combine a $CO_2$ sorbent and catalyst. In the presence of $H_2$, the gaseous or captured form of $CO_2$ is partially converted. In DFMs, endothermic $CO_2$ desorption is coupled to exothermic $CO_2$ hydrogenation, resulting in an integrated heat exchange. Here we will show that sorbent/catalyst interactions exist in a DFM of $K_2CO_3$ (sorbent) and ruthenium nanoparticles (catalyst) supported on α-$Al_2O_3$.

$$K_2CO_3 + CO_2 + H_2O \underset{\text{Upon heating, 100-150 °C}}{\overset{\text{Ambient air, room temperature}}{\rightleftharpoons}} 2\ KHCO_3 \xrightarrow[\text{Ruthenium}]{H_2} K_2CO_3 + CH_4 + H_2O$$

**Experimental/methodology.**

The aim of this study was to identify interactions between $K_2CO_3$ and Ru in a DFM. To do so, the DFM Ru/$K_2CO_3$/α-$Al_2O_3$ was compared to a physical mixture of Ru/α-$Al_2O_3$ and $K_2CO_3$/α-$Al_2O_3$.

To synthesize the DFM, the support was impregnated with ruthenium(III) nitrosyl nitrate. After drying and a heat treatment in $N_2$ at 450 °C, the support was impregnated with $K_2CO_3$. The materials were tested in a packed bed reactor through which air (420 ppm $CO_2$) was flown at 30 °C to capture $CO_2$. The reactor was then heated to 200 °C (10 °C $min^{-1}$) under $H_2$. $CO_2$ was quantified using an IR detector and hydrogenation products were identified using mass spectrometry.

**Results and discussion.**

Figure 1A shows the $CO_2$ concentration and the massspectrometer m/z=15 signal (methane) during the desorption/conversion phase. $CO_2$ desorbed over a temperature range of 60-150 °C. The physical mixture produced methane over a temperature range of 100-200 °C, while this occurred at a higher temperature for the DMF around 200 °C. We hypothesize that in the DFM, reactive intermediates are more strongly bound to the ruthenium surface, hence methane is released at a higher temperature. In such a material, the conversion should thus be directly correlated with available Ru sites.

To investigate this, the loadings of Ru and $K_2CO_3$ were varied on the DFM (Figure 1B). By increasing Ru loading from 0.7 to 2.4 wt%, $CO_2$ conversion increased. An increase in conversion was also achieved by lowering $K_2CO_3$ loading from 10 to 2.5-5 wt%. The improved conversion with increased Ru loading is likely a result of more available Ru sites. Potentially, $K_2CO_3$ partially covers the Ru surface with a 10 wt% loading. Lowering the $K_2CO_3$ loading to 2.5-5 wt% might thus make more sites available, increasing conversion.

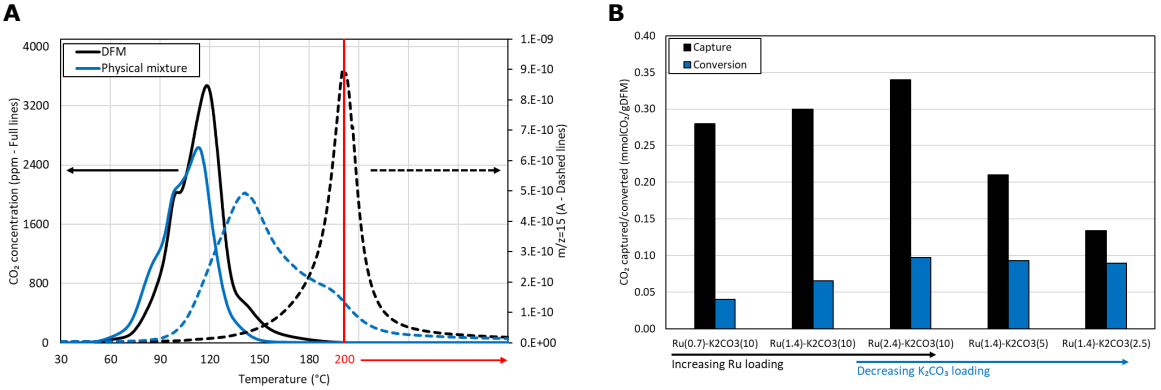

*Figure 1: A) $CO_2$ concentration (full lines) and mass spectrometry m/z=15 signal (dashed lines) during the desorption/conversion phase of the DFM (black) and physical mixture (blue). B) $CO_2$ capture and conversion for materials with various Ru/$K_2CO_3$ loadings. Weight loadings (%) in both figures are between brackets.*

# Mechanism for $SO_2$ Poisoning of Cu-CHA during Low Temperature $NH_3$-SCR

J.D. Bjerregaard[1*], M. Votsmeier[2], H. Grönbeck[1]

[1]*Department of Physics, Chalmers University of Technology, Gothenburg, Sweden*
[2]*Umicore AG & Co. KG, Hanau, Germany*
[*]*Joachim.bjerregaard@chalmers.se*

**Introduction.** Copper exchanged chabazite (Cu-CHA) is state-of-art catalyst for deNOx by ammonia-assisted selective catalytic reduction ($NH_3$-SCR) in diesel emission control. It is widely used thanks to its good low-temperature activity and hydrothermal stability [1]. However, the catalyst is sensitive to small amounts of sulfur species present in the exhaust stream that accumulate in the catalyst and lead to deactivation over time [2]. A better understanding of the deactivation mechanism is desired to develop catalysts with higher sulfur resistance. The objective of this study is to propose a mechanism for $SO_2$ poisoning of Cu-CHA during low temperature $NH_3$-SCR from first principles calculations. This work has been previously published in the Journal of Catalysis, volume 417, January 2023.

**Experimental/methodology.** Spin polarized density functional theory calculations have been performed in the Vienna Ab initio Simulation Package (VASP). The PBE functional is used to describe the exchange-correlation term, augmented with Grimme 3D approach to describe van der Waals interactions, and a Hubbard term to describe the localization of electrons in the 3d orbital of Cu. Transition states are located using climbing image nudged elastic band (CI-NEB) and ab initio molecular dynamics (AIMD) simulations are performed to investigate the flat energy landscape and to study diffusion of Cu species. Ab initio thermodynamic analyses are carried out to study the stable structures at reaction conditions.

**Results and discussion.** During typical reaction conditions, the Cu ions are solvated by $NH_3$, forming $[Cu(NH_3)_2]^+$ [3], which are inter-cage mobile. If two $[Cu(NH_3)_2]^+$ complexes are present in the same cage, $O_2$ can be activated, forming $[Cu_2(NH_3)_4O_2]^{2+}$, which is a critical step in low-temperature $NH_3$-SCR [4]. We find that $SO_2$ forms a stable complex $[Cu_2(NH_3)_4SO_4]^{2+}$ when interacting with $[Cu_2(NH_3)_4O_2]^{2+}$. We propose a reaction mechanism in which $NH_3$ and NO couple over $[Cu_2(NH_3)_4SO_4]^{2+}$ forming $H_2SO_4$, $H_2O$ and $N_2$. The inter-cage diffusion of $H_2SO_4$ has a barrier of 1.45 eV suggesting that sulfur might accumulate inside the CHA-cage. Furthermore, we find that $H_2SO_4$ can undergo an acid-base reaction and that $HSO_4(NH_4)$ is most stable species at typical reaction conditions. Based on these results, we investigate how the presence of multiple $HSO_4(NH_4)$ species in the CHA-cage may deactivate the catalyst. Constrained AIMD simulations are performed to investigate the stability of paired $[Cu(NH_3)_2]^+$ complexes in presence of zero, one or two $HSO_4(NH_4)$ species, and results are shown in Figure 1. We conclude that the pairing of $[Cu(NH_3)_2]^+$ is destabilized in presence of two $HSO_4(NH_4)$ species, which prevents $O_2$ activations. This gives a possible explanation for how $HSO_4(NH_4)$ deactivates the catalyst. Our results suggest that low-temperature $SO_2$ poisoning is of physical character, in which the presence of sulfur species hinders the activation of $O_2$ over two $[Cu(NH_3)_2]^+$ complexes. Thus maintaining facile diffusion of $[Cu(NH_3)_2]^+$ is critical for preventing loss in SCR activity.

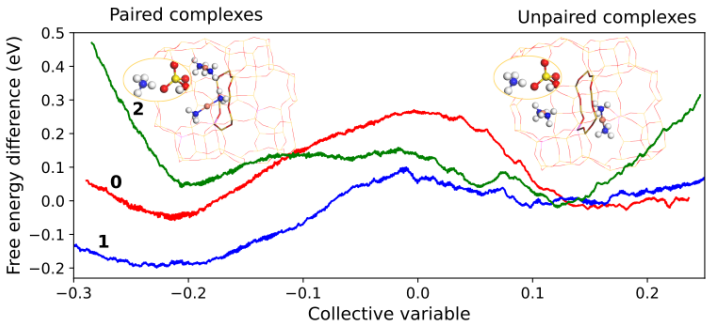

**Figure SEQ Figure * ARABIC 1** - AIMD simulations for diffusion of a [Cu(NH3)2]+ complex through an eight-membered ring in presence of zero (red), one(blue) and two (green) HSO4(NH4) in the cage.

**Keywords:** methane oxidation, noble metal clusters, emission control

**Introduction.** Methane/biomethane is a key energy carrier for the transition from fossil to more sustainable resources. Due to the high hydrogen-to-carbon-ratio in $CH_4$, the $CO_2$ emissions can be significantly reduced compared to those resulting from the combustion of other hydrocarbons [1], with a major decrease recorded especially for biomethane and methane obtained from green hydrogen. Nevertheless, an important drawback is the high greenhouse gas potential of methane itself. Among different catalysts tested for reducing the $CH_4$ slip, Pd-based systems are known to show the highest efficiency. However, they still suffer from sulfur poisoning and water deactivation. Numerous attempts have been undertaken to understand the deactivation and regeneration behavior of Pd-catalysts, and a clear influence of the carrier material and gas composition was observed [2,3].

**Experimental/methodology.** A series of Pd-$CeO_2$ based catalysts with different noble metal loadings (13 wt.%) were prepared by incipient wetness impregnation. After different pre-treatment procedures, the catalytic performance was investigated in plug-flow reactor between 200-550 °C using a gas mixture containing 3200 ppm $CH_4$, 10% $O_2$ in $N_2$. To obtain structure-activity correlations, the catalysts were characterized by complementary *in situ* and *ex situ* methods including: X-ray diffraction (XRD), temperature programmed reduction, electron microscopy and X-ray absorption spectroscopy (XAS). Additionally, the nature of active species was identified by *in situ* diffuse reflectance infrared Fourier transform spectroscopy (DRIFTS) measurements supplemented by density functional theory (DFT) calculations.

**Results and discussion.** The results obtained in this study indicate a strong impact of catalyst pre-treatment conditions on the activity of $Pd/CeO_2$-catalysts. Whereas an oxidizing treatment at high temperatures results in catalyst deactivation, a significant activity gain was obtained upon reduction in CO- or $H_2$-containing gas mixtures. In line with our previous studies [4,5], this positive effect of a reducing treatment could be correlated with the tuning of the interface between the reduced noble metal nanoparticles and ceria support. The formation or redispersion of Pd nanoparticles depending on the catalyst treatment was revealed by environmental transmission electron microscopy (ETEM) measurements. Further differences in the noble metal structure leading to a higher or lower catalyst durability were uncovered by *in situ* DRIFTS and *operando* XAS characterization, and were additionally supported by DFT calculations [6].

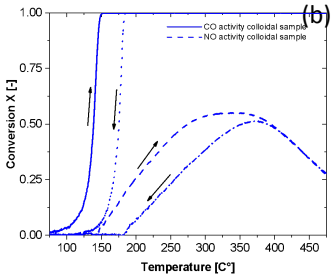
**Introduction.** Pt and Pd are commonly used in emission control for catalytic oxidation of harmful and toxic pollutants such as carbon monoxide, nitrogen oxide or hydrocarbons. Their limited supply, however, requires an efficient use. One option to increase the activity, stability and poisoning tolerance of such catalysts is the use of bimetallic PtPd samples. [1] Despite numerous studies have reported synergistic effects, the exact nature of Pt-Pd interaction, noble metal distribution and state as well as the surface/bulk composition of bimetallic particles are still subject to extensive discussion. [2, 3, 4] In our study, the impact of the catalyst preparation method on the Pt-Pd bimetallic particle structure and evolution during CO, NO and CO/NO oxidation is systematically investigated.

**Experimental/methodology.** Catalysts containing 1 wt% Pt and 1 wt% Pd on γ-$Al_2O_3$ were prepared by conventional and advanced preparation methods such as incipient wetness impregnation, colloidal synthesis, supercritical fluid reactive deposition and flame spray pyrolysis. [4, 5, 6] The resulting samples were in-depth characterized by XRD, TEM, EDXS, $N_2$-physisorption and *in situ* XAS measurements. Activity tests were conducted for CO-, NO- and combined CO/NO-oxidation in excess oxygen.

(a) 



(b) 

**Fig.1: (a) Uniform distribution of PtPd particles obtained by colloidal synthesis on γ-$Al_2O_3$ support; (b) Corresponding CO and NO oxidation activity**

**Results and discussion.** Significant differences in Pt-Pd nanoparticle size, structure and composition were obtained by varying the preparation procedure. In general, a poor catalyst uniformity was found for most conventional synthesis methods. In contrast, a high alloying degree and good distribution resulted by colloidal synthesis of bimetallic nanoparticles. Such uniform Pt-Pd bimetallic catalysts allow a better understanding of the CO, NO and CO/NO conversion profiles in comparison to those obtained for the corresponding Pt and Pd-monometallic samples. Combined with *ex situ* and *in situ* characterization, the emerging characteristics of this class of bimetallic catalysts and their advantages as well as functionality can be unambiguously identified.

**Introduction.** The oxidation of $CH_4$ under stoichiometric feed represents a key point for the performance of Pd-based Three Way Catalysts (TWC) for Natural Gas fueled Vehicles (NGVs) [1]. The absence of excess $O_2$ leads to facile reduction of PdO to metallic $Pd^0$ species, which are only active on pure $Al_2O_3$ if high dispersion is maintained [2]. Other studies report that balanced core-shell Pd-PdO particles possess high activity, but rich-lean pulses are required, leading to a sensible increase in fuel consumption [3]. Here, we study the evolution of Pd-$CeO_2$ catalysts prepared by dry milling under stoichiometric conditions [4] prompted by the unique behavior displayed under lean and rich methane abatement conditions [5,6].

**Experimental.** 4wt%Pd/$CeO_2$ catalysts were prepared by milling (M) and by incipient wetness impregnation (IW) following established procedures [4,5] on commercial ceria (BET S.A.≈25 $m^2g^{-1}$). $CH_4$ oxidation tests were carried out on 30 mg of powder sample at a GHSV=400000 $h^{-1}$ under dry (0.5% $CH_4$, 1% $O_2$ in He) and wet (with 10vol% $H_2O$) gas feed conditions. The Pd and $CeO_2$ surface and bulk structure were followed *in-situ* by synchrotron X-ray Diffraction (XRD) and Ambient-Pressure X-ray Photoelecton Spectroscopy (XPS).

**Results and discussion.** Under stoichiometric 1:2 $CH_4$:$O_2$ feed the samples prepared by milling (M) outperformed the reference IW catalyst, with a measured reaction rate of 13.5 *vs* 4.8 $\mu mol_{CH4} \cdot g_{Pd}^{-1} \cdot s^{-1}$, respectively, in dry conditions at 563K, and 14.9 *vs* 4.2 $\mu mol_{CH4} \cdot g_{Pd}^{-1} \cdot s^{-1}$ at 613K in wet conditions. *In-situ* XRD analysis revealed stable particle size during reaction, likely due to the high temperatures reached during a pre-treatment oxidation cycle (1173K) to simulate real catalyst operation. Remarkably, the main differences are observed by AP-XPS spectra (Figure 1), which highlight a balanced Pd:PdO ratio on the Milled sample and predominant $Pd^{2+}$ on the IW sample. In addition, heavy accumulation of OH species on the IW catalyst is observed, indicating it as the main inhibition mechanism on the standard catalyst. The reported results show the unique role of $CeO_2$ as a support oxide, promoting the generation of a mixed $Pd^0$/$Pd^{2+}$ state which appears to be the best performing state in interaction with $CeO_2$, compared to pure $Pd^0$ on $Al_2O_3$ [2] or predominant $Pd^{2+}$ under lean conditions [5,6].

**Figure 1. NAP-XPS spectra collected in the Pd 3d (A,C) and O 1s (B,D) regions under 0.6 mbar $CH_4$, 1.4 mbar $O_2$ at increasing temperatures (673K, 773K, 873K). (A-B): 4PdCeIW, (C,D): 4PdAcCeM.**

# Non-stoichiometric spinels ferrites ($Co_xFe_{3-x}O_4$ and $Mn_xFe_{3-x}O_4$) in study on methane oxidation

A. DECOSTER*, F. DHAINAUT, P. GRANGER

**Keywords:** Methane oxidation, induction heating, spinel ferrite

**Introduction:** Natural gas vehicles (NGV) are an alternative solution to fossil fuelled engines to reduce $CO_2$ emissions and lower the contribution to the greenhouse gas effect. The abatement of low unburnt methane emissions from the exhaust is a prerequisite due to methane's greenhouse gas effect higher than $CO_2$. [1][2] Pd-catalysts are recognized as benchmark for this application mostly in lean conditions. Presently, the development of platinum group metal free catalysts is strongly encouraged capable to run in more representative three-way operating conditions, e.g. near stoichiometry. The catalytic performances of novel spinel $Co_xFe_{3-x}O_4$ and $Mn_xFe_{3-x}O_4$ catalysts have been evaluated in terms of activity and thermal stability. In parallel their magnetic properties were studied in order to set up induction heating technology with the aim to enhance catalysis and lower the operating temperature conditions.

**Experimental/methodology:** $M_xFe_{3-x}O_4$ catalysts were prepared according to a conventionnel precipitation method. Structural analyses were made by XRD and Raman. Determination of oxidation states was made by XPS. Reducibility behaviours were studied by $H_2$-TPR analysis and cation distribution was done by Mössbauer spectrometry. Moreover, Vibrating Sample Magnetometer (VSM) was used to determine magnetic behaviour of all spinels and conclude on heating mechanism. Catalytic performed at 600°C in a plug flow reactor (figure 1) in stoichiometric and lean condition in the presence and in the absence of steam.

**Results and discussion:** XRD and Raman analyses confirmed predominant spinel structure but showed a structural modification which induce by change in the reducibility. Mössbauer spectra of $Co_xFe_{3-x}O_4$ provide additional information related to the migration of Co inside the lattice. Ferromagnetic behaviour was characterized at 2K while paramagnetic and superparamagnetic behaviours prevail at high temperature. These magnetic features underline the fact of no hysteresis heating can be done at room temperature for all spinels. Steady-state rate measurements reveal that $Co_2FeO_4$ exhibits the best activity. On the other hand, improved thermal stability was observed on the serie $Mn_xFe_{3-x}O_4$ with acceptable conversions. We observe globally a negative impact of steam and positive order with respect to oxygen concentration.

**Keywords:** Cryptomelane, $Cu_{1.5}Mn_{1.5}O_4$ spinel, CO oxidation, redox property

**Introduction:** Carbon monoxide (CO) removal is one of the most studied reaction in catalysis due to the high toxicity of this gas and because it is accepted as a model reaction [1]. Some of the commercially available catalyst are based on $CuMn_2O_4$ spinel and their activity is normally attributed to the flexibility of the $Cu^+/Cu^{2+}$ and $Mn^{3+}/Mn^{4+}$ couples, which improve their redox properties and activate the CO molecule [2].

**Experimental/methodology.** A series of Cu-MnOx catalysts were synthesized by a hydrothermal method using an aqueous solution of $KMnO_4$ and $Cu(NO_3)_2$ and ethanol as the reducing agent. The autoclave was heated to 100°C for 12 hours. The samples were dried overnight and then calcined at 500°C for 6 hours. The catalytic tests were performed using 50 mg of catalyst diluted with 100 mg of SiC, with a total flow rate of 100 mL/min and a gas composition of 1 vol.% CO, 0.6 vol.% O2, and 98.4 vol.%.

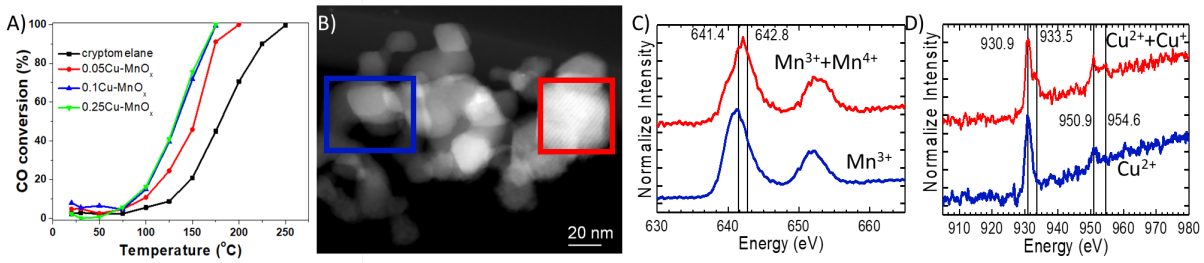

Figure 1 Catalytic performance of the samples (A), HAADF image where the EELS experiment were performed (B), Mn-$L_{2,3}$ edge(C) and Cu-$L_{2,3}$ (D) of the marked areas.

**Results and discussion.**

All catalysts were profoundly characterized using XRD, XRF, $N_2$ physisorption, XPS, TPD, CO-TPR and advanced transmission electron microscopy techniques (HAADF-STEM, EELS and EDS). The results revealed that the Cu:Mn molar ratio of the precursors had a significant impact on the crystalline structure and morphology of the synthesized samples. A Cu-doped cryptomelane with a nanorod morphology was observed when the Cu:Mn molar ratio was 0.05. Conversely, different mixture of Cu-doped cryptomelane nanorods, $Mn_2O_3$, and $Cu_{1.5}Mn_{1.5}O_4$ spinel nanoparticles were formed at higher molar ratios. As shown in Figure 1, the addition of Cu improves the catalytic activity and the presence of the Mn and Cu with different oxidation states was proven by EELS experiments. The effect of the redox properties and the coexistence of the manganese and copper with different oxidation states will be discussed.

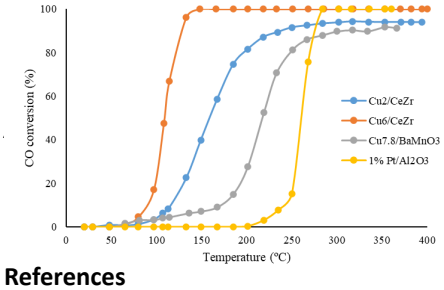
**Keywords:** ceria, praseodymia, copper, OSC, CO oxidation.

**Introduction.**



Nowadays, there is an important need to decrease global greenhouse gas emissions from vehicles exhaust. For this reason, ambitious measures must be taken in the automotive sector concerning improvements in engine combustion. In this sense, oxyfuel engines, capable of capturing the $CO_2$ emitted that can be used, eventually, for e-fuels processing, seems to be a promising option. To reach adequate aftertreatment systems, new catalytic formulations should be proposed under these demanding conditions. In this line, a catalytic system based on two phases should be designed: i) one of them able to capture and supply oxygen (e.g. ceria-praseodymia based oxides) in stoichiometric combustion engines, and ii) other one to promote the CO oxidation (e.g. copper/ceria-zirconia based catalysts) in lean combustion engines.

**Experimental/methodology.**

$Ce_{0.3}Pr_{0.7}O_2$ catalyst (CePr) has been synthesized by the direct calcination method of the metallic precursors [1]. Several conditions to evaluate its capacity to capture and release oxygen have been tested (Fig. 1). On the other hand, $Ce_{0.8}Zr_{0.2}O_2$ (CeZr) formulation has been synthesized using the co-precipitation method, and two copper loadings (2 and 6 %, respectively) have been introduced by the incipient wetness impregnation procedure. CO oxidation experiments were performed under Temperature-Programmed Reaction conditions using several reactant mixtures typical of conventional and oxy-fuel combustion exhausts.

**Results and discussion.**

Experiments of oxygen capture and subsequent release revealed that CePr catalyst could capture and emit oxygen between the 25 and 40 % of the total available oxygen with respect to that which would be released under reducing conditions, and the amount and rate of the oxygen release depend on the heating rate used, as reflected on Fig.1 (left). On the other hand, CO oxidation tests showed that Cu/CeZr catalysts present a better catalytic performance under oxy-fuel conditions than under conventional ones, and higher copper loadings allow increasing CO conversion efficiency, (see Fig. 1 (right)), and promote resistance to inhibition due to $CO_2$ presence, exhibiting much better performance than a commercial 1% $Pt/Al_2O_3$ and a home-made perovskite ($Cu7.8/BaMnO_3$).

# CO oxidation performance in GDI engine exhaust conditions of $Ba_xMn_{0.7}Cu_{0.3}O_3$ (x = 1, 0.9, 0.8 and 0.7) perovskite catalysts

A. Díaz-Verde[1*], E. L. dos Santos Veiga[2], H. Beltrán-Mir[2], V. Torregrosa-Rivero[1], M. J. Illán-Gómez[1], E. Cordoncillo-Cordoncillo[2]

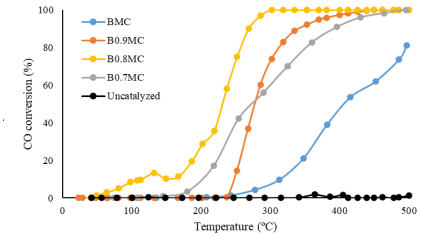
**Keywords:** perovskite, barium, manganese, CO oxidation, GDI engines.

**Introduction.**



Mixed oxides with perovskite-type structure ($ABO_3$) [1] present interesting catalytic properties to be used for atmospheric pollution control, being a promising alternative to noble metal based catalysts. A series of $BaMn_{1-x}Cu_xO_3$ perovskites has been studied for diesel soot oxidation, being $BaMn_{0.7}Cu_{0.3}O_3$ the best catalyst for this reaction. Additionally, the high selectivity to $CO_2$ observed for this catalyst revealed its high capacity to oxidise CO to $CO_2$ [2]. Therefore, in order to improve the catalytic performance for CO oxidation, in this work a series of $Ba_xMn_{0.7}Cu_{0.3}O_3$ (x = 1, 0.9, 0.8 and 0.7; named as BxMC) has been synthesized, characterized and tested for this reaction carried out in GDI engine exhaust conditions.

**Experimental/methodology.**

The synthesis of perovskite type catalysts was carried by the sol-gel method adapted to aqueous medium [2]. The catalysts were characterized by XRD, ICP-OES, $H_2$-TPR, XPS, impedance spectroscopy and $O_2$-TPD techniques. Catalytic activity for CO oxidation has been studied in Temperature-Programmed Reaction conditions (TPR) using three reactant mixtures: i) 0.1% CO + 1%$O_2$; ii) 1% CO + 1% $O_2$; and iii) 1% CO + 10% $O_2$. Stability and reciclability tests have also been performed for the most active samples.

**Results and discussion.**

XRD results showed that, as Ba content decreases, a change from h-polytype structure (a distortion of the hexagonal perovskite structure caused by the insertion of copper into the network of perovskite [1]) to hexagonal perovskite structure is promoted. $H_2$-TPR results reveal a Mn-Cu synergetic effect which allows a decrease in the temperature for Mn(IV)/Mn(III) reduction to Mn(II) and, finally, XPS results revealed the presence of surface oxygen vacancies. In Figure 1 the CO conversion profiles versus temperature for 1% CO + 1% $O_2$ reactant mixture is featured. All catalysts tested are active for CO oxidation, being the activity related with the amount of oxygen vacancies and copper located on the surface of catalysts.

**ı profiles for $Ba_xMn_{0.7}Cu_{0.3}O_3$ in 1% CO+1% $O_2$ reactant mixture.**

**Introduction.**

Catalysts based on supported noble metal (NM) particles play an important role in the synthesis of fine chemicals, fuel cells and also for the removal of environmentally harmful and toxic emissions. Due to their scarcity and costs, an efficient usage of these metals is therefore highly desirable. In this regard, the NM-support interaction, particularly for platinum group metals supported on $CeO_2$, gained strong attention. Particularly, this interaction leads to Pt redispersion under oxidizing conditions, enabling regeneration strategies for sintering.[1] Also, in the CO oxidation reaction, which is a model reaction for clean air emission control, Pt particles in the presence of $CeO_2$ were shown to be less inhibited by CO poisoning. The combination of both properties of $Pt/CeO_2$ gives an interesting opportunity to tune and exploit the interaction with the support. In this study, we investigate highly dispersed Pt species with maximized NM-support interface on $CeO_2$ to identify the active Pt species[2] and to improve the catalyst design by tuning the surface noble metal concentration[3].

**Experimental/methodology.**

$Pt/CeO_2$ based catalysts with varying Pt loadings (1.0 wt %, 2.3 wt % and 4.5 wt %) were synthesized by incipient wetness impregnation. As support, hydrothermally (100 °C for 21 h) prepared $CeO_2$ nanorods from $Ce(NO_3)_3 \cdot 6\ H_2O$ were used.[3] The CO oxidation activity were performed in plug-flow geometry. The catalyst, the mass of which was adjusted to the Pt loading, was used as sieved fraction and was diluted by $SiO_2$ (grain size of 125–250 µm) to a total of 1 g. In this way, a constant weight hourly space velocity (WHSV) of 60 000 L $g_{Pt}^{-1}$ $h^{-1}$ was retained for all samples. *In situ* and *operando* X-ray absorption spectroscopic (XAS) measurements at the Pt $L_3$ edge were performed at the CATACT and XAS beamlines of the KIT Light source and at P65 at DESY using a fluorescence detector.[2,3] For all experiments a quartz micro reactor (1-2 mm diameter) was filled with 7-10 mg of undiluted catalyst.

**Results and discussion.**

The initial state of Pt in all 3 catalyst samples was investigated by means of Transmission Electron Microscopy (TEM) and extended X-ray absorption fine structure spectroscopy (EXAFS). In all cases, Pt was found to be highly dispersed and oxidized. EXAFS fitting indicated the presence of both, single atomic species[2] and clusters.[3] Depending on the Pt weight loading, and thus surface noble metal concentration (SNMC), the samples varied strongly in CO oxidation activity. The ignition temperature of CO oxidation decreased by ~200 °C when going from the sample with the lowest SNMC to the one with the highest SNMC. This behaviour could be related to the Pt cluster formation by further Raman, *in situ* infrared and *operando* X-ray absorption spectroscopic investigations.[3] Together with DFT calculations, we were able to show that at a higher SNMC the Pt agglomeration is favoured statistically due to the proximity of Pt atoms, which is also lowering the Pt diffusion barriers on the $CeO_2$ surface. Our study emphasizes how the dynamics of Pt can be used to increase and stabilize the low temperature activity of such catalysts.

**Keywords:** $CeO_2$-$ZrO_2$, OSC material, Three-way catalyst, Automotive catalyst, Gasoline exhaust

**Introduction.** For stringent regulations of exhaust gasses from gasoline-powered vehicles, highly active three-way catalysts (TWCs) even at low temperature are strongly required [1]. Improvement of oxygen storage capacity (OSC) at low temperature is the most effective way to satisfy this requirement. In this study, we have developed low temperature active $CeO_2$-$ZrO_2$ material (CZ) based on new synthetic procedure and surface analysis.

**Experimental.** SCW-CZ shown below was prepared by the procedures as follows. A solution of $ZrO(NO_3)_2$ (162.3 mmol), $Ce(NO_3)_3$ (93.0 mmol), $La(NO_3)_3$ (4.91 mmol), $Nd(NO_3)_3$ (9.51 mmol), and $Pr(NO_3)_3$ (9.40 mmol) in $H_2O$ (370 mL) was added slowly-dropwise to an aqueous $NH_3$ (11wt%, 200 g) while taking a time of 80 minutes to neutralize the reaction mixture. The resulting precipitation was filtered, washed, and re-added to $H_2O$ to give a slurry (3.3 wt%). The slurry was treated under supercritical/subcritical condition (350 °C, 25MPa) using high pressure reactor. Following that, the treated slurry was dried at 120 °C overnight. The titel compound was given as beige colored complex oxide.

**Results and discussion.** In general, OSC of CZ is strongly affected by homogeneity of Ce and Zr conformation in the crystal structure. Homogeneous CZ as solid solution is equivalent to highly-crystallized CZ prepared by high temperature calcination (HTC) around at 1000 °C. However, HTC usually causes growth of crystal diameter and low surface area, which directly leads to decreasing OSC performances at low temperature [2]. Treatment with supercritical/subcritical water (SCW) is significant procedure to obtain homogeneous CZ without any HTC. It also makes a strong effect on diffusion behavior during formation of oxide precursor, resulting in unique distribution of Ce/Zr cations on the surface. To understand the details of CZ surface, $CH_3OH$ adsorption following IR spectroscopy can be often used [3]. Its spectrum provides the states of coordinatively saturation around Ce and Zr atoms involving the homogeneity. Figure 1 exhibits that SCW-CZ and HTC-CZ have larger ratio of peak area at 1035 $cm^{-1}$ and 1077 $cm^{-1}$ based on the area at 1105 $cm^{-1}$ than the conventional CZ (C-CZ). In particular, the peaks at 1035 $cm^{-1}$ and 1077 $cm^{-1}$ are attributed to $CH_3OH$ coordination on unsaturated Ce site which could be generated by site replacement of Zr with Ce as well as related to OSC performance. On the other hand, the peak at 1105 $cm^{-1}$ is attributed to saturated Ce site which could not be effective on OSC performance. Subsequently, OSC evaluations were performed at 300 °C and 400 °C. The result shows that SCW-CZ has higher OSC than HTC-CZ even though these CZ have similar surface state. This is because SCW-CZ has much smaller crystal diameter and higher surface area than HTC-CZ shown in Table 2. In conclusion, we found that SCW condition strongly prompts metal-site replacement to give highly-homogeneous CZ having small crystal diameter and high surface area. Accordingly, the obtained SCW-CZ exhibits higher OSC than the others at 300 °C where TWC is not fully-activated.

[*] *maximiliano.rodriguez@uclouvain.be*

**Introduction:** Plasma, known as the fourth state of matter, consists of an ionized gas with unique properties that permit significant improvement of traditional chemical processes, increase their efficiency, and stimulate chemical reactions impossible by conventional methods[1]. When plasma glidarc is used with humid air as feeding gas, some very reactive species are generated, which can carry out oxidation and reduction reactions depending on the target molecules present[2,3]. The oxidative and reductive abilities of glidarc plasma in humid air makes it a very attractive technique for synthesis of metal oxides for heterogeneous catalysis.

**Experimental:** A batch configuration of glidarc plasma was adopted with humid water as feeding gas[2]. The targets exposed were precursor solutions alone made of potassium permanganate ($KMnO_4$) or ammonium iron (II) sulfate hexahydrate (AFeS). Biomorphic ceria fibers were added in the reactor along with the solution of precursors, expecting the precipitates to anchor or nucleate on their surface. The added fibers (Fib Ce) were synthesized by means of a biotemplate (cotton) which was impregnated with a cerium precursor solution until saturation, then dried and finally calcined to remove the template[4]. The activity of the impregnated fibers for diesel soot oxidation was examined by Temperature programmed oxidation (TPO)[5] using a model soot (Printex U).

**Results and discussion:** The precipitates obtained after exposing the precursor solutions to glidarc plasma were identified by XRD analysis. A birnessite-type (KMO) and cryptomelane (OMS) phases were obtained after calcination of $KMnO_4$ precipitate at 400 °C and 600 °C, respectively. For AFeS, α-$Fe_2O_3$ hematite was formed after calcination at 600 °C. After the deposition of Mn in the presence of Fib Ce, no signals were detected beside the ones coming from the support (cubic ceria fluorite). In turn, a characteristic peak of α-$Fe_2O_3$ was seen for the deposition with AFeS on Fib Ce. Since XRD did not allow us to detect the presence of Mn species, EDX analysis were carried out and the atomic ratios of Mn and Fe referred to cerium were calculated (Table 1). Additionally, XPS quantification analysis confirmed the superficial enrichment of these species on the fibers. As Table 1 shows, the impregnation of Mn (Fib Ce-OMS) enhanced the activity of the bare fibers, whereas the deposition of Fe (Fib Ce-$Fe_2O_3$) was detrimental, despite being lower the metal content of the former, which highlights the beneficial effect of Mn(IV)-Mn(III) redox couple.

Table 1 - Atomic ratios of plasma-impregnated fibers and $T_M$ values in soot combustion.

| Catalyst | EDX* | | XPS | | $T_M$ (°C)** |
|---|---|---|---|---|---|
| | $(Fe/Ce)_{at.}$ | $(Mn/Ce)_{at.}$ | $(Fe/Ce)_{at.}$ | $(Mn/Ce)_{at.}$ | |
| Fib Ce | - | - | - | - | 420 |
| Fib Ce - $Fe_2O_3$ | 0.18 | - | 2.47 | - | 460 |
| Fib Ce - OMS | - | 0.06 | - | 0.32 | 400 |

[*]a.garcia@ua.es

**Introduction.** Due to their improved fuel efficiency, an increase in European and US market penetration is expected for Gasoline Direct Injection (GDI) vehicles in a near future. However, the use of GDI engines also carries unintended consequences, including significantly higher particulate emissions when compared to port-fuel injection (PFI) engines. A first approach to tackle these soot emissions is to incorporate a Gasoline Particulate Filter (GPF) downstream the TWC in the exhaust. However, to avoid severe problems such as growing back pressure due to soot deposition onto the filter, this device should be periodically regenerated. Unfortunately, the typical conditions of the exhaust are very unfavourable for soot combustion. In this demanding context, catalysts that exhibit high capacity for incorporating oxygen during the short pulses of oxygen, (fuel cuts) and an accentuated ability to a complete release of $O_2$ during the long periods under non-oxidant atmosphere (stoichiometric mode) would be highly desirable.

The present work focuses on a preliminary study of the behaviour of several ceria-praseodymia mixed oxides under $^{18}O_2$ pulses in an attempt to investigate their ability to interact with oxygen, (uptaking/releasing/exchanging) with their own lattice oxygen, under conditions which could simulate those existing in these exhaust gases. For this purpose, several Ce-Pr mixed oxides prepared by two different routes were synthesized in order to explore their responses under two consecutive isotopic $^{18}O_2$ pulses. The final goal is to stablish relationships among the physico-chemical properties of the catalysts, their capacities to interact with oxygen and their soot combustion activities under oxygen pulses.

**Experimental/methodology.** For this study, $Ce_{1-x}Pr_xO_{2-\delta}$ mixed oxides, (where x is 0.4, 0.6, 0.8 and 1) were prepared by two conventional methods (co-precipitation and intimate mixture of the metallic precursors) [1]. The solids obtained were calcined for 1 hour at 500°C. Pure ceria and a home-made 1.9%Pt/11.5%Ba/1.4%K/γ-$Al_2O_3$ catalyst were also analysed for comparative purposes. $^{18}O_2$ pulse experiments at several temperatures of interest (200-500°C) were performed (8.5 psi of pressure). The experiments were carried out with 100 mg of catalyst diluted with 180 mg of SiC. Previously, the catalysts were treated under He at 500°C (the temperature of preparation), in an attempt to simulate a long period of non-oxidant atmosphere. The same experiments were repeated in the presence of soot using a 1:20 soot:catalyst ratio (*loose-contact mode* of mixing).

**Results and discussion.** The results obtained with the all the catalysts illustrate that the extent of oxygen uptake and isotopic products distribution ($^{16}O_2$, $^{18}O^{16}O$, $^{18}O_2$) are dependent on the catalyst composition and the preparation procedure. It should be mentioned that the Pt-catalyst does not exhibit $O_2$ uptake whatever the temperature tested, meanwhile the Pr-containing catalysts present several extents of $O_2$ uptake. In general, the catalysts prepared by the Co-precipitation method exhibit higher uptake capacities than those prepared by the Direct calcination method, whatever the composition compared. Concerning soot combustion activities under these transient conditions, the whole experiments conducted point out that the presence of high Pr contents in the mixed oxides as well as high BET surface areas are crucial to achieve high soot combustion activities under these demanding conditions. The pattern of the profiles is very sensitive to the nature of the catalyst, since pure ceria exhibits sharp profiles of $C^{16}O_2$ emission during the $^{18}O_2$ pulse and fast decay of the $C^{16}O_2$ signal during the long inert period, meanwhile the Pr-containing mixed oxides exhibit wider $C^{16}O_2$ peaks with prolonged tails, thus suggesting a pronounced intervention of the active oxygen species even during the inert period. Conversely, Pt-catalyst present a very low soot combustion activity with null intervention of active oxygen species after finishing the $^{18}O_2$ pulses.

**Introduction.**

Noble metal based clusters or particles supported on high surface area metal oxides e.g. $CeO_2$, $TiO_2$ or $Al_2O_3$ belong to the essential compounds that are used in emission control catalysis both in mobile and stationary conditions. Due to their limited availability, a drastic reduction of noble metal loading is highly desirable, which, nevertheless, should not negatively affect their catalytic activity. As we have shown in our previous studies, noble metal catalysts, however, rarely retain their original structure under transient reaction conditions. [1-3] For this reason, a correct identification of active sites using a combination of complementary *operando* characterization techniques is crucial for establishment of proper structure-activity correlations. X-ray absorption spectroscopy (XAS) is ideal as it can give insight into the transformation from single sites to clusters or particles and vice versa. Herein, we aimed at a smart catalyst design to minimize a negative effect of structural changes occurring under reactive atmosphere, and to increase catalyst stability including reactivation for long-term applications under transient conditions.

**Experimental/methodology.**

In this study, a range of Pd/$CeO_2$-based catalysts with low Pd loading (≤1 wt.%) were synthesized by flame spray pyrolysis (FSP). The catalytic activity of Pd/$CeO_2$ samples was investigated during CO oxidation reaction (1000 ppm CO, 8% $O_2$ in $N_2$). For activity tests, the sieved catalyst (125-250 µm) was and placed in a plug-flow reactor and a Fourier transform infrared spectrometer (Multigas FTIR Spectroscopy, MKS) was used for product analysis at the reactor outlet. For *operando* X-ray absorption spectroscopy (XAS) measurements, a quartz glas microreactor with plug-flow geometry was used. The XAS spectra were recorded under transient conditions at the Pd K edge in fluorescence mode at the SAMBA beamline (SOLEIL). Similar to the catalytic tests in the lab, the gas composition was analyzed with on-line FTIR spectroscopy at the reactor outlet.

**Results and discussion.**

Using FSP as a synthesis method, very homogeneous Pd-catalysts with a high surface area in the range of 200250 $m^2\ g^{-1}$ were obtained according to *ex situ* characterization results (XRD, BET, HAAD-STEM, *ex situ* XAS). The activity tests indicate a high CO oxidation activity for the low-loaded Pd-catalysts, with a temperature of full conversion way below 150 °C. Moreover, this high activity remained unchanged during subsequent light-off/light-out cycles, showing the high stability of the FSP-prepared samples. Using a combination of complementary *operando* techniques, we were furthermore able to identify the active noble metal structure, and followed its evolution under reaction conditions. The results of this study underline the key role of *operando* characterization together with advanced synthesis methods for the knowledge-based catalyst design of low-loaded noble metal catalysts in the future.

**Keywords:** perovskite, barium, manganese, Cerium, Lanthanum, soot oxidation, GDI engines.

**Introduction.**

Soot and NOx emitted by automotive engines are responsible for severe environmental and health problems. It has been proposed that perovskites type mixed oxide are a feasible alternative to PGM-based catalysts because promote soot oxidation thanks to its particular properties that can be modulated by either synthesis procedure, composition (different A and B cations) and the partial substitution of A and/or B cations [1]. In a previous study, the authors concluded that $BaMn_{0.7}Cu_{0.3}O_3$ is the best catalyst for diesel soot removal from a series of $BaMn_{x-1}Cu_xO_3$ perovskites, due to its high amount of oxygen vacancies [2].In this work, $Ba_{0.9}A_{0.1}MnO_3$ and $Ba_{0.9}A_{0.1}Mn_{0.7}Cu_{0.3}$ $O_3$ (A= Ce, La) perovskites have been synthesized, characterized, and tested as catalysts for GDI soot oxidation.

**Experimental/methodology.**

The synthesis of the perovskites (named BM/BMA, and BMC/BMCA, A=Ce, La), was carried out by sol-gel method in an aqueous medium, using citric acid as a chelating agent. For sample characterization, BET, XRD, $H_2$-TPR, XPS and $O_2$-TPD have been employed. The catalytic activity for GDI soot oxidation has been studied under simulated GDI operation conditions (1% or 0% $O_2$ in He).

**Results and discussion.**

Characterization results revealed that copper is partially introduced into the structure of BM perovskite, showing BMCLa the highest amount of surface copper and BMCCe, the lowest one. BMCA shows, respect to BM, a slightly increase in the amount of oxygen surface defects, in the reducibility of manganese and in the amount of oxygen desorbed during an $O_2$-TPD. In Figure 1, as an example, the Temperature Programmed soot conversion profiles in 1% $O_2$ for catalysts are shown. Note that the doping with copper only increases the soot conversion respect to BM for BMCLa perovskite.

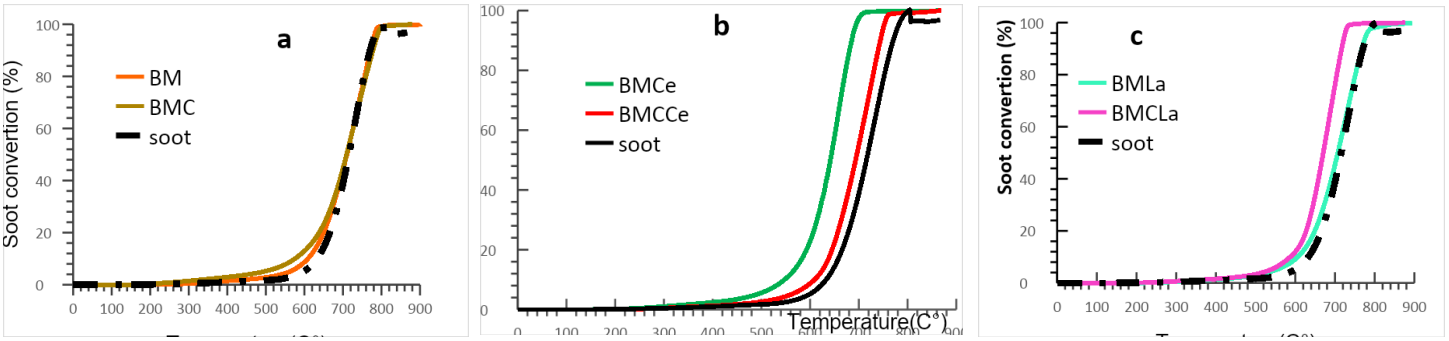

**Figure 1 (a,b,c). TPR soot conversion profiles for BMA and BMCA in 1%$O_2$.**

## Introduction

Catalytic oxidation of chlorinated VOCs is presented as an optimal strategy for the control of the emissions of this type of pollutants. In this sense, the choice of a suitable catalyst (active and selective towards deep oxidation products) is essential to achieve the desired target. Catalysts based on transition metal oxides, especially cobalt oxide, have proven to be effective in a wide range of catalytic reactions. On the other hand, over the last few years, materials with hollow nanostructure have received great attention due to their excellent performance in different applications [1]. Hollow nanostructures (nanotubes) can be obtained under mild conditions and without costly templates and corrosive acids following the Kirkendall effect. Thus, this study examines $Co_3O_4$ catalysts with a controlled 1D nanomorphology and evaluates their performance in the oxidative gas phase removal of 1000 ppm of Cl-VOCs (vinyl chloride and 1,2-dichloroethane as model compounds).

## Experimental/methodology

Bulk $Co_3O_4$ samples were synthesised following three precipitation routes based on the Kirkendall effect:

$Co_3O_4$-S: an oxalic acid solution was mixed with a cobalt chloride solution under stirring for 3 h. The precursor was filtered, washed, and dried. Then, it was dispersed in EtOH and an ethanolic solution of NaOH was added dropwise. After 3 h under stirring the product was filtered, washed, dried, and calcined in air at 500 ºC for 4 h.

$Co_3O_4$-A: an aqueous solution of ammonia was added drop by drop to an ethanolic solution of cobalt acetate and the mixture was kept under stirring for 6 days. Afterwards, the solid was centrifugated, washed, dried, and calcined in air at 290 ºC and 500 ºC for 4 h.

$Co_3O_4$-U: two ethanolic solutions of cobalt acetate and urea were mixed under stirring at 65 ºC for 4 h. Then, the precursor was filtered, washed, dried, and calcined under controlled atmosphere (5% $O_2$/He) at 350 ºC and 500 ºC for 4 h.

## Results and discussion

Cobalt oxide catalysts with a hollow nanotube structure were obtained as confirmed by SEM. Among the different samples, the $Co_3O_4$-U oxide exhibited the highest surface area (19 $m^2\ g^{-1}$) and the smallest crystallite size (22 nm). Moreover, $H_2$-TPR and XPS results revealed a higher amount of $Co^{2+}$ species in this oxide, both at bulk and surface level. Additionally, the presence of $Co^{2+}$ species is usually connected to the formation of low coordination defect lattice oxygen sites. This assumption was confirmed by Raman spectroscopy, as a shift of the $A_{1g}$ vibration towards lower frequencies is an indication of a highly defective structure [2]. In agreement with these results, the catalytic activity runs also clearly evidenced the highest efficiency of the $Co_3O_4$-U sample for the oxidative removal of VC and DCE ($T_{50}$ of 260 ºC and 325 ºC, respectively). Accordingly, this structure-activity relationship was consistent with the highest specific rate of the $Co_3O_4$-U sample (Figure 1). In conclusion, the reason for this improved performance was the formation of surface oxygen defects, due to a high concentration of $Co^{2+}$ that promoted the generation of active oxygen species along with the adsorption capacity of the chlorocarbons.

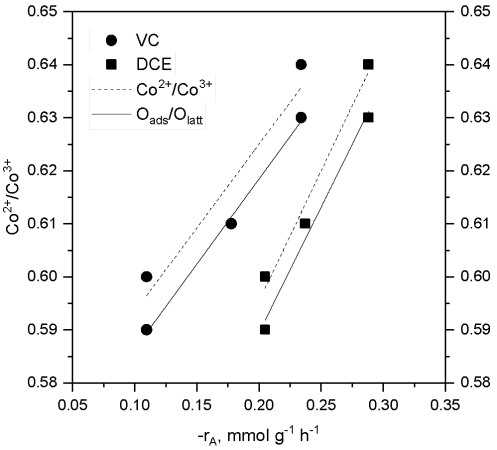

**Figure 1.** Relationship among the reactivity and the $Co^{2+}/Co^{3+}$ and $O_{ads}/O_{latt}$ molar ratios.

# Oxidation of 1,2-dichlorobenzene (o-DCB) with $MnO_X$-$CeO_2$ formulation

J.A. Martín-Martín, M.P. González-Marcos, A. Aranzabal, J.R. González-Velasco

The University of the Basque Country, UPV/EHU*, Bilbao, Spain*

**Introduction.**

$MnO_X$-$CeO_2$ catalytic formulation has been proposed in many studies as an excellent catalyst for low temperature SCR [1], which would avoid the typical reheating of gases fed to the current SCR units in tail-end position. This formulation is also reported to be active in catalytic oxidation reactions [2], which means the posibility of abating simultaneously $NO_X$ and chlorinated VOCs in the same catalytic unit. The aim of this work is to evaluate the $MnO_X$-$CeO_2$ formulation in o-DCB oxidation (model compound of PCDD/Fs).

**Experimental/methodology.**

$MnO_X$-$CeO_2$ catalysts were prepared by co-precipitation, adding an ammonium carbamate solution (precipitating agent) unil reaching a pH=9. Calcination was carried out in static air at 500 ºC (1 ºC/min). For catalytic activity tests, 1.5 g of catalyst and a feeding stream (2 L/min) composed of o-DCB (100 ppm), $O_2$ (10%) and Ar to balance were used.

**Results and discussion.**

The results of light-off experiments concluded that $MnO_X$-$CeO_2$ formulation is active for o-DCB oxidation. The increase in Mn content shifts the conversion profile to lower temperatures. Nonetheless, the presence of Ce also plays an important role, especially in the low temperature range (<300 ºC). The better catalytic activity of the catalysts with high Mn content is related to, on the one hand, the promotion of morphological properties, and, on the other hand, the co-existence of two crystalline phases at the structural level (mixed oxide phase and seggregated $Mn_2O_3$) whose synergy improves the oxygen mobility/storage and redox properties.

The analysis of adsorbed species by in-situ FTIR showed that the first steps of oxidation reaction are two nucleophilic substitutions followed by the cleavage of aromatic ring. After these steps, a different distribution of intermediate species with temperature was observed, which suggests oxidation reaction occurs differently with temperature. Thus, the main species at low temperature were phenate and maleate, wheras acetate and formate species were the ones at high temperature.

In order to evaluate whether oxidation reaction performed with $MnO_X$-$CeO_2$ formulation occurs differently with temperature, time on stream (TOS) experiments were carried out in the low and high temperature range. The results showed a strong catalyst deactivation at low temperature due to the deposition of chlorine and carbonaceous matter. TOS experiments also evidenced a change in the product distribution at high temperature, in which CO and chlorinated organic compounds were produced (to a lower extent than $CO_2$) after a period of time. Interestingly, this fact did not occur in the low temperature range, where the only reaction product was $CO_2$ (together with water).

Therefore, both FTIR and TOS results suggest a change in oxidation reaction pathway with temperature. To understand this fact, it is important to note the results of characterization: $MnO_X$-$CeO_2$ catalyst was composed of two phases with a different Mn and Ce interaction degree and, consequently, different oxidative capability. This fact is proposed to provide the catalyst active sites with diferent activity. Thus, the active sites with higher oxidative capability mainly contribute to oxidation reaction. However, they are strongly deactivated. At high temperature, the active sites with lower oxidative capability become active, but favouring the oxidation of intermediate species more slowly. This fact facilitates chlorination reactions (at high temperature, Cl is more weakly adsorbed) leading to chlorinated by-products, whose number of carbons, interestingly, matchs with that of intermediate species identified at this condition.

# Design of subsurface single-atom catalysts for oxidation chemistry

*Xuze Guan*,[1] *Feng Ryan Wang*,[1*]

[1]*Department of Chemical Engineering, University College London, Roberts Building, Torrington Place, London WC1E 7JE, UK*

**e-mail: ryan.wang@ucl.ac.uk*

**Introduction.**

Single-atom catalysts (SACs) have become the research frontier in heterogeneous catalysis because of their high atom utilization and special metal-support interactions. The locations of isolated metal atoms on supports determine their catalytic performances[1,2]. Typically, single metal atoms are anchored onto the support surface. Applications of surface single-atom catalysts are usually hampered by limited catalyst stability, which is caused by sintering[3,4]. Therefore, understanding the structure-activity relationship of SACs under various reaction conditions, and exploring and controlling the location of single atoms that is resistant to sintering, are crucial to the design of SACs for practical applications.

**Experimental/methodology.**

The CuO-$Fe_2O_3$ catalyst with 1wt% Cu was prepared first by the coprecipitation method. The Cu sites were atomically dispersed over $Fe_2O_3$. Cu single sites were introduced onto $Fe_2O_3$ supports to tune the surface redox ability and to anchor formed NO during the reactions[5]. Then, the Cu single sites were immersed into the subsurface *via* ball milling.

**Results and discussion.**

Here, we inserted the single Cu atoms into the subsurface of $Fe_2O_3$ support (Fig. 1a), showing drastically different dynamics and adsorption behaviours under the reaction conditions. Extended X-ray absorption fine structure (EXAFS) spectra indicate atomically dispersed Cu. An increase in the coordination number of Cu–Fe (from 2.2 to 2.7) indicates Cu single atoms enter the interior of the $Fe_2O_3$. The X-ray photoelectron spectroscopy (XPS) exhibited the Cu signal of the fresh catalyst. In comparison, the Cu in the ball-milled catalyst cannot be measured by XPS, indicating the isolated Cu atoms were not on the surface of $Fe_2O_3$. Compared with surface Cu single atoms, subsurface Cu single atoms show a high resistance against sintering. After $NH_3$ pretreatment, the $N_2$ selectivity decrease significantly for the surface single-atom catalyst, while the subsurface Cu single-atom catalyst is much more stable and active for $NH_3$ oxidation (Fig. 1b,c). The ability to control the single-atom location opens promising perspectives to turn reducible oxides into reactive materials in oxidation reactions.

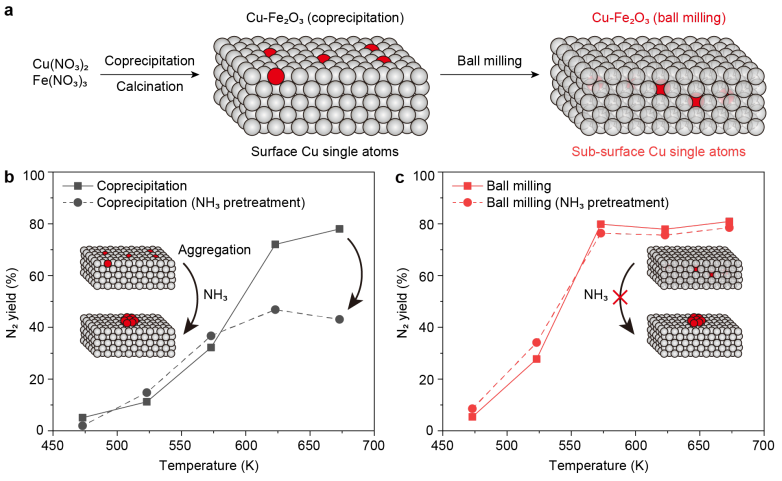

**Figure 1. Synthetic scheme and ex-situ characterizations of catalysts. a**, Schematic illustration of immersing Cu into $Fe_2O_3$ *via* ball milling. **b**, $N_2$ yield of 1wt% CuO-$Fe_2O_3$ (coprecipitation) before and after $NH_3$ pre-treatment. **c**, $N_2$ yield of 1wt% CuO-$Fe_2O_3$ (ball milling) before and after $NH_3$ pre-treatment.

# Modulation of the redox capacity of copper by calcium during the reduction of NO by CO and Naphthalene

J. Herrera[1], G. Aguila[2], S. Guerrero[1*]

[1]*Universidad de los Andes, Santiago, Chile*
[2]*Universidad Andres Bello, Santiago, Chile*
[*]*sguerrero@uandes.cl*

**Keywords:** NO reduction, Copper catalyst, CO, Naphthalene

**Introduction.** The present study uses CO and naphthalene to reduce nitric oxide to $N_2$ in the presence of $O_2$. The challenge in this reaction is to prevent CO and naphthalene from being oxidized instead of being used as NO reducers. This study will show that the combination of copper and calcium on core-shell support, $YCeO_2$@$TiO_2$, can effectively modulate the oxidation of the reducing agents favoring the selectivity to $N_2$.

**Experimental/methodology.** A core-shell $YCeO_2$@$TiO_2$ support was prepared by a reverse micelle procedure and further sequentially wet-impregnated with copper and calcium. The catalytic bed consisted of a proper amount of catalyst deposited on a mineral wool bed inside a quartz tube reactor (1 cm I.D.) and set in a split-oven. The simulated gaseous mixture (GHSV = 10,000 $h^{-1}$) consisted of 500 ppm naphthalene, 500 ppm NO, 1% CO, and 10% $O_2$, balanced in He, flowing at 50 cc/min. The outlet from the reactor was screened to monitor the presence of NO, $NO_2$, $N_2O$, CO, and naphthalene, among others, by using infrared spectrometry, gas chromatography, and mass spectrometry.

**Results and discussion.** Figure 1A shows that the Ca/Cu/$YCeO_2$@$TiO_2$ catalyst is highly active fully converting CO and naphthalene, with NO reaching a maximum of 60% conversion to $N_2$ at 276°C. The reduction profile shown in Figure 1B shows how the addition of calcium displaces the copper reduction to high temperatures and decreases the overall $H_2$ consumption when compared with the calcium-free sample (Cu/$YCeO_2$@$TiO_2$). The latter suggests a higher Ca-O-Cu interaction which makes it more difficult to reduce the copper phase. Therefore, the addition of calcium might be used to modulate the redox capacity of copper to avoid the direct oxidation of the reducing agent instead of reacting with NO.

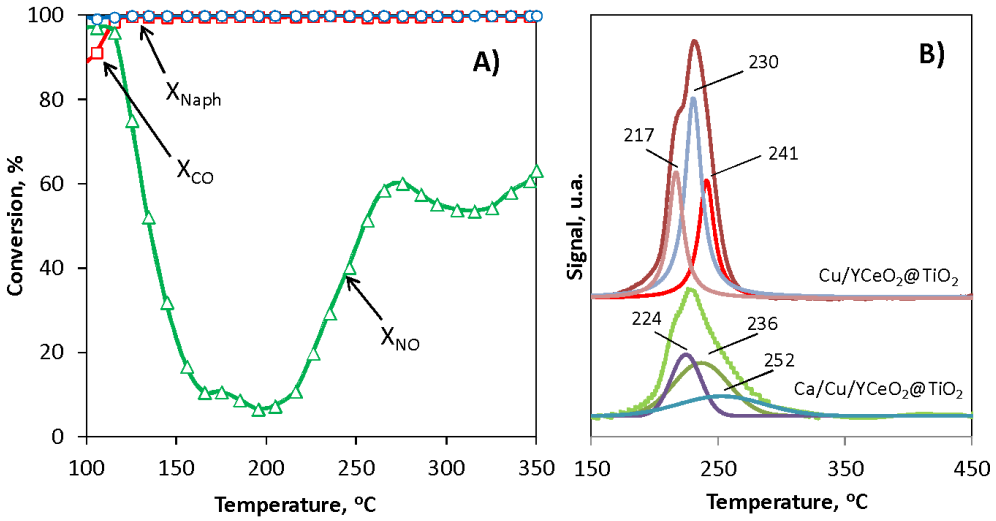

Figure 1. A) Reduction of NO with CO and naphtalene on Ca/Cu/$YCeO_2$@$TiO_2$ in the presence of $O_2$ and B) $H_2$-TPR on Cu/$YCeO_2$@$TiO_2$ and Ca/Cu/$YCeO_2$@$TiO_2$.

# Alkaline Earth Containing Yttrium Oxide Based Catalysts for High-Temperature NO Decomposition Reaction

K. Takenaka, Y. Hayashi, Y. Nishida, M. Haneda*

*Advanced Ceramics Research Center, Nagoya Institute of Tehnology, Tajimi, Japan*

**Keywords:** NO decomposition, Alkaline earth additive, Yttrium oxide, Transition metal oxide additive

**Introduction.** Among the various catalytic $NO_x$ removal technologies, NO decomposition is regarded as the most ideal method. This is because reducing agents such as $NH_3$ for NO reduction are not necessary. We have so far investigated yttrium oxide-based catalysts, and found that co-doping of Ba and $CeO_2$ into $Y_2O_3$ is quite effective to achieve high NO decomposition activity at 900ºC [1,2]. However, its activity and stability in higher temperature region above 1000 ºC is still problem. In this study, we have investigated the additive effect of transition metals to improve the activity and stability of $Ba/Ce/Y_2O_3$. The effect of alkaline earth elements was also investigated to gain insight into the improvement of the activity under the realistic condition in the presence of $CO_2$.

**Experimental.** All the catalysts were prepared by coprecipitation method. The composition was 8mol% alkaline earth (A: Mg, Ca, Sr, Ba), 10 mol% $CeO_2$ and 3mol% transition metals (M: Mn, Fe, Co, Ni, Cu), 79mol% $Y_2O_3$ as oxide. The resulting precipitate was dried at 110°C, and then calcined at 1000°C for 5h in air. The catalyst is hereinafter referred to as $ACeM/Y_2O_3$. NO decomposition reaction was carried out with a fixed bed flow reactor by passing a reaction gas composed of 0.1% NO diluted He to the catalyst bed ($W/F=1.0 g \cdot s \cdot cm^{-3}$). The steady state activity was evaluated at each temperature in the range of 900 – 1100°C. As the characterizations, $O_2$-TPD and $CO_2$-TPD were performed.

**Results and discussion.** Fig.1 shows the effect of transition metal on the NO decomposition activity of $BaCe/Y_2O_3$. Among the additives, Fe was found to be the most effective. $BaFeCe/Y_2O_3$ showed quite high activity in 900 - 1100°C temperature range. From $O_2$-TPD measurements, the essential role of Fe was to promote oxygen desorption. The activity of Fe-doped $Ce/Y_2O_3$ was found to be strongly dependent on the alkaline earth element. The effective additive was Ba and Sr. In order to gain information on the difference in the catalytic performance of Ba- and Sr-doped catalyst, the catalytic activity was evaluated in the presence of 1% $CO_2$. It was dound that Ba- and Sr-doped catalysts shows similar catalytic activity, although Ba-doped catalyst is quite effective in the absence of $CO_2$. $CO_2$-TPD suggested the advantage of Sr-doped catalyst by the presence of relatively weak basic sites.

Fig.1 Effect of transition metal additive on the NO decomposition activity of $BaCe/Y_2O_3$.

**Introduction.**

Despite their extensive worldwide use, thermal deactivation and processes occurring on an atomic scale during long-term application of emission control catalysts are not yet completely understood. Typically, segregation, sintering, solid-state reactions and encapsulation are observed thus affecting the properties of both the active species and the supports.[1,2,3] Common support materials for three-way catalyst are oxides like γ-$Al_2O_3$ or $CeO_2$-$ZrO_2$; γ-$Al_2O_3$ exhibits a high surface area, while $CeO_2$-$ZrO_2$ are applied for their oxygen storage capacity to balance out fluctuations in the stoichiometric air-to-fuel ratio needed for an optimal performance.[2,4] Additionally, they sustain the noble metal dispersion during high temperature utilization. For the noble metals, i. e. Pd, Pt and Rh, commonly employed in the three-way catalyst, thermal deactivation processes are known to not only dependent on the aging temperature but also on the applied gas atmosphere.[5,6] Our study aims at elucidating the behavior of Rh and Pd during thermal deactivation by systematic catalyst preparation, testing and in-depth *ex situ/in situ* characterization.

**Experimental/methodology.**

A series of different Pd- and Rh-catalysts supported on $CeO_2$-$ZrO_2$ were prepared by incipient wetness impregnation and the resulting powders were aged under oxidizing or inert conditions. The structural öfeatures of the resulting samples were revealed by complementary *ex situ* and *in situ* characterization techniques including XRD, $H_2$-TPR, XPS, $N_2$-physisorption and XAS measurements. Several light-off/light-out cycles were performed while monitoring the gas mixture with and FTIR spectrometer (MKS) to evaluate the catalytic activity.

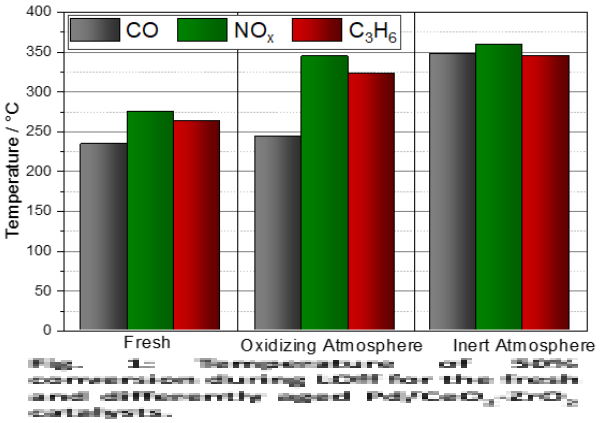

Fig. 1: Temperature of 50% conversion during LOff for the fresh and differently aged Pd/$CeO_2$-$ZrO_2$ catalysts.

**Results and discussion.**

While studying the impact of the aging conditions on the catalytic activity, a major drop in the conversion of all three pollutants CO, $NO_x$ and $C_3H_6$ was observed for the samples exposed to high temperatures and inert atmosphere. In contrast, pretreating the catalyst in oxidizing atmosphere mainly affects $NO_x$ and $C_3H_6$ conversion, whereas the catalytic activity towards CO oxidation was only slightly impaired. XRD measurements demonstrated a severe sintering of the support material independent of the aging condition; *ex situ* XANES and EXAFS characterization revealed that aging in oxidizing atmosphere promotes the formation of larger oxidized noble metal particles.

**Keywords:** Fe-UZM-35; Interzeolite conversion route; One-pot synthesis; High reproducibility; $NH_3$-SCR

**Introduction.** Fe-UZM-35 with MSE topology of particular interest in that its low-temperature activity in $NH_3$-SCR is best among the Fe-zeolites known to date[1]. However, owing to the narrow crystallization field, the synthesis of this large-pore zeolite starting from amorphous reagents in the presence of dimethyldipropylammonium ions as an organic structure-directing agent is often non-reproducible[2]. Moreover, $Fe^{2+}$ exchange in zeolites requires the prevention of $Fe^{2+}$ oxidation to trivalent iron species such as FeO(OH), which cannot be easily introduced into the zeolite pores during ion exchange [3], requiring the use of inert $N_2$ atmosphere. Here we describe novel synthesis routes to UZM-35 and Fe-UZM-35.

**Experimental/methodology.** The interzeolite conversion (IZC) synthesis of UZM-35, which uses ultra-stable Y (USY) zeolites as the sole source of Si and Al, as well as the one-pot-synthesis of Fe-UZM-35, was performed using aluminosilicate gels with the composition $4.50DMDPAOH{\cdot}0.25Na_2O{\cdot}0.75K_2O{\cdot}xFe^{II}O{\cdot}yAl_2O_3{\cdot}10.0SiO_2{\cdot}155H_2O$, where $x$ is varied between $0 \le x \le 0.50$ and $0.017 \le y \le 0.067$, respectively. If required, a small amount of previously synthesized and calcined UZM-35 (4 wt% of USY used) was added as seed crystals, respectively. The final mixture was placed into a 45 mL Teflon-lined autoclave and heated under static conditions at 170 °C for 0.5-7 days.

**Results and discussion.** We were able to synthesize pure UZM-35 by combining the IZC route with the seeding method, using USY zeolites as both Al and Si-sources in the presence of DMDPA as an OSDA (**Figure 1a**). We were also successful in the one-pot-synthesis of Fe-UZM-35 (**Figure 1b**), which is much more convenient and reproducible than the post-synthetic preparation of iron-exchanged UZM-35; there is no need for careful iron exchange under $N_2$ atmosphere and repeated calcination steps. More importantly, the $NH_3$-SCR activities of one-pot-synthesized and post-synthetically exchanged Fe-UZM-35 zeolites with similar Fe/Al ratios (ca. 0.23) were found to be essentially identical to each other in the reaction temperature range studied (**Figure 1c**).

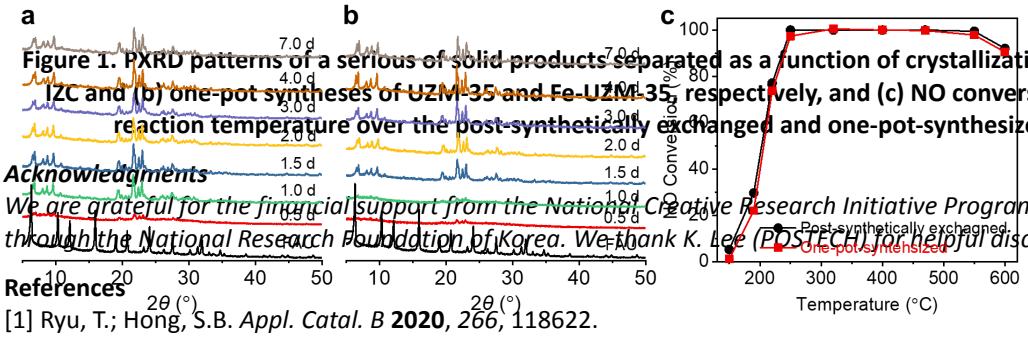

**Figure 1. PXRD patterns of a serious of solid products separated as a function of crystallization time during the (a) IZC and (b) one-pot syntheses of UZM-35 and Fe-UZM-35, respectively, and (c) NO conversion as a function of reaction temperature over the post-synthetically exchanged and one-pot-synthesized Fe-UZM-35**

**Keywords:** nitrous oxide, ammonia, shipping, catalytic decomposition, selective catalytic reduction

**Introduction.** According to the International Maritime Organization (IMO), present shipping activities are responsible for ~2.5% of global GHG emissions and this contribution is expected to increase in the coming years due to increasing global trade. Taking these into consideration, the IMO has come to an agreement to work towards certain ambitious targets such as reducing GHG emissions from international shipping by at least 50% by 2050, decreasing carbon intensity by at least 40% (compared to a benchmark set in 2008) by 2030 and achieving complete decarbonization of the shipping sector by the end of the 21st century (1).

The first step towards achieving these goals is to come up with an alternative, carbon-free fuel. Ammonia ($NH_3$) is one such promising candidate for fueling ship engines because, unlike hydrogen, ammonia can be stored in liquid form at room temperature and low pressure for long-distance voyages. However, it leads to the emissions of $NO_x$, $N_2O$ (nitrous oxide) and unburnt $NH_3$, which need to be managed by using a dedicated Exhaust Aftertreatment System (EATS). Among the flue gas species, $N_2O$ has a concerning potential for global warming. $N_2O$ is known to be ~300 times more potent to cause global warming than $CO_2$ on a per mass basis (2). In addition, $N_2O$ can react with oxygen in the atmosphere to form nitric oxide, which is one of the contributors of ozone layer depletion (2, 3). Anthropogenic sources are responsible for ~35% of $N_2O$ emissions and $N_2O$ concentration in the atmosphere has increased at an alarming rate of ~0.2–0.3%/year in the last century (2). $N_2O$ emissions can be countered by either direct catalytic decomposition into $N_2$ and $O_2$ or selective catalytic reduction (SCR) into $N_2$ and $H_2O$ (2, 4).

In this contribution, we explore the catalytic performance of K-promoted Co/BEA catalysts for the removal of $N_2O$ and compare it to that of commercially available Fe-BEA catalysts. The novelty of this work lies in the use of Co/BEA catalysts, which have been scarcely reported in the literature for $N_2O$ abatement.

**Experimental/methodology.** Catalytic experiments were carried out in a quartz U-tube reactor using two catalysts – K-Co/BEA and Fe-BEA. The K-Co/BEA catalyst was synthesized via incipient wetness impregnation while the Fe-BEA catalyst was procured from Topsoe A/S. Catalytic decomposition of $N_2O$ was carried out in the presence and absence of water. Further, removal of $N_2O$ was also investigated using ammonia as reductant in the presence of water. The reactions were performed in the range of 150-500 °C.

**Results and discussion.** For catalytic decomposition, in the absence of $H_2O$, both K-Co/BEA and Fe-BEA show similar catalytic activity in the temperature range of 400-500 °C. In the presence of $H_2O$, K-Co/BEA performs much better than Fe-BEA, even though the $N_2O$ conversion for K-Co/BEA reduces by ~50%. Further, with the introduction of $NH_3$, the $N_2O$ conversion for Fe-BEA shoots up and reaches the highest value observed in any of the experiments, while the final value for K-Co/FEA remains almost unchanged.

**Keywords:** Mn-Ce/CuX catalyst, different zinc species poisoning, low-temperature $NH_3$-SCR

**Introduction.** Nitrogen oxides (NOx), emitted from coal-fired power plants and other nonelectric industries, are one of the main air pollutants to cause harm for human health and environments. [1].The zeolite-based catalysts were widely used in denitration removal reaction [2-4], especially Cu-exchanged zeolite catalysts owing to the high SCR activity [4-6]. Our recent research [7] discovered that the X zeolite supported catalyst performed better low-temperature NO conversion than that of other zeolite catalysts, such as ZSM-5 and Beta zeolites. Then the X zeolite was synthesized from waste BFS using seed methods, and the Mn-Ce co-doping CuX catalyst was prepared via ion exchange and impregnation methods, and it exhibited excellent catalytic activity and $SO_2/H_2O$ resistance [8, 9]. However, owing to the low-temperature catalysts for $NH_3$-SCR suffering from poisoning effect of heavy metals in the sintering flue gas, herein, the influence of different zinc species ($ZnCl_2$, $Zn(NO_3)_2$, $ZnSO_4$ and $ZnCO_3$) on blast furnace slag-derived Mn-Ce/CuX catalyst for low-temperature $NH_3$-SCR were compared and studied.

**Experimental/methodology.** Poisoned catalysts were prepared by impregnating with $ZnCl_2$, $Zn(NO_3)_2$, $ZnSO_4$ and $ZnCO_3$ aqueous solutions, respectively. The catalytic activities of all catalysts were measured, and the physicochemical properties of zinc poisoned catalysts were investigated.

**Results and discussion.** After zinc species poisoning, catalytic activity decreased significantly in the low temperature range, and the poisoning degree followed $ZnSO_4$ > $ZnCO_3$ > $Zn(NO_3)_2$ > $ZnCl_2$. The Zn salts poisoning catalysts have lower acidity and redox ability compared with fresh Mn-Ce/CuX catalysts, resulting in the lower SCR activity. Furthermore, all the catalysts were governed by both Langmiur-Hinshelwood (L-H) and Eley-Rideal (E-R) mechanism via *in situ* DRIFTS spectra, the possible mechanism for different zinc species poisoning on Mn-Ce/CuX catalyst was summarized as well.

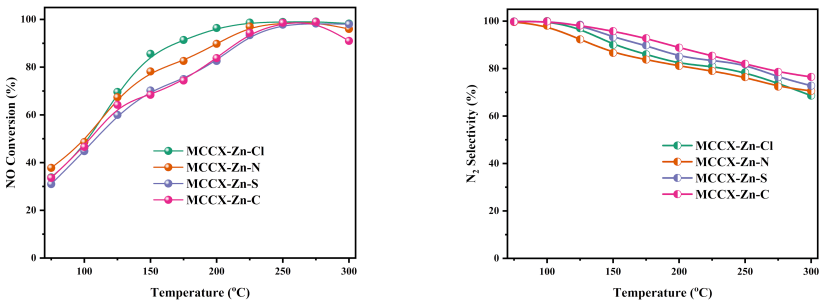

**Fig.1**. $NH_3$-SCR activity of MCCX-Zn-Cl, MCCX-Zn-N, MCCX-Zn-S and MCCX-Zn-C catalysts: (a) NO conversion with temperature; (b) $N_2$ selectivity with temperature.

**Keywords:** Cobalt oxide, CO oxidation, catalyst morphology

**Introduction.** Supported noble metals such as Pd and Pt are known for their superior performance in catalytic oxidation of CO, however, their high cost limits their extended use in commercial applications. Transition and rare-earth metal oxide catalysts have received considerable attention due to both their high efficiency and low cost. Cobalt oxide is known as the most active catalyst for CO oxidation due to its weak oxygen bond strength and high turnover frequency for redox reaction [1]. Lately, a plethora of research studies focus on morphology-dependent nanocatalysis, while the synthesis method seems to have a crucial effect on the structural properties of catalytic materials (e.g. surface area, oxidation state, dispersion of actives sites, etc). Cobalt-doped alumina nanosheets were prepared as oxidation catalysts by dynamic hydrothermal method, and then further promoted with precious metal Ru or Pd. Cobalt doping imparted the prominent redox ability to irreducible alumina nanosheets and established the strong metal-support interaction and easy activation of gaseous oxygen [2]. In another recent study, $Co_3O_4$/a-$Al_2O_3$ catalysts were prepared by a rotary chemical vapor deposition (CVD) method, aiming to the formation of finely dispersed nanoparticles of $Co_3O_4$ on the a-$Al_2O_3$ surface, presenting thus high catalytic activity in CO oxidation with the minimum Co content [3]. The present work deals with the development of Co/alumina (promoted or not with minimum Pd amounts) materials evaluated as novel oxidation catalysts.

**Experimental/methodology.** Introduction of Co and Pd was realized applying either the conventional wet impregnation (WI) or the advanced spray impregnation (SI) technique towards the synthesis of core-shell catalytic nanostructures to secure chemical/thermal stability of active site on the catalyst carrier. The physicochemical characteristics of as-synthesized materials were evaluated by various complimentary, conventional and advanced techniques ($N_2$ Physisorption, XRD, $H_2$-TPR, $O_2$-TPD, SEM and TEM) to elucidate differences between synthesis methods. The catalytic CO oxidation efficiency was evaluated in the 150-500°C temperature range in a fixed-bed reactor, using a feed of 1% CO, 1% or 10% $O_2$, in He (GHSV: 40000 $h^{-1}$).

**Results and discussion.** Pd/Co-alumina catalysts synthesized by the spray impregnation method showed improved CO oxidation efficiency, due to their optimum physicochemical properties and mainly their enhanced reducibility related with better dispersion of Co and Pd active sites 0.5Pd-1Co/Al-SI was the most efficient catalyst presenting T50%= 170°C and achieving ~100% CO conversion at 190°C (Figure 1). Pd incorporation is also attempted via SI, targeting to even lower Pd content, while selected catalytic materials are also investigated as methanol oxidation catalysts.

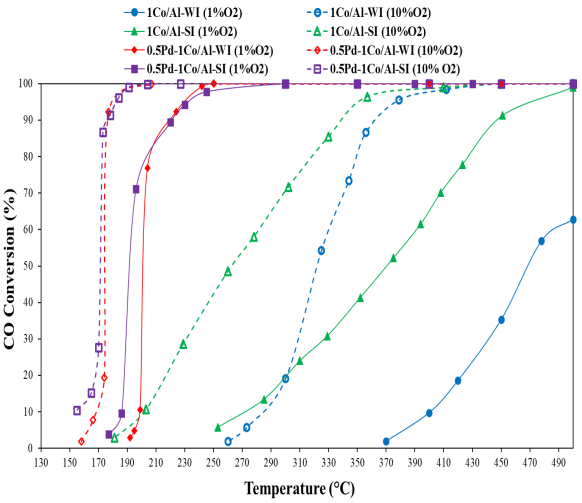

**Figure 1.** *CO conversion (%) vs. temperature for all (Pd)Co/Al catalysts.*

[*]*aleksandra1.jankowska@uj.edu.pl*

**Introduction.** The reduction of nitrogen oxides ($NO_x$) emissions from stationary sources is most often achieved by the use of the technology of selective catalytic reduction of NOx with ammonia ($NH_3$-SCR). Nevertheless, the commercially used $NH_3$-SCR catalyst is effective only in a relatively narrow temperature range (300-400°C), which limits its use outside the temperature window of its effective operation.[1] To meet the requirements of modern $NH_3$-SCR installations it is necessary to design a new generation of catalytic systems. For this purpose, mesoporous spherical MCM-41 was functionalized with transition metals (copper or iron) using an innovative technique of template ion-exchange (TIE).[2]
**Experimental/methodology.** The obtained materials were tested in the role of $NH_3$-SCR catalysts and the influence of their intrinsic properties on the catalytic performance was analysed using various characterization methods, including e.g. P-XRD, low-temperature $N_2$-sorption, ICP, UV-vis DR spectroscopy.
**Results and discussion.** The catalytic performance of tested $NH_3$-SCR catalysts was strictly dependent on the form and aggregation of the deposited metal (Cu or Fe), the control of which was possible with the applied TIE method and its modification. In the case of copper-doped MCM-41, materials containing well-dispersed monomeric copper species were more active in comparison to samples characterized by the presence of bulky copper oxide forms. The effective range of the catalyst work for the most active catalyst was between 200 and 325°C with very high selectivity to $N_2$ (Figure 1). Iron-modified porous nanospheres were active in the elevated temperature range (350-475°C) of the $NH_3$-SCR process, indicating a slightly higher activity of small oligomeric iron oxide aggregates (Figure 1). The obtained materials showed promising activity in the low-temperature as well as the high-temperature range of the $NH_3$-SCR process. Thus, it is an attractive alternative to be used in this process to replace a commercially used $V_2O_5$-$TiO_2$ oxide system.

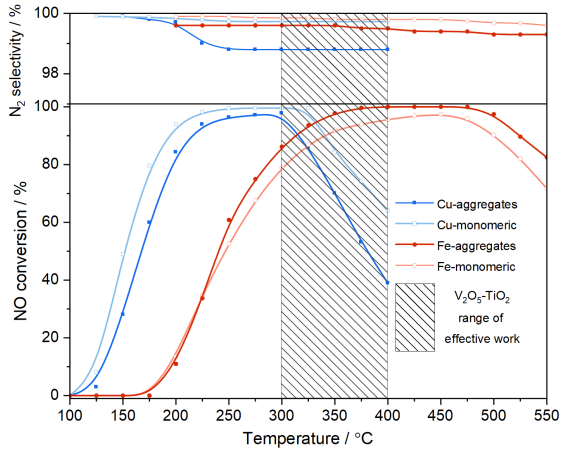

**Figure 1. $NH_3$-SCR catalytic tests obtained for the spherical MCM-41 modified with Cu or Fe with various degrees of aggregation and comparing them with the window of effective operation of the commercial $V_2O_5$-$TiO_2$ system.**

## Introduction

Global air pollution caused by various industrial as well as human activities has led to major health issues and damage to the environment. As a result, scientists all over the world came up with catalytic solutions to overcome the emission problems. Development of Three-Way Catalyst (TWC) technology is the key development in maintaining air quality regulations for gasoline engines. Even though the technology has been successfully implemented for more than 5 decades for internal combustion engines, maintaining the quality of the catalyst, developing engine compatible solutions with respect to continuously tighter emission regulations remains a big challenge. The combination of bi- (PtRh / PdRh) or tri-metallic (PtPdRh) formulations/solutions along with an appropriate Oxygen Storage Component (OSC) result in the formulation of successful TWC catalyst [1-2]. Rh is an important component of the TWC as it helps in reduction of NOx. In spite of these evident advantages some major challenges with regard to TWCs are still open: (i) Broadening of the operating air/fuel window (ii) Promoting the intrinsic activity by increasing the efficiency of TWCs by making them more cost efficient. (iii) using an alternative formulation by minimizing the use of rare and expensive Rh with very volatile costs [3].

## Methodology & Results

Considering Rh prices increased significantly (Rh prices ranging from 379€/g to 860€/g in 2021, and currently again falling to 410€/g 2023) in previous years we developed a TWC composition containing only Ru and Ru with dopants (Ru: 17€/g – Jan 2023).

**Comparison of Catalytic Activity under Fresh and Aged Conditions**

The developed Ru catalyst compositions show the same and even better performance than current PtRh 1/1 or PtRh 5/1 TWCs under rich conditions. An cost effective Ru based TWC has been developed which can be effectively used under rich engine conditions.

# Noble metal catalysts for plasma-assisted oxidation of methane

J. Palo[1], J.Kihlman[1]

[1]*VTT Technical Research Centre of Finland, Espoo, Finland*
[*]*jasmiina.palo@vtt.fi*

**Keywords:** methane oxidation, non-thermal plasma, emission reduction, Pd, NH4-ZSM-5

**Introduction.** Dairy and meat production are accountable for around 150 Mt $CO_2$ equivalent of methane emissions every year in Europe [1]. These scattered, point-source emissions are found e.g., in cowsheds in ultra-low concentrations (50 – 200 ppmv). Currently there is no feasible technology to abate them, but the new EU regulations in Fit for 55 legislation package [2] will set target of reaching carbon neutrality for agricultural sector by 2035. Horizon Europe funded project CANMILK focuses on developing a combined process based on adsorption, catalysis and non-thermal plasma technologies to mitigate enteric methane emissions by converting $CH_4$ to less harmful $CO_2$.

Catalytic oxidation of methane to $CO_2$ is a mature technology used to convert dilute methane emitted during coal mines' venting and from vehicle exhaust [3]. In thermal processes, complete methane oxidation can be achieved at temperatures of 400 °C, and the reaction is typically catalyzed by noble metals such as Pd or Pt [3,4]. However, plasma technologies have potential to reduce environmental pollutants at ambient conditions and utilize renewable electricity for operation. A limited number of publications exist where plasma-assisted $CH_4$ oxidation is studied, especially for ultra-low methane concentrations.

**Experimental.** Non-thermal plasma or cold plasma is electrically charged matter in its gaseous form and can be generated by passing gases through an electric field [5]. However, plasma itself is non-selective. To counter the effect, a catalyst can be introduced into the reactor to improve product selectivity and conversion. These experiments were carried out by feeding simulated cowshed air to a dielectric barrier discharge (DBD) reactor, having a structure that enables the study of a catalyst within the plasma zone.

**Results and discussion.** The scope of this work was to study Pd catalysts supported on $Al_2O_3$ and $NH_4$-ZSM-5. The catalysts were synthesized for the experiments and compared for their activity to $CH_4$ oxidation reaction under similar operating conditions. The effect of material choice on system performance was further studied by means of applied power and gas hourly space velocity. As $N_2$ molecules can break down to N* radicals and further react with available O atoms to form nitric oxides, the formation of $NO_x$ compounds was monitored during experiments, along with the surface temperature of the DBD reactor caused by the exothermicity of oxidation reactions. The effect of plasma on the studied catalyst was systematically evaluated using several characterization methods, including XRD, ICP, $N_2$ physisorption, and $H_2$ chemisorption.

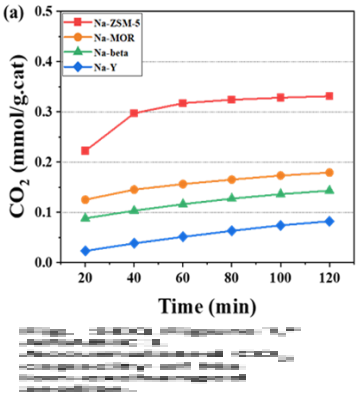
**Keywords:** Na cation, Zeolite, Direct Air Capture

**Introduction.**



An increase in global temperature due to the greenhouse effect of carbon dioxide is an unavoidable fact. As part of efforts to reduce $CO_2$, direct air capture (DAC) technology removing $CO_2$ from ambient air using an efficient adsorbent at room temperature has been developing. A useful strategy for enhancing DAC performance is the chemical functionalization of zeolites such as an active cation into zeolite via ion exchange [1]. This work has investigated DAC performance with respect to the zeolite structure (beta, ZSM-5, mordenite, and Y). To determine the critical factor influencing $CO_2$ trapping and desorption behavior, analyses of the impacts of Na cation exchange in zeolites also have been done.

**Experimental/methodology.**

Four types of zeolites such as beta , ZSM-5 and Y zeolites provided from Zeolyst, and mordenite from Albemarle were characterized of the DAC performance. Na-form zeolite was synthesized by ion-exchange Na into $NH_4$-form zeolites using 0.8 M NaCl aqueous solution. The $CO_2$ adsorption breakthrough curves were observed with 400 ppm $CO_2$ and He balances at 25 °C. The desorption profiles were acquired by purging and ramping the temperature from 25 to 300 °C, respectively, in order to determine the physiosorbed and chemisorbed $CO_2$ on zeolites. The in-situ surface behavior of $CO_2$ adsorption on Na-exchanged zeolites was analyzed using DRIFT spectra, and the IR spectra of $CO_2$ desorption were also collected as a function of temperature (25, 70, 150, and 250 °C). $NH_3$-TPD and pyridine-IR were used to determine the characteristics and amounts of acidic sites.

**Results and discussion.**

In figure 1, the Na-ZSM-5 showed the maximum capacity of $CO_2$ with 0.33 mmol $g^{-1}$ at room temperature and faster kinetics reaching breakthrough in less than an hour. For the chemisorbed $CO_2$ species, the Na-ZSM-5 had a distinctive desorption behavior, exhibiting two desorption peaks at different ramp temperatures, 65 and 260 °C, respectively. The doublet desorption peaks at relatively lower and higher temperatures provide evidence for two Na cation adsorption sites, Na I and Na II, respectively, in the ZSM-5 framework [2].

The behavior of $CO_2$ species on Na-zeolite adsorption sites was examined using in-situ DIRFTs to study surface adsorption. Unlike other zeolites, the Na-ZSM-5 showed a distinct $CO_2$ adsorption peak at 1638 $cm^{-1}$, which can be explained by the formation of carbonate species on the basic site of an Al-O group [3]. Furthermore, the complete desorption of $CO_2$ at 150 °C demonstrates how strongly the gas is absorbed as carbonate. A strong interaction between $CO_2$ and the basic site of zeolitic oxygen is critical for the capture of $CO_2$ chemisorbed over the Na-ZSM-5. The basicity of zeolitic oxygen (acido-basic site) could be caused by the strong Lewis acidity of the Na cation exchanged. According to the results of $NH_3$-TPD and pyridine-IR, the Na-ZSM-5 has stronger Lewis acid sites than Na-beta, -MOR, and -Y, showing that the ZSM-5 utilizes Na cation more effectively in the frameworks.

# Performance of Ni-Mn and Ni-Co-Mn mixed oxide catalysts in total oxidation of volatile organic compounds

T. Babii[1], K. Jirátová[2], J. Balabánová[2], M. Koštejn[2], J. Maixner[1], F. Kovanda[1*]

**Keywords:** Ni-Co-Mn oxides, mixed oxide catalysts, VOC total oxidation

**Introduction.** Volatile organic compounds (VOC) can be removed from air by catalytic total oxidation to carbon dioxide and water as end products. Transition metal oxides are often used as catalysts in this process. The combination of multiple transition metal cations in these catalysts may increase their activity in VOC oxidation due to a possible synergistic effect. Recently we observed an enhanced catalytic performance of Co-Mn mixed oxides in the deep ethanol oxidation compared to Co and Mn oxides alone [1], whereas activity of the Ni-Co oxides decreased with increasing Ni content in the catalysts [2]. To investigate the activity of other types of oxides, we prepared Ni-Mn and Ni-Co-Mn catalysts by heating coprecipitated precursors and examined the effect of metal cations molar ratio in the catalysts on their physical chemical properties and catalytic performance in the VOC total oxidation.

**Experimental/methodology.** The oxide catalysts were obtained by heating of precursors, prepared by coprecipitation of nitrate solutions containing Ni, Co, and Mn in various molar ratios; the aqueous solution containing NaOH and $Na_2CO_3$ was used as precipitation agent. The washed and dried products were calcined for 4 h at 500 °C in air. The prepared catalysts were characterized by various methods (powder XRD, Raman spectroscopy, $N_2$ adsorption, $H_2$-TPR) and tested in the deep oxidation of ethanol and toluene, which were used as model VOC. The catalytic reaction was carried out in a fixed bed reactor with the inlet concentration in air of 750 (ethanol) and 780 ppm (toluene) at GHSV of 20 l $g_{cat}^{-1}$ $h^{-1}$, using a tempereture ramp of 2.0 °C $min^{-1}$. The $T_{50}$ and $T_{90}(CO_2)$ temperatures required to achieve 50% conversion of ethanol or toluene and 90% conversion of all organic compounds to $CO_2$ were chosen as a measure of catalyst activity.

**Results and discussion.** The Ni-Mn catalysts contained Ni-Mn mixed oxides ($Ni_6MnO_8$ and $NiMnO_3$ with murdochite and ilmenite structure). Powder XRD patterns of the Ni-Co-Mn catalysts showed mixed oxides with spinel structure, together with $(Ni,Co)MnO_3$ in the sample with high Mn content and NiO in the samples with high Ni content. Slight changes in spinel lattice parameter in dependence on the samples composition and broadening of the peaks in Raman spectra indicated a disordered distribution of cations in the spinel structure. In the ethanol oxidation, the Ni-Mn catalysts with Ni:Mn molar ratio of 1:1 showed the lowest $T_{50}$ and $T_{90}(CO_2)$ temperatures (91 and 172 °C, respectively), indicating high activity of this catalyst. Similar $T_{50}$ and $T_{90}(CO_2)$ temperatures were observed also for the Ni-Co-Mn oxide catalysts with lower Ni content. These catalysts showed also very good activity in the toluene oxidation with $T_{50}$ temperatures around 230-235 °C. Surface area of the oxides had only minor effect on their catalytic performance. Acetaldehyde and carbon monoxide were detected as the main by-products of ethanol oxidation on the investigated catalysts. The mixed oxide catalysts with molar ratios of Ni:Mn and Ni:Co:Mn of 1:1 and 1:1:1 showed the highest activity and good selectivity in the deep ethanol oxidation among the prepared Ni-Mn and Ni-Co-Mn oxide catalysts. The presence of Co in the ternary Ni-Co-Mn catalysts did not have a significant effect on the catalytic activity compared to Ni-Mn catalyst with Ni:Mn molar ratio of 1:1 but impaired the selectivity of catalysts, specifically, increased formation of carbon monoxide was observed.

# Investigating of metal vanadate based catalysts in expediting NOx reduction at ultra-low temperatures and their applications

D.W. Kwon*, H.P. Ha

*Korea Institute of Science and Technology, Seoul, South Korea*
**Corresponding Author's E-mail address*

**Keywords:** $NH_3$-SCR, NOx reduction, metal vanadates, $SO_2$ resistance

**Introduction.**

Inventing a catalytic solid with high activity and selectivity to reduce NOx by $NH_3$ to form $N_2$ and $H_2O$ ($NH_3$-SCR) at ultra-low temperatures is recently sought after to attenuate the atmospheric concentration of NOx, leading to mitigate severe air pollution.

**Experimental/methodology.**

$V_2O_5$ has been modified through the incorporation of secondary metal species to synthesize catalysts that outperform commercial catalysts for $NH_3$-SCR. It is the formation of a novel and interesting class of bimetallic V oxides such as $MeVO_4$. The $NH_3$-SCR performance was experimented in a fixed bed reactor (including Lab. and pilot scales).

**Results and discussion.**

The influence of metal vanadate catalyst on its activity and durability in the SCR (selective catalytic reduction) of NOx by $NH_3$ was investigated. The addition of Me-Sb adjusted the surface species composition and increased the number of Brønsted acid sites. The redox properties, number of surface oxygen vacancies, and amount of active labile oxygen were enhanced by the presence of metal vanadates. This species contributed to the improved moisture/sulfur resistance by causing sufficiently enhanced surface acidity and reduced $SO_2$ adsorption. In the NO rich condition, active oxygen and oxygen vacancies improved performance by achieving an optimal Me/V ratio. In contrast, in the $NO_2$ rich condition, the NOx reduction rate increased with the decrease in activation energy from the increase in Me/V ratio. The catalysts synthesized according to the Me/V ratio resulted in changes in the reaction rate and the type of adsorbed species. In this presentation, we highlight our recent pilot studies of the metal vanadate catalysts to diagnose its practical applicability as a $NH_3$-SCR unit. The metal vanadates catalyst is mass-produced, engineered to be a honeycomb monolith-typed catalyst bed, and installed in several $NH_3$-SCR units used for the stationery NOx-emitting sources (pilot test of combined cycle power plant). Our pilot studies corroborate that in comparison with a commercial catalyst, the metal vanadates catalyst reveals greater NOx conversions and superior resistance to poisons including $SO_2$ and ammonium (bi) sulfate. Furthermore, the metal vanadates catalyst, can provide outstanding long-term stability to catalyze $NH_3$-SCR at ultra-low temperatures. This is evidenced by the enhanced performance of the metal vanadate catalyst in real exhaust gas streams at 180 °C or lower temperature.

**Keywords:** Lean $NO_x$ reduction, HC-SCR reaction, Ag catalysts

**Introduction.**
Nitrogen oxides (NO, $NO_2$ and $N_2O$) derived from transport and power plants, are a major source of air pollution which contributes significantly to the formation of photochemical smog, acid rain and eutrophication, as well as being directly harmful to human health [1]. Among the various strategies used to remove these pollutants, a potential method is the selective catalytic reduction of NO (SCR) that showed excellent performance in reducing $NO_x$ emissions from the diesel engine. Hydrocarbons (HC) / oxygenated hydrocarbons, unburnt alcohols (HCO) could be used as reducing agent in SCR reaction, simplifying the plant, reducing costs and making this process of particular interest [2], [3]. In this study the role of ethanol ($C_2H_5OH$) and propene ($C_3H_6$), as reducing agents in the NO-SCR over Ag catalysts deposited on $CeO_2$, $MnO_2$ and a $CeMnO_x$ mixed oxide, was investigated.

**Experimental/methodology.**
All the oxides, $CeO_2$, $MnO_2$ and $CeMnO_x$ (with molar ratio Ce/Mn = 1) were synthesized with the sol-gel method, using citric acid as a chelating agent (citrate method). The supports thus obtained were impregnated with aqueous solutions of $[Ag(NH_3)_2]\cdot NO_3$, in order to obtain catalysts with Ag loads of 1% by weight. The calcination of the oxides was carried out at 500 °C for 3 hours, while the catalysts with Ag were calcined in air at 500 °C for 2 hours. To estimate the activity of NO SCR and the effects of the different hydrocarbons, catalytic tests were performed using propene and ethanol. In the case of $C_3H_6$-SCR test, the mixture was composed of 1000 ppm in NO, 3600 ppm $C_3H_6$, 10 %vol in $O_2$, 2.9 %vol $H_2$ and He as balance gas; while EtOH-SCR tests were conducted using a reaction mixture composed of 1000 ppm of NO, 2 %vol of $C_2H_5OH$ and 10 %vol of $O_2$ in He. The physiochemical properties of the catalysts were obtained by several characterization techniques, such as XRD, $H_2$–TPR, $N_2$-physisorption and Raman spectroscopy.

**Results and discussion.**
The NO SCR activity of Ag catalysts in presence of $C_2H_5OH$ and $C_3H_6$ strongly depends on the nature of the reducing agent, but also on the support composition and as well on the oxidation state and particle size of silver. Catalysts with uniformly distributed $Ag^+$ and/or $Ag_n^{\delta+}$ species are the most active in the NO-SCR reaction, while the metallic clusters of $Ag_n^0$ are responsible for the non-selective oxidation of ethanol and propene.

# The use of Spaci-MS to spatio-temporally resolve Three-Way Catalysts

A. Lanza*, S. Raphy, L. Phillipson, A. Kolpin, D. Bounechada, A.P.E. York

*Johnson Matthey Technology Centre, Sonning Common, United Kingdon*

**Keywords:** Spatially resolved capillary inlet Mass Spectrometry, Oxygen storage catalyst material, Three-way Catalyst, Automotive, Emission Control

**Introduction.** Spatially Resolved Capillary Inlet Mass Spectrometry (SPACI-MS, Figure 1a) [1,2] is a technique which allow to measure gaseous concentration and temperature along the axial profile of a structured catalyst's channel (figure 1b). The gas concentration is sampled through a capillary and analysed by a Mass Spectrometer. Three Way Catalyst (TWC) is the aftertreatment technology used to control emissions from Gasoline engines under a several air-to fuel ratios (rich/lean). Active sites are typically made by Platinum group metals, while supports as $Ce_xZr_{1-x}O_2$ play the role to store and provide oxygen when this is not available in the gas phase: lack of $O_2$ favours NO removal to $N_2$, but can also lead to undesired secondary emissions as $NH_3$ and $N_2O$ (greenhouse gases). In this work, effect of the Oxygen Storage Catalyst material (OSC) was investigated by measuring the stored oxygen and the secondary emissions along the catalyst coordinate using SPACI-MS.

**Experimental/methodology.** Two JM TWC cores (OD = 1", L = 4.5", 600 CPSI) with and without Ce-based mixed oxide (with and without OSC) were tested under Lean to Rich cycles (30 s each). Feed composition of CO=0/2%, $O_2$=1/0%, NO=0-2000 ppm, $H_2O$ =6%, carrier Ar (tot flow= 30 L/min), T=450-650°C. Gas phase composition and temperature were spatially (along the length of the channel) and temporally resolved with SPACI-MS (HIDEN®). An FTIR was used to check the outlet gas composition.

**Results and discussion.**

Figures 1a and 1b show the $O_2$ concentrations measured at each axial coordinate during the lean half cycle for both samples without NO (not reported for brevity). The gaseous $O_2$ is gradually stored along the catalyst channel, and the breakthrough of $O_2$ is delayed for the OSC core compared to the one without, thanks to the presence of the Ce oxide. The cumulative stored $O_2$ was reported in Figure 1c which shows less than half stored without the OSC material, if compared with the OSC core. NO was then co-fed on top of the original mixture to capture any change on the stored gaseous oxygen and NOx removal: NO partially stored [3] and oxidize to $NO_2$ during the the lean half cycle, while the remaining slips. When the CO oxidation front propagates by consuming the stored $O_2$ along the length, local rich conditions occur leading to $H_2$ and $N_2O$/ $N_2$/ $NH_3$ (Fig. 1d only $NH_3$ scan reported for brevity) via WGS reaction and NO reduction (and by stored $NO_x$ surface species [3]), respectively. Within rich conditions the catalyst without OSC showed the highest $NH_3$ production due to the lower oxygen storage capacity which leads to higher $H_2$ production. In contrast, the OSC core showed the lowest $NH_3$ make since the $H_2$ was produced toward the rear of the core. In this work we demonstrated the capability to quantify oxygen storage and secondary emissions with a SPACI-MS during representative gasoline conditions. The catalyst with OSC showed the highest availability of stored oxygen along the whole channel, and the lowest $NH_3$ make as the higher oxygen storage capacity shifted the onset of rich conditions (therefore lower $H_2$ production from WGS) towards the rear of the core.

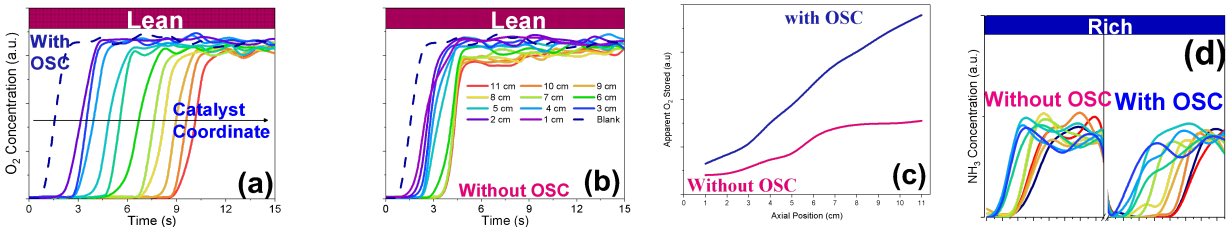

**Figure 1.** a.) Spatiotemporal profiles of $O_2$ (a) with OSC and (b) without OSC cores, NO=0 ppm, 600°C. (c) Overall $O_2$ stored. (d) $NH_3$ profiles

**Introduction.** Such particulates like soot, road dust or ashes suspended in the air show many adverse features, including those leading sometimes to various respiratory and circulatory diseases or, in unfavorable scenarios, to cancerous mutagenic changes. The use of alkali and transition metals can be considered as the most promising alternative to noble metals as catalytic components for soot combustion. Due to their relatively high desorption ability from oxide surfaces, alkali metals have to be intentionally stabilized within bulk matrices. Interesting results in this regard were obtained among others for such alkali-immobilizing matrices as glassy phases. There is however a lack of more systematic studies on doping of such alkali glass-based systems with transition metals (TMs) of pronounced redox properties, playing a role of active sites in many oxidation catalytic reactions. This work aimed to elucidate how doping of alkali glasses with such TMs as Mn, Fe, Co, Cu, Ni, and Ce can influence their properties in catalytic soot combustion.

**Experimental/methodology.** Potassium-silicate glass ($25K_2O$-$59SiO_2$-16CaO mol%) was synthesized from $SiO_2$, $K_2CO_3$, and $CaCO_3$ by simultaneous melting of this mixture at 1345°C for 1h. The doped glasses (containing 5 mol.% of individual dopant) were prepared by a consecutive melting of the parent system with a proper amount of TM (Mn, Fe, Co, Cu, Ni, Ce) oxide at 1340°C for 0.5h. Typical of glasses, the amorphous structure of the synthesized samples, was confirmed by XRD, RS and FTIR, their chemical composition by XRF, and surface properties were investigated by XPS, DRIFT and UV/Vis-DR. The activity of the synthesized samples was determined for both tight and loose contacts in the atmosphere intentionally enriched with NO and without this additive.

**Results and discussion.** Characterization techniques confirmed the amorphous character of the investigated samples typical of glass structures. The activity in soot combustion of all catalysts was high, however, the presence of Cu and Co additives led to an increase in activity in comparison to an undoped glass, while the remaining dopants did not influence or even decreased catalyst activity in soot combustion. A correlation between thermal potassium stability and catalytic activity was found (Fig. 1): the presence of stable surface potassium species resulted in a higher reactivity in soot combustion. This observation confirmed the theory of active carbonate species on the surface of alkali glasses.

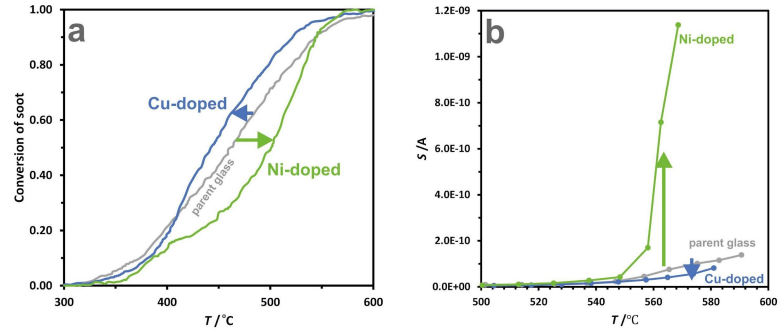

**Fig. 1. Conversion of soot on Ni-, Cu-doped and undoped glass catalyst as a function of temperature (a) and thermal potassium desorption flux from those surfaces (b).**

**Keywords:** $CeO_2$-$WO_3$-$SnO_2$, $NH_3$-SCR, Hydrocarbon resistance, HCN emission, Ammoxidation

**Introduction.** The tolerance of $NH_3$-SCR catalysts towards hydrocarbon compounds (HCs) is very important for their practical application on diesel vehicles. Recently we developed a Ce-W-Sn composite oxide catalyst (hereafter referred to as $CeWSnO_x$) that exhibited fairly high effectiveness for $NO_x$ reduction and superior hydrothermal stability.[1-2] Even after extreme hydrothermal aging treatment at 1000 °C for 3 h, this catalyst still showed >90 % $NO_x$ conversion at 300-550 °C. To further evaluate the possibility of practical application of this catalyst for diesel emission control, the effects of hydrocarbons on the $NH_3$-SCR activity of the $CeWSnO_x$ catalyst were systematically investigated in this work. For comparison purposes, the commercially available $NH_3$-SCR catalyst, namely Cu-SSZ-13, was also examined under the same conditions.

**Experimental/methodology.** The $CeWSnO_x$ catalyst with Ce: W: Sn molar ratio of 1: 0.24: 2 was prepared by a coprecipitation method using ammonium hydroxide as the precipitant. The catalytic activity tests were carried out in a quartz tube plug flow reactor. The simulated reaction gases consisted of 530 ppm $NH_3$, 500 ppm NO, 5 vol. % $O_2$, 5 vol. % $H_2O$ and balance $N_2$ with 859 ppm of propene.

**Results and discussion.** Experimental results[3] suggested that the $CeWSnO_x$ showed much better HC tolerance than the Cu-SSZ-13 (**Figure 1**). This property mainly originated from the strong HC oxidation capacity of the $CeWSnO_x$ due to Sn introduction, which significantly inhibited side reactions, including the HC ammoxidation and the carbon deposition reactions. In contrast, an undesired HC ammoxidation reaction occurred at medium temperatures over the Cu-SSZ-13 in the presence of propene, accompanied by the emission of toxic HCN gas. The high HC tolerance of $CeWSnO_x$ gives it promise for application on heavy-duty diesel after-treatment systems in the future, especially those with the SCR-on-DPF or cc-SCR configuration.

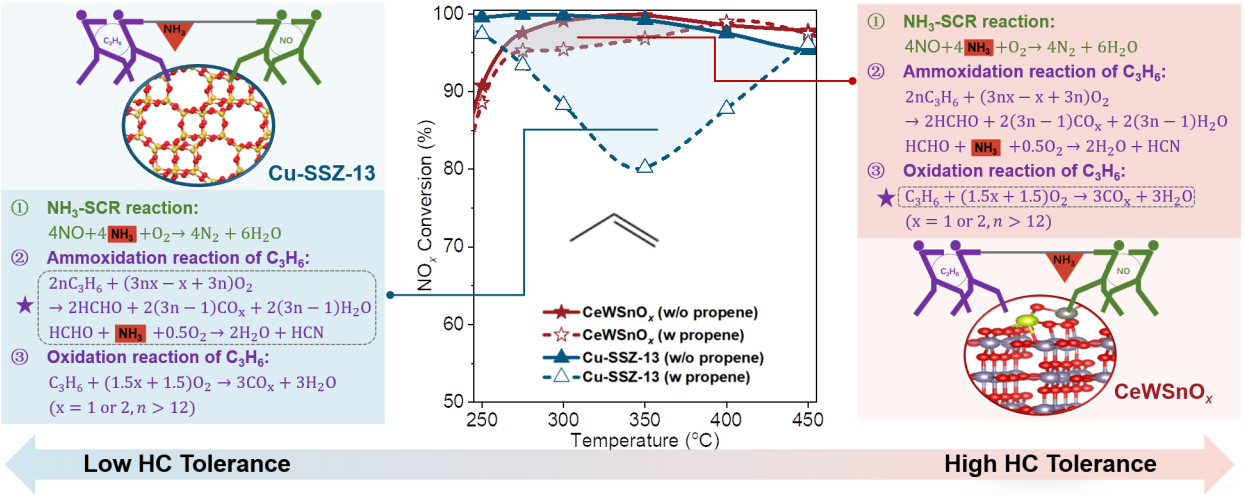

**Figure 1. The effects of propene on the $NH_3$-SCR performance of $CeWSnO_x$ and Cu-SSZ-13 catalysts.**

# Small Gas Molecule CO *in situ* Directed Highly Stable In-Plane 1T phase Boost Co-$MoS_2$ Thiophene Hydrodesulfurization

Lei Liu, Ning Liu, Biaohua Chen*
*Faculty of Enviroment and Life, Beijing, China (100124)*
* chenbh@bjut.edu.cn

**Keywords:** 1T phase transition, CO structure directing agent, hydrodesulfurization, basal plane activation

**Introduction.** $MoS_2$ is a typical hydrodesulfurization (HDS) catalyst [1], which has also been widely applied in the electronic devices, optoelectronics and energy storage. Considering the basal plane covering huge area of $MoS_2$, however, being inert for the reactions, great attentions have been recently concentrated on the basal plane activation to promote $MoS_2$ activity. The 2H⟶1T phase transition can efficiently activate the basal plane of $MoS_2$ [2], which however greatly suffers from the low thermostability of the transformed 1T phase. In this regard, developing a simple 2H⟶1T phase transition method to form stable in-plane 1T phase sites is highly desirable to activate the basal plane of $MoS_2$.

**Experimental/methodology.** A series of Co-$MoS_2$-n (n=0, 0.3, 1.0 and 2.0, representing CO pressure) was synthesized by hydrothermal synthesis approach with *in situ* introducing CO into the system. The XRD, Raman, XPS, EPR, HRTEM, Cs-corrected TEM and EXAFS were employed to characterize synthesized samples and the density functional theory (DFT) and ab initio molecular dynamic (AIMD) were employed to shed deeper insight into the effect of CO during 2H⟶1T phase transition.

**Results and discussion.**

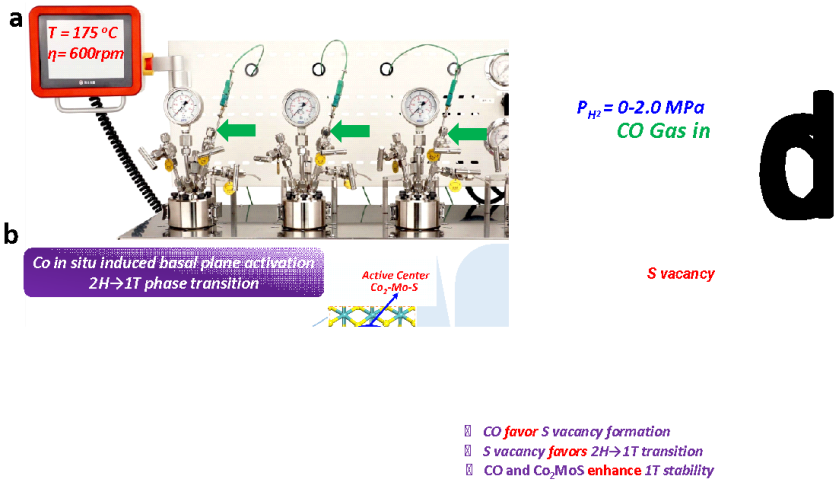

**Fig. 1** Schematic illustration of CO assisted one-step synthesis of Co-$MoS_2$-n and thiophene HDS activity measurement.

Present work utilzing CO as the SDA successfully syntheiaze one type of Co-$MoS_2$-0.3 with high ratio of thermostalbey 1T pahse (70.6%, after 350 °C annealing). The realted thiophene HDS activity (see Fig. 1c) surpasses most of recently reported $MoS_2$-based catalysts. The the kinetics and thermodynamics effects of CO on 2H⟶1T phase transition were well illustrated based on the combined experimental and theoretical studies. A basic atomic structure of "$Co_2$-Mo-S" (in-plane S being coordinated by two Co and one Mo) was identified based on the EXAFS (extended X-ray adsorption fine structure), Cs corrected TEM and DFT (density functional theory) calculation, which significantly favors the CO-directed 2H⟶1T phase transition and thiophene HDS. Present work has developed a simple phase-engineering approach to achieve high ratio of thermostable in-plane 1T phase, which would substantially favor other highly efficient $MoS_2$-based catalyst designs.

**Keywords:** model soot, GDI soot, soot combustion, praseodymia-based catalysts, kinetic study

**Introduction.** By 2020, the European Union has imposed a $CO_2$ emission target of 95 g/km for passenger cars. Gasoline Direct Injection (GDI) engines technology has the potential of substantially improving the overall fuel economy and thus, reducing $CO_2$ levels. One of the main disadvantages of GDI engines is the high emission of particles (mainly those of very low size) compared to conventional gasoline engines. Therefore, GPFs (Gasoline Particulate Filters) have been commercialized and are rapidly becoming a ubiquitous part of new GDI after-treatment systems [1]. In the present communication, the goal is to analyse the uncatalysed and catalysed combustion behaviour of model soot (Printex-U) and a GDI soot.

**Experimental/methodology.** For this study, Printex-U (model soot supplied by Evonik-Degussa) and a real GDI soot (supplied by CMT-UPV) were used to evaluate the uncatalysed soot oxidation characteristics. The soot (1 mg) was placed in a crucible in a TG-MS apparatus, by conducting isothermal tests at the temperature range of interest because of the application studied (500-525-550°C), combined with different $O_2$ concentrations (0.25-1.3-16.6%). These values emulate real working conditions of a GDI engine. Besides, soot combustion activity was evaluated by using a catalyst/soot weight ratio of 20/1 under *loose contact* mode. The selected catalysts ($PrO_2$, $Ce_{0.2}Pr_{0.8}O_2$, $Ce_{0.3}Pr_{0.7}O_2$) were prepared by the direct calcination of the cerium and praseodymium nitrate precursors for 1 hour at 500°C [1].

**Results and discussion.** The detailed analysis of the results suggests that whatever the conditions tested, GDI soot is more reactive than Printex-U, especially at low carbon conversions. For instance, Printex-U shows reaction order values around 0.45, independently on the oxygen concentration studied in this case. This differs slightly from those values expected for shirking core model (0.67) studied, which considers soot particles as non-porous spheres. The effect of the $O_2$ concentration on the soot oxidation was also analysed in terms of temporal evolution of $m_c/m_{c0}$. Soot

consumption rates clearly increase upon increasing the oxygen concentration, being more critical from 0.25% to 1.3% in $O_2$ (see Fig. 1). For the catalysed reaction, paying attention to the rate of $CO_2$ emission for GDI soot (Fig. 2), it is worth to note that very high rates of consumption are reached at the very beginning of the reaction (with nearly 100% of selectivity towards $CO_2$). The set of catalysts chosen are very promising for this demanding application, being $Ce_{0.2}Pr_{0.8}O_2$, which presents an interesting balance among textural and redox properties, the optimal composition found.

# Pd-Pt catalysts supported over Co modified alumina for the methane combustion and CO oxidation

Lazar Minkov[1*], An. Naydenov[2], Il. Hristova[1], H. Kolev[1], S. Todorova[1]

[1] Institute of Catalysis, Bulgarian Academy of Sciences, Sofia 1113, Acad. G. Bonchev str., bl.11, Bulgaria
[2] Institute of General and Inorganic Chemistry, Bulgarian Academy of Sciences, Sofia 1113, Bulgaria

**Keywords:** methane combustion; CO oxidation, Pd-Pt-Co catalysts

**Introduction.** Methane, a potent greenhouse gas, is recognized to contribute more to global atmosphere warming than carbon dioxide at equivalent emission rates. Moreover, methane is the hydrocarbon with the lowest reactivity and therefore the most difficult to be oxidized. Among noble metals, palladium is widely considered to be capable of guaranteeing high activity towards methane combustion. According to the literature date that modification of Pd with Pt results in catalysts with improved resilience with time on stream and increased catalytic activity in comparison to monometallic Pd catalysts. In our previous investigations we found that the addition of Co significantly improves the catalytic activity, and this depended on the sequence of cobalt and Pd introduction. That was the reason to direct our research to the system Pd−Pt−Co supported on $Al_2O_3$.

**Experimental/methodology.** The $Al_2O_3$ (SBET=225 $m^2/g$) was first impregnated with aqueous solution of $Co(NO_3)_2.6H_2O$ and calcined 2 h at 450 °C in air. After that the monometallic and bimetallic samples were prepared by impregnation of Co-$Al_2O_3$ or by successive impregnation with the corresponding salts or from a mixed solution. After each impregnation the catalysts were calcined 2 h at 450 °C in air. The as prepared catalysts were tested in $CH_4$ combustion and CO oxidation. Characterization techniques, X-ray photoelectron spectroscopy (XPS), powder X-ray diffraction (XRD) and FTIR have been used to investigate the surface structure and bulk composition all catalysts.

**Results and discussion.** No palladium, palladium and cobalt phases were detected by XRD, revealing finely divided of Pd, Pt and cobalt particles. FTIR spectra of the fresh and worked Pd-Pt-Co catalysts show two wide bands one in the region 550-600 $cm^{-1}$ and other in the interval 650–700 $cm^{-1}$. IR absorption at 670 $cm^{-1}$ is ascribed to the vibrational bands of $Co^{2+}$ in the $Co^{II}Al_2O_4$ spinel phase. The pink colour of the sample suggests that in this sample the Co ions have not undergone any oxidation process and they exist as $Co^{2+}$ species in the octahedral sites.

| Sample | $S_{BET}$, $m^2/g$ |
|---|---|
| Pd+Pt/ Co-$Al_2O_3$ | 223 |
| Pd+Pt/ Co-$Al_2O_3$-MS | 236 |
| Pt/Co- $Al_2O_3$ | 232 |
| Pd+Pt/Co-$Al_2O_3$ | 227 |

Table 1. Samples characteristics

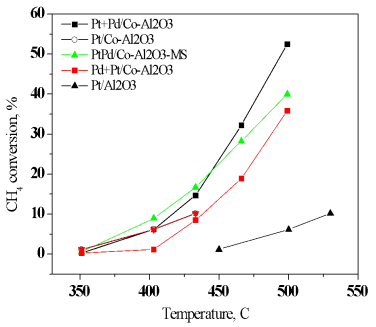

Figure 1. Conversion vs. temperature in the reaction of complete methane oxidation

$H_2O$ and $CO_2$ were the only detectable reaction products on all studied samples in methane oxidation. The low activity in CO oxidation was observed for a tested catalyst. The improving in activity was observed for Pt catalysts modified with Co also. The additional increase in activity was seen after Pd addition. The row of activity in as follows: Pt-Pd> PdPt Ms > Pd-Pt>Pt.

**Keywords:** DeNO$_x$ hybrid technology, NSR-SCR, Cu-CHA-zeolites, SAPO-34, SSZ-13

**Introduction.**

Road-transpor sector is still the major air pollution contributor of harmful NO$_x$ emissions in Europe. The new Euro 7 regulation declared the importance of the development of DeNO$_x$ technologies, based on the combination of the current technologies and knowledge of all relevant pollutants control systems. Two catalytic technologies are widely used for this purpose are NO$_x$ Storage and Reduction (NSR) and Selective Catalytic Reduction (SCR) in diesel engines. The coupling between a NO$_x$-Trap followed by a NH$_3$-SCR catalyst leads to an improved N$_2$-selectivity, by the storage and reaction of the undesired NH$_3$ produced in the NSR catalyst in the downstream SCR system. This contribution is focused on the synthesis of two isostructural CHA-zeolites with Cu integrated in their structure, SAPO-34 and SSZ-13, and the combination and analysis of the behavior in NO$_x$ abatement activity in the NSR-SCR hybrid system.

**Experimental/methodology.**

For the NSR system, a model catalyst (Pt-Ba-K/$Al_2O_3$) was used [1]. As SCR catalysts, Cu-CHA-zeolites precursor gel phase was synthesized containing 2 wt.% of Cu by an ultrasound-assisted hydrothermal method and the calcined materials were identified as 2Cu-SAPO-34 and 2Cu-SSZ-13. Cu-zeolites were well-characterized. DeNO$_x$ activity of the NSR+SCR system was evaluated in a fixed-bed tubular reactor in isothermal and transient regime using a MultiGas MKS 2030 FTIR analyzer and the QMS200 Mass Spectrometer for online monitoring the outlet product distribution. Cyclic alternating lean (3%$O_2$) and rich (1%$H_2$) fuel conditions were used maintaining the concentration of NO (600 ppm), $CO_2$ (0.3%) and $H_2O$ (1.5%) He-balanced, GHSV=30000h$^{-1}$ and the T-range of 200-350ºC.

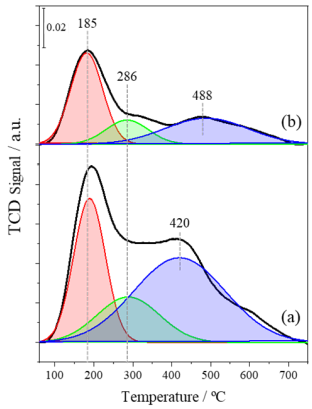

**Figure 1**. NH$_3$-TPD profiles for Cu-CHA-zeolites: (a)2Cu-SAPO-34 and (b) 2Cu-SSZ-13

**Results and discussion.**

**Table 1**. DeNO$_x$ activity results at 250 ºC

| Configuration | $X_{NO_x}$ (%) | $S_{N_2}$ (%) | $S_{NH_3}$ (%) | $S_{N_2O}$ (%) |
|---|---|---|---|---|
| NSR | 52.3 | 69.6 | 21.6 | 8.8 |
| NSR+2Cu-SAPO-34 | 63.7 | 89.4 | 0.02 | 9.6 |
| NSR+2Cu-SSZ-13 | 58.8 | 94.1 | 0.00 | 5.8 |

In NH$_3$-TPD profiles (Fig. 1) a low-temperature (185ºC) signal related to Brønsted acid sites was observed, a medium-temperature signal (286ºC) due to NH$_3$-adsorbed on strong Lewis acidic sites, associated with

isolated $Cu^{2+}$ sites, was identified for both Cu-zeolites but more evident for Cu-SAPO-34. The existence of different Cu-species (confirmed by FTIR analysis with probe molecules) causes the shift to the T-max desorption signal of the Brønsted sites and influences the de$NO_x$ activity. $NO_x$ conversion and selectivity values (Table 1) indicated an enhancement of $NO_x$ removal capacity for both hybrid systems compared to the single bed, due to the $NH_3$-SCR reaction. 2Cu-SSZ-13 catalyst presented a lower acidity and a lower $Cu^{2+}$ ion population that, in spite of not being as active in NO conversion, is able to inhibit the occurrence of parallel reactions with $N_2O$ formation, increasing nitrogen selectivity, with values around 94%, which makes this catalyst more suitable for its use in the hybrid catalytic system.

[2] *Felix Bloch Institute for Solid State Physics, Universität Leipzig, Leipzig, Germany*
[*]*magdalena.jablonska@uni-leipzig.de*

**Keywords:** $NH_3$-SCR-DeNO$_x$, SSZ-13, ERI, copper.

**Introduction.** The selective catalytic reduction of nitrogen oxides by ammonia ($NH_3$-SCR-DeNO$_x$) is the most used emission control process for both stationary and mobile sources of NO$_x$. Copper-containing catalysts have been broadly investigated in $NH_3$-SCR-DeNO$_x$, while some reports claim an increase in NO conversion over micro-/mesoporous Cu-containing ZSM-5 or SAPO-34 [1,2]. On the contrary, it has been claimed that the mesopores introduced into Cu-containing zeolites ZSM-5 or Y do not play any direct role in the activity on $NH_3$-SCR-DeNO$_x$ [3,4]. Thus, further research is needed to explore these contradictions.

**Experimental/methodology.** SSZ-13 and ERI (obtained from Clariant) were subjected to post-synthetic treatments with an acidic and/or an alkali solution, followed by filtration and washing until neutral pH. Afterward, they were ion-exchanged with an aqueous $NH_4NO_3$ solution, calcined, and finally ion-exchanged with Cu(II) acetate. After pretreatment, the samples were investigated in the $NH_3$-SCR-DeNO$_x$ and thoroughly characterized with respect to their structure, composition, morphology (XRD, ICP-OES, SEM), texture ($N_2$ sorption), and redox properties, as well as the nature of their copper species (TPR-$H_2$, DR UV-Vis, EPR).

**Results and discussion.** The comparison of Cu-containing zeolites with different topologies (ERI and SSZ-13, Fig. 1a) reveals that Cu-SSZ-13 exhibits a significantly higher NO conversion than the other catalysts. The post-synthetic modification of the investigated zeolites influences the catalytic activity in different ways. Regarding the Cu-containing ERI, the NO conversion is higher for catalysts with modified supports (Fig. 1b). The NO conversion does not vary among different post-synthetic treatments, with either NaOH or $HNO_3$. For the Cu-containing SSZ-13 catalysts (with modified zeolites), a lower NO conversion in $NH_3$-SCR-DeNO$_x$ is observed. According to physico-chemical characterization, the modification of the supports results in the presence of different amounts and kinds of copper species (especially isolated $Cu^{2+}$ and aggregated Cu species).

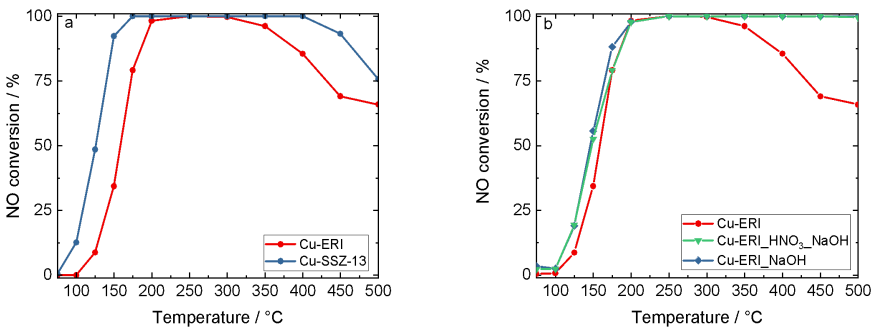

**Figure 1. NO conversion over Cu-containing zeolites with different topologies (a) and different post-synthetic treatments of the support (b) studied in $NH_3$-SCR-DeNO$_x$.**

**Keywords:** clinoptilolite, hydrotalcite, transition metals, $DeNO_x$

**Introduction.** Clinoptilolite, which belongs to the heulandite (HEU) family, is one of the most common natural zeolites and, due to its advantageous physicochemical properties, it has been used in many industrial processes [1]. It was proved [2] that iron-modified clinoptilolite exhibits very promising catalytic features as a support for $NH_3$-SCR catalysts. However, one of the challenges for the implementation of this material is to change its temperature window to the lower range. The problem can be solved by the deposition of a well-dispersed active phase in the form of mixed metal oxides, which contribute to low-temperature NO conversion. This goal can be reached by co-precipitation of hydrotalcite-like (HT) phase on the surface of clinoptilolite. The advantage of such modification is related to the fact that $Mg^{2+}$ and $Al^{3+}$ in HT building units can be substituted by catalytically active chemical elements, such as $Cu^{2+}$ and $Fe^{2+}$ [3]. Additionally, calcination of hydrotalcite-like materials yields mixed metal oxides, which could contribute to NO reduction in both the low- and high-temperature range. Therefore, the presented studies were focused on the synthesis, physicochemical characterization, and $NH_3$-SCR catalytic performance of clinoptilolite covered with hydrotalcite-like phase.

**Experimental/methodology.** Natural clinoptilolite was hydrogenated using HCl solution and modified with hydrotalcite by co-precipitation at constant pH. The HT phase contained $Al^{3+}$ and $Fe^{3+}$ (as trivalent metals, $Me^{3+}$) and $Mg^{2+}$ and $Cu^{2+}$ (as divalent metals, $Me^{2+}$) and the $Me^{2+}/Me^{3+}$ molar ratio was 3:1. The amounts of metal precursors were adequately adjusted to obtain 20, 25, and 30 wt% coverage of the zeolite with HT phase. The physicochemical properties of the samples were determined using ICP-OES, low-temperature $N_2$ sorption, XRD, UV-Vis, TGA, FT-IR, and SEM, while the catalytic performance was investigated within 150-450 °C using a model gas mixture containing 800 ppm NO, 800 ppm $NH_3$, 3.5 vol.% $O_2$, and He as an inert.

**Results and discussion.** The obtained results showed that the $NH_3$-SCR catalytic performance of the materials was not related to the HT loading on the clinoptilolite. The deposition of the HT phase on the zeolitic support had a positive impact on NO conversion within 250-450 °C, which was related to the Brönsted acid sites present on the surface of clinoptilolite. UV-vis experiments on the spent catalysts indicated formation of Fe- and Cu-sites of higher nuclearity during the catalytic reaction. Hence, calcination prior to the catalytic reaction was not required for satisfactory NO conversion in the investigated temperature range.

[*]*chiara.nannuzzi@unito.it*

**Introduction.** Power plants, ships, and diesel engines are producing $NO_x$ (NO and $NO_2$) during combustion processes in oxygen-rich conditions. The selective catalytic reduction by ammonia ($NH_3$-SCR) converts $NO_x$ into $N_2$ and water, preventing the release of these compounds in the atmosphere, with related health and environmental concerns [1]. $VO_x/TiO_2$ based catalysts are the catalysts of choice in heavy-duty vehicles and large plants, usually promoted with Mo and/or W to improve thermal stability and activity. The role of promoters on the active sites could be chemical (modification of the electronic properties of $VO_x$) or physical (modification of $VO_x$ dispersion by 'crowding'), as debated in the literature [2,3].

**Experimental/methodology.** A series of $VO_x/TiO_2$ with variable $VO_x$ and two series of $VO_x/WO_3/TiO_2$ catalysts with fixed $VO_x$ and variable $WO_x$ content were prepared, tested in the title reaction and characterized by IR of CO probe molecules and Raman spectroscopies.

**Results and discussion.** Raman spectroscopy shows a good dispersion of V-O-V and V-O-W species in all catalysts. In both $VO_x/WO_3/TiO_2$ series, keeping constant the amount of V the activity increases with W up to 5 (V+W) atoms/nm$^2$ (Figure 1a), which would correspond to the monolayer according to IR spectra of adsorbed CO.

According to a widely accepted mechanism, the active $V^{5+}$=O site is reduced during the reaction to $V^{4+}$ and rapidly oxidized again [3]. This would imply that in oligomeric V-O-V and V-O-W species, one V atom is the active redox site and the second one is helping in the reoxidation step. Following this hypothesis, the rate constant has been normalized to the theoretical amount of V active sites for each catalyst. Figure 1b shows higher values for W-free catalysts, suggesting a higher activity for V-O-V than V-O-W pairs. This points to the conclusion that the effect of W on the catalytic activity is to favor the formation of V-O-V species by crowding effect.

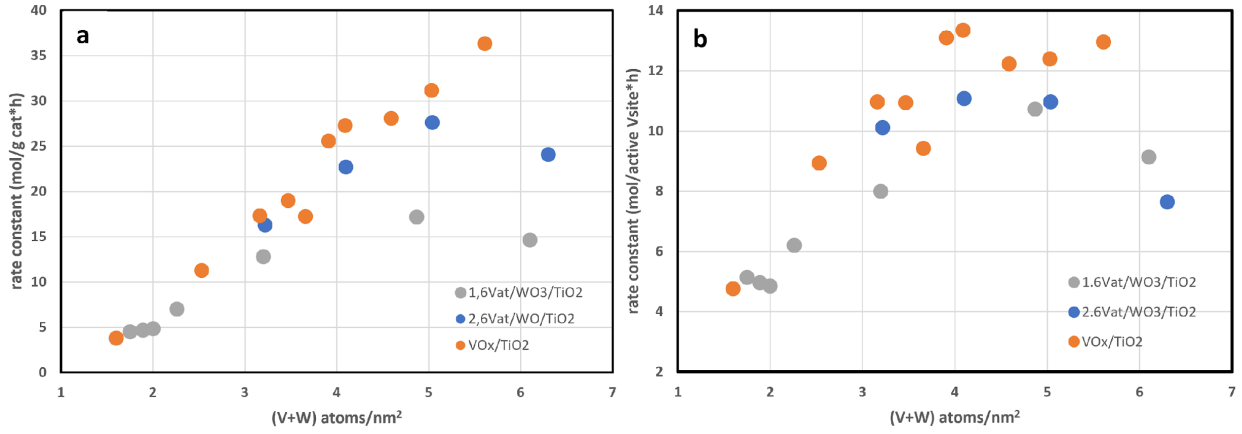

**Figure 1. Rate constant at 250°C normalized to a) catalyst mass and b) theoretical amount of V active sites for two series of $VO_x/WO_3/TiO_2$ and $VO_x/TiO_2$ catalysts.**

# Surface property studies on Sb promoted $VO_x/TiO_2$ $NH_3$-SCR catalysts

Alexander Nellessen[1,2], Andreas Schaefer[1,2], Anna Martinelli[1], Per-Anders Carlsson[1,2*]

Chalmers University of Technology, Department of Chemistry and Chemical Engineering
[1]*Division of Applied Chemistry and* [2]*Competence Center for Catalysis, SE-41296 Gothenburg, Sweden*
[*]*per-anders.carlsson@chalmers.se*

**Keywords:** in situ DRIFTS, $NH_3$-SCR, $VO_x/TiO_2$, Sb.

**Introduction.** Environmental protection and the legislative tightening of $NO_x$ emissions in the mobile sector have provoked many efforts for the development of effective catalytic systems in the $NH_3$-SCR technology. Among these, titania supported V-based catalysts are commonly used, given to the low material costs and high resistance to sulfur compounds.[1] However, the catalyst has to work under dynamic conditions in a broad temperature window. Both low-temperature activity and stability at high temperatures are needed. The introduction of antimony on the catalysts have found to be an effective promoter to meet these requirements.[2] Our work is focused on surface properties studies on metal promoted $VO_x/TiO_2$ catalysts to understand the interaction of antimony with the $TiO_2$ support and vanadium.

**Experimental/methodology.** A series of Sb-promoted support and $VO_x/TiO_2$ catalyst was prepared via incipient wetness impregnation and additionaly thermally treated to mimic a long term use. The surface species and catalyst morphology were studied by in-situ infrared spectroscopy in diffuse reflectance mode (DRIFTS), Raman spectroscopy, $NH_3$-TPD, and surface BET area.

**Results and discussion.** The results from the $NH_3$-TPD show that the Sb-promoted $TiO_2$ support reveals a higher $NH_3$ adsorption capacity after the thermal treatment. In addition the adsorption capacity of the promoted catalyst is slightly decreased, indicating that antimony stabilizes both the support and the vanadium species.
The DRIFTS spectra of the Sb promoted support for the $NH_3$ adsorption at room temperature show that both promoted support and catalyst show a higher intensity for the negative OH bands after the thermal treatment. This can related to the formation of Sb-OH-Ti and V-OH-Sb groups that provide additional reaction sites in the SCR reaction. In the NH region, the higher intensity of the bands between 1483-1433 $cm^{-1}$ indicates a higher amount of Brönsted acid sites by formation of Sb-OH-Ti.

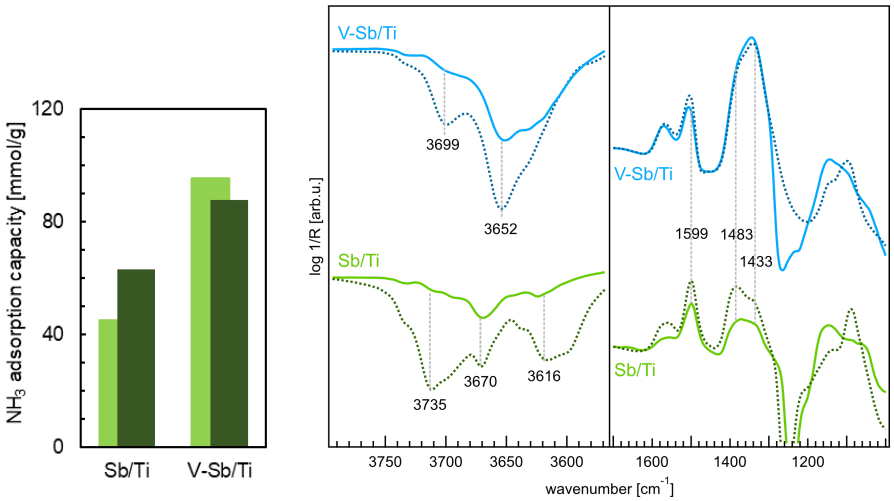

**Figure 1: Integrated areas of $NH_3$-TPD profiles (a) and in situ DRIFTS spectra for the $NH_3$ adsorption at 25 °C of Sb promoted $TiO_2$ support and $VO_x/TiO_2$ catalyst before (solid line) and after thermal treatment (dashed line).**

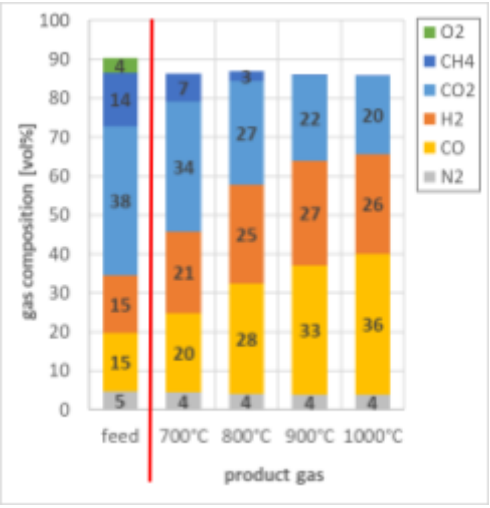
# Processing a burner gas from autothermal biogas combustion for syngas production

K. Neubauer[1], U. Armbruster[1], S. Wohlrab[1*], S. Anger[2], H.-P. Schmidt[3]



[1]*Leibniz Institute for Catalysis, Rostock, Germany*
[2]*DBI – Gastechnologisches Institut gGmbH Freiberg, Freiberg, Germany*
[3]*WS Reformer GmbH, Renningen, Germany*
[*]*sebastian.wohlrab@catalysis.de*

**Keywords:** syngas production from biogas, high-temperature catalyst, reforming

**Introduction.** Typically, biogas (mainly containing $CH_4$ and $CO_2$) is often used in low-value applications such as heating. In contrast, it can be converted into syngas by reforming to produce high-value liquid fuels or chemicals without the need for prior $CO_2$ capture [1]. This process is often called 'bi-reforming' or Steam Biogas Reforming (SBR), which combines steam and $CO_2$ reforming of methane [2].

**Experimental/methodology.** Using a simulated feed gas composition derived from modeling the effluent from autothermal combustion of biogas with $O_2$, the reforming activity of various catalysts was investigated in a laboratory facility with a 3-zone high-temperature furnace above 950 °C. The feed gas was composed of 5 pure gases ($CH_4$, CO, $CO_2$, $H_2$ and $O_2$) mixed with evaporated water. Measurement of the feed and product gas composition was done online via FID and TCD detection with $N_2$ as internal standard.

**Results and discussion.** An innovative process for the production of methanol from biogas using hydrogen and oxygen from renewable sources is being developed. The decisive step is the coupling of a new burner concept (ADROX-FLOX) with high-temperature catalysts for downstream gas conditioning towards syngas.

Catalysts with spinel or perovskite structure as well as metals supported on alumina were investigated. For example, Co-$AlLaO_x$ showed very good stability at high temperatures due to formation of mixed oxide as support [3]. The $LaAlO_3$ perovskite structure is stable up to 1000 °C. Under reductive atmosphere, the formation of $Co^0$ was detected at temperatures above 400 °C which is the active species for methane reforming.

All tested catalysts were active in bi-reforming at 700-1000 °C and high water contents (18 vol%) in the feed gas mixture. Using Co-$AlLaO_x$, the conversion of $CH_4$ was almost complete at 800 °C (see Fig. 1). The high stability of Co-$AlLaO_x$ for $CH_4$ reforming was confirmed in experiments running more than 40 h.

These results show that by coupling autothermal combustion of biogas and catalytic reforming of the remaining methane at very high temperatures with stable catalysts, synthesis gas yields > 90% are possible, which can be converted, e.g., into methanol in subsequent process steps.

# Mechanistic Insights of Total Methane Oxidation over Iron-Containing Beta Zeolites

A. Niederdränk[1,2*], T. Kratky[1,2], J. Schobel[1,2], S. Günther[1,2], O. Hinrichsen[1,2]

[1]*Technical University of Munich, School of Natural Sciences, Garching, Germany*
[2]*Technical University of Munich, Catalysis Research Center, Garching, Germany*
[*]*anne.niederdraenk@tum.de*

**Keywords:** methane oxidation, iron beta zeolite

**Introduction.** Due to the growing demand for improved environmental and climate protection, dual fuel and gas-powered marine engines offer high potential in the maritime sector owing to reduced emissions of greenhouse gases (GHG), such as $CO_2$, $NO_x$ and particulate matter. [1] However, these engines also emit unburnt $CH_4$, acting as potent GHG demanding for further oxidation of $CH_4$ to $CO_2$. Until now, catalysts with platinum group metals have typically been used for total oxidation of $CH_4$. Due to their high costs, novel non-precious catalysts with high activities and stabilities need to be developed. Iron-containing beta zeolites have already been proven for selective catalytic reduction (SCR) of $NO_x$ in exhaust catalysis. [2] Aiming at a coupling of SCR and methane oxidation, various cheap and non-toxic iron beta zeolites were synthesized and successfully applied in the total oxidation of methane.

**Experimental.** The investigated catalysts were synthesized by doping commercial beta zeolites with iron nitrate based on wetness impregnation, solid ion exchange, liquid ion exchange and liquid ion exchange modified with sonication. The materials were subsequently calcined at 550 °C. Structural analysis was carried out by means of X-ray powder diffraction, $N_2$ physisorption analysis, Raman spectroscopy and X-ray photoelectron spectroscopy. Activity measurements were performed under 5000 ppm $CH_4$ and 19% $O_2$ in He at temperatures ranging from 220 – 600 °C at pressures up to 3 bar.

**Results and discussion.** Thorough characterization of the synthesized catalysts has shown that the procedure of iron incorporation into the zeolite affects both, the distribution and the type of iron species incorporated in the zeolite. Preparation by means of solid ion exchange resulted in the formation of a hematite phase. In contrast, no crystalline iron phase could be detected for the other synthesis routes, suggesting a fine dispersion or even an incorporation of iron into the zeolite structure. Activity measurements revealed an impact of iron species on the activity for complete methane oxidation. Here, the catalyst evincing a hematite phase revealed the lowest activity. In order to investigate the active centers for methane oxidation, *in situ* XPS measurements combined with mass spectrometry were carried out on hematite as model system. At ambient conditions, hematite converted $CH_4$ to $CO_2$. Temperature-programmed desorption revealed formate as intermediate species. *Ex situ* XPS indicated $Fe^{3+}$ as predominant surface species. Due to the low sticking of $CH_4$, no carbon could be observed on the surface after the reaction. In order to shed light on the active surface species during catalysis, the oxidation of acetylene over iron oxide was followed by *in situ* XPS making use of the higher sticking of acetylene. Activity measurements at ambient pressure proved a higher activity compared to methane oxidation involving formate species as intermediates. Characterizing the surface *in situ* by XPS also revealed $Fe^{3+}$ as predominant surface species. It could be shown that the novel iron oxide catalysts are very stable against coking and maintain their high activity.

**Keywords:** soot combustion, catalyzed gasoline particulate filter, doped silver zirconia catalyst

**Introduction.** Petroleum-based fuels are still the predominant energy used in transportation. Strict energy and environmental policies to fight climate change dictate the necessary improvement of conventional aftertreatment technologies for internal combustion engines. One way to make soot removal from gasoline direct injection (GDI) engine exhaust more efficient is to load a catalyst to a gasoline particulate filter (GPF). This study presents the results for soot oxidation under low oxygen concentration using silver-zirconia catalysts doped with Y, La, Ce and Pr. The gasoline soot oxidation activity of fresh and aged catalysts was compared in view of practical GPF applications.

**Experimental/methodology.** A series of doped $Ag/M\text{-}ZrO_2$ catalysts (M is Y or La or Ce or Pr) was synthesized by a citric-assisted sol-gel method using metal nitrates as precursors in amounts to obtain 10 wt% of Ag and 8 mol% of M-dopant oxide in the mixed oxide. Before testing, the catalysts were dried at 200°C overnight followed by calcination in air at 550°C for 6 h.

The resulting catalysts were characterized by BET, XRD, XPS and $O_2$-TPD methods. The fresh and aged catalysts were eveluated for soot oxidation under low oxygen concentration. Carbon black was tightly mixed with a catalyst in a w/w ratio of 1:10.

**Results and discussion.** During preliminary temperature programmed oxidation (TPO) testing, the $Ag/La\text{-}ZrO_2$ and $Ag/Y\text{-}ZrO_2$ catalysts revealed the best activity and thermal stability among a series of catalysts when tested fresh and after thermal aging at 700°C 6 h. Table 1 shows the testing results of these two catalysts in comparison to the undoped catalyst in the presence of gas components in concentrations simulating stoichiometric GDI exhaust [1]. Similar soot oxidation activity ($T_{max}$ of 405°C) was found for the fresh catalysts modified by La or Y, however, after aging the $Ag/La\text{-}ZrO_2$ catalyst revealed the best stability exhibiting the lowest $T_{max}$ of 419°C of the two. The catalyst modification with La and Y also resulted in improved activity for co-oxidation of CO and $C_3H_6$, which need to be removed as well. The most reasonable cause for the increase in the oxidative activity and stability of doped catalysts is a combination of changes in textural and structural properties, as well as in the number of oxygen vacancies and the degree of oxygen desorption of modified materials.

Table 1. $T_{max}$ and $T_{50}$ as a measure of catalytic activity for soot oxidation and CO and $C_3H_6$ co-oxidation of fresh and aged catalysts tested under simulated GDI exhaust conditions. Testing conditions: 12 vol% $H_2O$, 12 vol% $CO_2$, 1.5 vol% $O_2$, 5000 ppm CO, 1000 ppm NO, 500 ppm $C_3H_6$, balance $N_2$, tight contact, 250 mg catalyst : carbon = 10:1 w/w ratio, catalyst : cordierite = 1:1 w/w ratio

| Catalyst | Soot oxidation $T_{max}$ (°C) | | CO oxidation $T_{50}$ (°C) | | $C_3H_6$ oxidation $T_{50}$ (°C) | |
|---|---|---|---|---|---|---|
| | Fresh | Aged | Fresh | Aged | Fresh | Aged |
| $Ag/ZrO_2$ | 425 | 476 | 286 | 395 | 330 | 435 |
| $Ag/Y\text{-}ZrO_2$ | 405 | 432 | 257 | 336 | 297 | 379 |
| $Ag/La\text{-}ZrO_2$ | 404 | 419 | 254 | 308 | 295 | 345 |

# Mn substitution of Co in mixed oxides – effect on physical, chemical and catalytic properties in direct NO decomposition

*Bílková T.[a], Pacultová K.[a], Fridrichová D.[a], Karásková K.[a], Koštejn M.[b], Jirátová K.[b], Obalová L.[a]*

**Keywords:** nitric oxide, Co-based mixed oxides, K-promoter, structure-activity relationship

**Introduction.** NO together with $NO_2$ are known as $NO_x$, which are mainly produced by anthropogenic activities (combustion of fossil fuels, in cars and industry) and their emissions represent serious environmental problems causing formation of photochemical smog and acid rains. Commonly used methods (selective catalytic reduction and selective non-catalytic reduction) are effective, however, reducing agent ($NH_3$, urea) is needed. Co-based mixed oxides catalysts modified by K were found to be active in direct NO decomposition [1, 2] producing $N_2$ and $O_2$ as the final products. It is known that addition of K to Co oxides ensures the required catalytic properties. Partial substitution of Co by Mg in $K/Co_4MnAlO_x$ was performed [3] and the catalytic activity did not change. It suggests that Co, which is corrosive, toxic and expensive, can be replaced by another metal without loss of activity.

**Experimental/methodology.** In this study, Mn was used for substitution for Co. The set of samples denoted as $Co_zMn_{5-z}AlO_x$ was prepared by co-precipitation of corresponding nitrates and modified by 2 wt.% of K. Using several characterization techniques (AAS, XPS, XRD, $S_{BET}$ TEM, TPR $H_2$, TPD $CO_2$, TPD NO, XAS), the physico-chemical properties of prepared catalysts were studied in relation to their catalytic performance.

**Results and discussion.** From obtained results, it can be concluded that potassium and Co play the key role in NO decomposition reaction, since the $K/Mn_5AlO_x$ is totally inactive. The increase of NO conversion can be observed up to molar ratio Co/Mn = 3/2, higher amounts of cobalt in the sample do not influence obtained conversion. Presence of manganese affects the catalyst long term stability. The most stable catalyst is $K/Co_4MnAlO_x$ which also showed the largest $S_{BET}$.

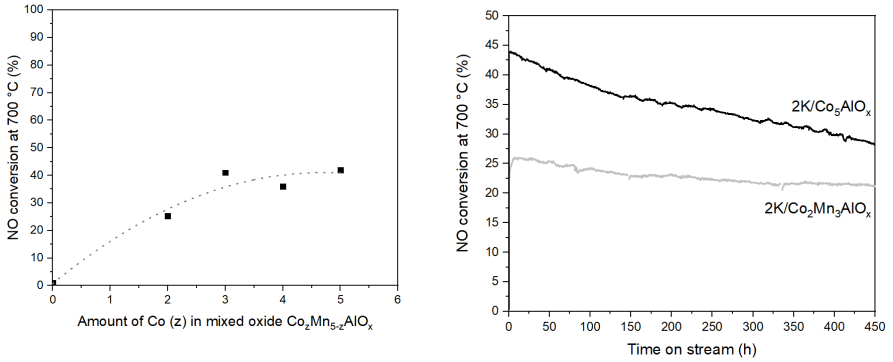

**Fig. 1**: Dependence of NO conversion (700 °C) on Co molar content in $Co_zMn_{5-z}AlO_x$ mixed oxide (left) and long term stability of selected samples (right). Conditions: 1000 ppm NO in $N_2$, GHSV = 6 l $g^{-1}$ $h^{-1}$.

**Keywords:** Methane oxidation, Nickel, Exsolution, ADP, Perovskites

**Introduction.** Methane can represent a renewable and low carbon fuel if derived from biomass anaerobic digestion to biogas, which can be fed in the already existing natural-gas pipelines and vehicles. $CH_4$ oxidation is a key reaction taking place in post-combustion three-way catalytic converters (TWC) applied to methane-fed vehicles [1]. However, conventional catalytic formulations rely on noble metal particles, especially Pd [2], therefore its replacement with cheaper and more earth-abundant materials would be desirable. Among transition metals, Ni is widely adopted for other $CH_4$ activation reactions, such as Steam Reforming and Dry Reforming. Perovskites were already found suitable materials to stabilize the dispersion of Platinum Group Metals (PGMs) catalysts, thanks to a self-regenerative process in which PGMs can reversibly exit from and re-enter the perovskite structure in oscillating reducing-oxidizing conditions typical of TWC operating around the stoichiometric air/fuel ratio [3]. There is some evidence that a similar mechanism can also occur for non-noble transition metals like Ni [4]. Based on the above considerations, we hereby propose perovskite-supported Ni catalysts for the complete $CH_4$ combustion to $CO_2$. A LaMn-perovskite was chosen, for its good oxidation activity and oxygen storage capacity, with A-site deficient composition ($La_{0.8}MnO_3$), which should favor the generation of oxygen vacancies and thus the absorption of gas-phase reactants.

**Experimental/methodology.** Perovskites were synthesized by means of the citrate sol-gel route with final calcination in air at 750°C; different citric acid amounts (molar ratio CA/metals = 1.1 or 1.5) were evaluated. Ni was added to the catalytic formulation according to two different methods: i) perovskite B-site doping to obtain $La_{0.8}Mn_{1-x}Ni_xO_3$ (x = 0.1 or 0.2) compositions, followed by $Ni^0$ exsolution out of the oxide matrix through a reductive treatment in 5% $H_2$/Ar; ii) Ammonia-driven deposition precipitation (ADP), i.e. $Ni^{2+}$ precipitation onto pre-calcined $La_{0.8}MnO_3$ support by $NH_3$ addition, followed by calcination in air and reduction to $Ni^0$ in 5% $H_2$/Ar. The obtained catalysts were characterized by XRD, XPS, $N_2$ physisorption, SEM-EDX, $H_2$-TPR and $H_2$-pulsed chemisorption. Catalytic $CH_4$ oxidation tests with stoichiometric $O_2$ were carried out in a simplified reaction mixture, in the temperature range 300-800°C, with a WHSV of 120 L $h^{-1}$ $g^{-1}$. Catalytic activity of both freshly calcined and reduced catalysts was evaluated.

**Results and discussion.** Physicochemical properties of the obtained perovskites were deeply influenced by the amount of citric acid: more favorable surface area, reducibility and availability of surface oxygen species were obtained with molar ratio CA/metals of 1.1 with respect to 1.5, leading to higher $CH_4$ oxidation activity in the former case. Compared to benchmark $La_{0.8}MnO_3$, B-site Ni doping slightly enhanced catalytic performances at low temperatures, whereas a greater beneficial effect was obtained with NiO-ADP in the whole T range, highlighting the promising activity of $Ni^{2+}$ species. After reduction from NiO to $Ni^0$, confirmed by XRD, ADP sample did not reveal any significant difference in catalytic performances, whereas a slight improvement was achieved through $Ni^0$ exsolution from B-site doped compositions. However, the extent of exsolution was rather low since low metal dispersion values were obtained by $H_2$ chemisorption; an optimization of the exsolution process is therefore required to further improve catalytic performances.

# Facile synthesis of Ir/$LaFeO_3$ catalyst for propene total oxidation

F. Pan[1], W. Zhang[1], C. Ferronato[1], J. Valverde[2], A. Giroir-Fendler[1,*]

[1] *Univ. Lyon, Université Claude Bernard Lyon 1, CNRS, IRCELYON, Villeurbanne, France*

**Keywords: iridium, perovskite, catalytic oxidation**

**Introduction.** In recent years, volatile organic compounds (VOCs) have become one of the main contributors to air pollution [1]. Catalytic oxidation is one of the most efficient ways to eliminate VOCs. Supported noble metal catalysis is one of the most investigated fields in heterogeneous catalysis because of presenting outstanding catalytic behavior as well as mitigating the rising environmental and energy challenges [2].

**Experimental.** In this study, Ir/$LaFeO_3$ was synthesized by a facile grinding method [3]. Iridium acetylacetonate and $LaFeO_3$ were ground in a mortar, followed by calcined at different temperatures (300-600 °C). The physicochemical properties of these catalysts were characterized by TG/TDA, ICP analysis, FTIR, XRD, Raman, $N_2$ adsorption, HRTEM, XPS, and $H_2$-TPR.

**Results and discussion.** No characteristic peaks of Ir or $IrO_2$ were observed in XRD, Raman and FTIR spectra, indicating the high dispersion of Ir on the $LaFeO_3$ support. In addition, no iridium particles or aggregates could be found by HRTEM though EDX analysis demonstrated the presence of Ir element, which probably suggests atomic dispersion of Ir due to the strong interaction with the perovskite. Ir loading hardly changed the specific surface area and orthorhombic structure of $LaFeO_3$, whereas greatly enhanced the reducibility. XPS results indicated the presence of a higher amount of surface $Ir^{3+}$ and adsorbed oxygen species on Ir/$LaFeO_3$-300 than those on Ir/$LaFeO_3$-600. The propene oxidation performance of $LaFeO_3$ was significantly promoted by Ir. All Ir catalysts can achieve 100% propene conversion to $CO_2$ and $H_2O$ below 320 °C, Ir/$LaFeO_3$-300 being the best catalyst (100% conversion at 250 °C). The catalytic activity decreases with the calcination temperature, which correlates well with the low-temperature reducibility of the catalysts. Moreover, the optimal catalyst Ir/$LaFeO_3$-300 showed decent long-term stability and water resistance.

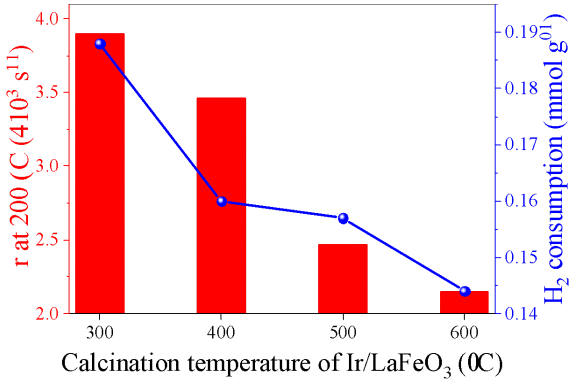

**Fig. 1 $H_2$ consumption in $H_2$-TPR and propene oxidation rate (r) at 200 °C over Ir/$LaFeO_3$ calcined at different temperatures.**

**Keywords:** iron oxides, AlSBA-15, ZrSBA-15, SBA-15, toluene oxidation, VOC removal

**Introduction.** There are increasing environmental concerns regarding anthropogenic releases of volatile organic compounds (VOCs) that have serious impact on the environment since they are linked to ozone formation, acid rain and formation of fine particles and smog [1,2]. A promising approach for VOCs reduction has been the application of catalytic oxidation. The main challenge to achieving high efficiency of this process is the development of a stable, cost-effective catalytic system with high conversion of VOCs into non-pollutants.

**In this study**, Fe-containing SBA-15, ZrSBA-15 and AlSBA-15 were synthesized and tested for removal of toluene as a model compound for the oxidation of VOCs. The influence of the synthesis procedure and the chemical composition on the physico-chemical and catalytic properties of the obtained materials was studied.

**Experimental.** The obtained materials were characterized by X-ray powder diffraction, $N_2$ physisorption, temperature-programmed reduction (TPR-TGA), TEM and XPS spectroscopy. The reaction of toluene oxidation was monitored at atmospheric pressure using a vertical fixed-bed flow reactor with air as carrier gas (30 ml/min). The air flow was purged through toluene equilibrated at 0 °C ($p_{toluene}$= 0.9 kPa).

**Results and discussion.** Transition metals as catalysts for total VOC oxidation at low temperatures (150-280 °C) pose a big challenge nowadays. Therefore, iron modified SBA-15, AlSBA-15 and ZrSBA-15 materials with 0.5 to 5.0 wt.% Fe loading were prepared and tested for toluene oxidation. It was found that increasing Fe loading significantly improved the rate of oxidation and lowered the temperature of achieving 100% removal of toluene from above 500 °C for the supports (AlSBA-15 and ZrSBA-15) to below 400 °C for 5FeZrSBA-15. The formation of finely dispersed iron-oxide active sites with a particle size less than <5 nm was observed on all the SBA-15, AlSBA-15 and ZrSBA-15 supports. It was found that the surface properties of the mesoporous support due to the addition of Al or Zr predetermined the type of formed iron oxide species and their localization on the support surface. Fe containing SBA-15 and AlSBEA-15 showed activity in total toluene oxidation at higher temperatures (280 – 450 °C). However, 5 wt. % Fe containing ZrSBA-15 showed excellent activity in total oxidation of toluene as a model VOC at lower temperatures (150 – 380 °C) due to the synergistics effect of Fe-Zr and the presence of accessible and stable $Fe^{2+}/Fe^{3+}$ active sites.

**Keywords:** Microwaves, direct oxidation catalysts, mixed-conducting oxides, activation

**Introduction.**
Recently, microwave-assisted heterogeneous catalysis has gained increased attention as a method to quickly, efficiently and selectively facilitate the catalytic conversion of exhaust gas components[1,2]. In this study we investigated the direct oxidation of carbon monoxide and methane in a microwave-assisted catalysis process employing perovskite (La,Sr)$CoO_3$ and fluorite type Cu-$CeO_2$. A microwave-based pre-treatment of the catalyst showed a significant influence on the obtained results.

**Experimental/methodology.**
A monomode microwave setup was used to heat and activate the granuled catalyst materials in a flow-reactor configuration[3]. The experiments were conducted both in dry and humidified atmosphere to serve as a model environment for the development of a microwave-assisted exhaust aftertreatment process. The concentration of CO in the gas stream was quantified by means of FTIR-spectroscopy. Partially substituted perovskite and fluorite type oxides were synthesized to create materials with both a large number of oxygen vacancies and suitable microwave susceptibility.

**Results and discussion.**
Our research revealed that the catalysts performance of the materials under investigation depends not only on composition (i.e. the degree of substitution in the oxide lattice) but also on the specifics of a microwave based reductive activation pretreatment. This activation treatment leads to considerably increased catalytic activity with activation energies for dry CO oxidation decreasing from 35.90 kJ/mol (pristine sample) to 23.07 kJ/mol (MW-activated sample) in the case of $La_{0.8}Sr_{0.2}CoO_3$. This approach thus offers the possibility for an efficient low-temperature exhaust aftertreatment process. These results show promising potential for microwave-assisted catalysis in direct oxidation of exhaust gas components and can lead to a better understanding of the material dependant changes of the catalysts under MW-irradiation.

**Keywords:** soot oxidation, NO oxidation, $MnO_X$-$CeO_2$ catalyst,

**Introduction.** Soot removal (oxidation) from diesel engine exhaust is a crucial process in terms of environment and health. Soot, due to its size and floating time in the air, is one of the causes of several diseases (e.g. lung cancer) and also contributes to the greenhouse effect. Currently, a common method to prevent the emission of this type of pollutant is the installation of a catalytic diesel particle filter (CDPF) in the engine exhaust system. This solution is based on noble metals, so a cheaper alternative is sought. One such proposal is the use of manganese-cerium mixed oxides, which are active in both direct soot oxidation and $NO_X$-assisted soot oxidation.

**Experimental/methodology.** Catalytic materials were prepared by co-precipitation from aqueous solutions of acetate salts by adding ammonium carbonate. The catalyst precursors were dried at room temperature, then at 110°C for 5 hours, and calcined at 500°C for 2 hours. Physicochemical properties were tested using XRF, BET, XRD, Raman, and XPS methods. Catalytic abilities were analyzed in a gas mixture containing oxygen and NO in tight and loose contact.

**Results and discussion.** The catalysts contain various amounts of manganese and cerium and are characterized by different surface areas, average pore diameter, and the volume of pores (Table 1). The 0.25Mn-0.75Ce catalyst shows the highest activity in the process of soot oxidation both in tight and loose contact (Figure 1). However, in loose contact, the soot oxidation temperature is shifted to a higher temperature by more than 100°C compared to tight contact.

*Table 1. Results of XRF and BET analysis.*

| Catalyst | Metal content (wt. %) | | Total BET surface area ($m^2$/g) | Average pore diameter (nm) | The volume of pores ($cm^3$/g) |
|---|---|---|---|---|---|
| | Mn | Ce | | | |
| Mn | 71 | 0 | 7.5 | 30.94 | 0.05 |
| 0.75Mn-0.25Ce | 40.2 | 31.7 | 76.5 | 7.77 | 0.14 |
| 0.5Mn-0.5Ce | 22.6 | 53.1 | 101.6 | 5.81 | 0.10 |

**Keywords:** layered zeolites, ITQ-2, Fe, one-pot synthesis, $DeNO_x$

**Introduction.** The zeolites exhibiting MWW morphology found many applications in the industry, mainly because of their well-developed porous texture, mild acid performance, and high hydrothermal stability. One of the interesting representatives of this group is ITQ-2, obtained from the layered precursor, MCM-22 (P) and characterized a delaminated structure, so-called "house of cards" [1]. The unique morphological and chemical features of ITQ-2 make the material an attractive support for the catalyst of the reactions which require micro-mesoporous texture and abundance of acid centers, i.e. selective catalytic reduction of nitrogen oxides with ammonia ($NH_3$-SCR). One of the major problems related to the industrial catalyst of $NH_3$-SCR is related to its narrow temperature window and toxicity of the active phase [2]. Hence, the goal of the presented studies was to investigate the catalytic potential of iron-modified ITQ-2 as an alternative, non-toxic catalyst for $NH_3$-SCR. Since the catalytic performance of metal-zeolites is determined by the speciation of the active phase, we prepared the samples using a one-pot synthesis to promote the incorporation of the isolated $Fe^{3+}$ cations in the framework positions of the zeolite [3]. Additionally, we analyzed the relation between the Si/Fe molar ratio in the samples and their physicochemical and catalytic characteristics.

**Experimental/methodology.** The series of one-pot synthesized Fe-ITQ-2 samples was prepared according to Chen et al. [3]. The molar composition of the reacting gel was optimized to obtain the samples with Si/Fe molar ratio of 20 or 10. To compare the one-pot synthesis and post-synthesis procedure, the reference catalyst was prepared by the adsorption of $Fe^{3+}$ cations from the aqueous solution. The materials were characterized by ICP-OES, low-temperature $N_2$ sorption, XRD, UV-Vis, Py-IR sorption, FT-IR, and SEM. The catalytic performance of $NH_3$-SCR was investigated within 150-450 °C using a model gas mixture consisting of NO, $NH_3$, $O_2$, and He as an inert.

**Results and discussion.** In our work, we have demonstrated that Fe-modified ITQ-2 can be successfully prepared by one-pot synthesis. The introduction of iron into the synthesis gel did not interrupt the formation of MWW layers. The superior low-temperature activity of one-pot synthesized catalysts was related to the abundance of the framework and extra-framework $Fe^{3+}$ cations. Moreover, the decrease of the Si/Fe molar ratio resulted in the formation of bulky aggregates of iron oxide, which contributed to undesired reactions, such as oxidation of ammonia in the high-temperature range.

Figure. Copper effect on toluene oxidation

The emission of aromatic VOC impacts not only health but also the environment due to its stability, reactivity, and resistance to oxidation [1]. Catalytic oxidation is presented as a promising alternative to reduce these emissions at low temperature. In this study, the effect of copper addition on the perovskite $LaMnO_3$ (**LM**), towards toluene oxidation efficiency was evaluated [2, 3]. The catalysts were prepared by self-combustion method and the copper addition was carried out by incipient impregnation. The solids obtained were characterized by XRD, XPS, TPD-$O_2$, TPR-$H_2$. Catalytic evaluation was carried out using 1000 ppmv of toluene in air and the combustion products ($CO_2$ and $H_2O$) were followed by mass spectrometry. The results indicated that the solid (Cu/LM_0.3) increased the efficiency in the oxidation of toluene, reducing the oxidation temperature by almost 50 °C with respect to the perovskite without copper whose $T_{50}$ was 290 °C (See figure). The presence of Cu on the surface favored the reducibility processes in the catalyst and the activation of labile oxygen, since part of the copper migrates into the structure, generating vacancies. However, it was observed that for copper impregnations greater than 0.3, the catalytic activity was detrimental. The same happened when the incorporation of copper was done by doping the structure with similar copper amounts during the combustion synthesis.

**Introduction.** Airborne transmission is the main propagation vector for respiratory infections such as flu, cold, SARS-CoV-2 and other infections of the lower respiratory tract, which account for 2.5 million deaths every year [1]. The virus aerosols linger in air and remain infectious for hours. In order to avoid infection propagation, technologies of virus inactivation are needed [2]. Here, we propose the use of catalytic filters, for indoor air-cleaning devices; these will inactivate viruses by oxidative stress of their membrane and/or proteins by selectively heating the filter to mild temperatures.

**Experimental/methodology.** Active oxidative phase was impregnated on two families of filters: ceramic and polymeric. A pre-screening methodology, based on acellular assays, has been developed to evaluate the oxidative potential of the filters thus minimizing biological risk associated with airborne viruses inactivation test. The pre-screening uses organic molecules probe test. A large number of catalytic systems were tested and compared with representative virus inactivation plaque assays in solution, which consist on . These were made with human coronavirus (HCoV-229E), severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) and rhinovirus (HRV-14). Virus inactivation capacity was assessed by quantifying the number of plaque-forming units (pfu) recovered on susceptible cell cultures. The assays were performed by inoculating 100 µL of the virus suspension onto the surface of the polymeric or ceramic filter with and without active oxidation phase(CONTROL). Runs were made at 37 ºC for 1h.

**Results and discussion.** The acellular oxidative potential (oxidation probe reaction) of different filters was evaluated and compared with its virus inactivation performance in the assays of virus inactivation. A good correlation was observed, concluding that when the oxidation capacity was greater than 60%, the filters efficiently inactivate HCoV-229E virus. The better performing filters were also evaluated for SARS-CoV-2 and HRV-14 inactivation (37 °C, 1 h). Table 1 shows representative viral titer of a catalyic phase on two catalytic materials (C1: ceramic; P1: polymeric) against SARS-CoV-2 and HRV-14. An effective inactivation was observed with both viruses using the two types of filters. This pre-screening approach is used to select those implemented in catalytic filters in an aerosol chamber prepared ad hoc for these analyses in a P2 biological safety lab.

**Table 1.** Viral titer after treatment at 37 ºC and 1h with ceramic filter (C1) and polymeric filter (P1) (* the detection limit is 5 pfu/mL).

| | **SARS-CoV-2** | | | **HRV-14** | | |
|---|---|---|---|---|---|---|
| | CONTROL | C1 | P1 | CONTROL | C1 | P1 |
| Viral titer (pfu/mL) | $4{\cdot}10^4$ | $\leq 5$* | $\leq 5$* | $7{\cdot}10^4$ | $\leq 5$* | $\leq 25$ |

# Pt and Pd-based catalysts for NOx reduction from $H_2$ combustion engines

Jieling Shao, Phuoc Hoang Ho, Derek Creaser, Louise Olsson*

*Chemical Engineering, Competence Centre of Catalysis, Chalmers University of Technology, Gothenburg, Sweden*

**louise.olsson@chalmers.se*

**Keywords:** $H_2$-SCR, Pd/SSZ-13, $N_2$ selectivity

**Introduction.** In view of approaching stringent regulations, especially for greenhouse gas emissions, interest has been raised in carbon-free hydrogen vehicles. To cope with the small but unavoidable amount of NOx produced by internal combustion engines, selective catalytic reduction (SCR) of NOx by $H_2$ is being investigated as an attractive technology that does not require any additional reductant fluid or gas onboard the vehicles [1]. In this work, we have compared the catalytic performance of PtPd/SSZ13 bimetallic catalysts with their monometallic counterparts and we show that Pd/SSZ-13 catalyst has a superior $N_2$ selectivity of almost 80% and with a wider working temperature window. But, the NO conversion is lower on Pd/SSZ-13.

**Experimental/methodology.** SSZ-13 zeolite was synthesized using a hydrothermal method [2]. Pt-, Pd-, and PtPd/SSZ-13 catalysts were prepared by an incipient impregnation technique. The de-greened powder materials were characterized with various techniques such as elemental analysis, CO chemisorption, $N_2$ physisorption, XPS and STEM. The synthesized catalyst powder was then coated onto a honeycomb monolith (Cordierite, DxL=1.5 cmx2.0 cm, 400 cpsi). Activity tests were performed with a flow reactor with five cycles of heating and cooling over a temperature range of 80 to 500℃ in a typical lean $H_2$ combustion gaseous mixture consisting of 10% $O_2$, 5% $CO_2$, 5% $H_2O$, 500 ppm NO and 5000ppm $H_2$ in Ar.

**Results and discussion.** Figure 1a shows the activity test performance of the 1 wt% Pd/SSZ-13 catalyst regarding the product gas outlet concentrations and NO conversion during $H_2$-SCR. It is demonstrated that $N_2$ was the main product and with two maximum formation peaks at around 130℃ and 230℃, respectively. $NO_2$ was only formed by NO oxidation at temperatures higher than 300°C because hydrogen was mostly consumed by its combustion. The conversion of NO follows the same trend. Figure 1b illustrates that with the same metal loadings, the Pd catalyst has higher maximum $N_2$ selectivity than the Pt catalyst (80% versus 70%) and also with a wider working temperature window. However, the conversion is lower. The performance of the PtPd bimetallic catalyst is close to the Pt monometallic catalyst, which is not shown here.

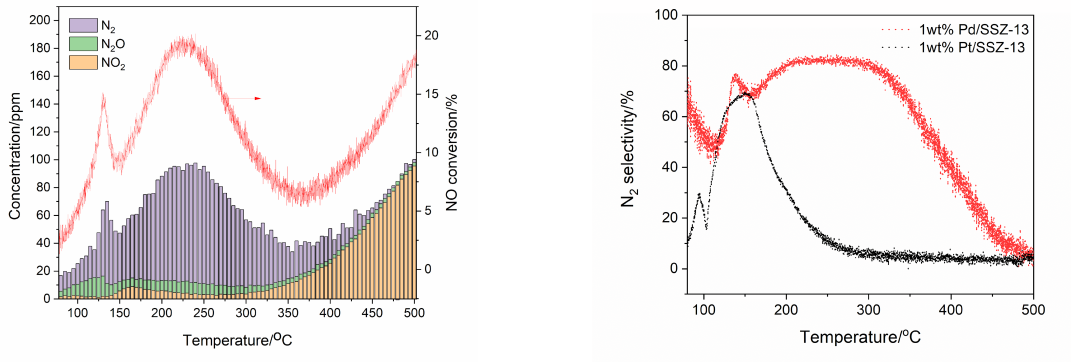

Figure 1. a) Product concentrations and NO conversion of $H_2$-SCR on 1wt% Pd/SSZ-13 catalyst b) $N_2$ selectivities of 1wt% Pd/SSZ-13 catalyst and 1wt% Pt/SSZ-13 catalyst (gas inlet: 10% $O_2$, 5% $CO_2$, 5% $H_2O$, 500 ppm NO and 5000ppm $H_2$).

# Promotional effect of $MoO_x$ for the $H_2$-de$NO_x$ reaction using $Pt/ZrO_2$ catalysts

D. Schröder [1], S. Kureti [1,*]

[1] *TU Freiberg, Chair of Reaction Engineering, Germany*

**Introduction**

For $NO_x$ removal from lean exhaust gases, selective catalytic reduction (SCR) and $NO_x$ storage catalysts are established technologies, whereas they operate efficiently only above 175°C. Contrary, future $NO_x$ emissions limits (e.g. Euro-7) will require an effective abatement of $NO_x$ even at low temperatures. For this purpose, the $NO_x$ reduction by $H_2$ ($H_2$-de$NO_x$) on Pt catalysts is a promising technique. However, these catalysts still suffer from significant $N_2O$ and/or $NH_3$ by-production. Recently, the modification of $Pt/ZrO_2$ with W was reported to provide high activity at low temperatures as well as reduced $N_2O$ emissions [1]. The present paper aims the further advancement of the highly active $Pt/ZrO_2$ catalyst using $MoO_x$ as promising promotor [2].

**Methodology**

$Pt/xMo/ZrO_2$ catalysts were prepared by incipient wetness impregnation of monoclinic $ZrO_2$ with aqueous solution of $Pt(NO_3)_2$ and $(NH_4)_6Mo_7O_{24} \cdot 4\ H_2O$ resulting in a Pt load of 0.25 wt.% and Mo contents between 0 and 10 wt.%. After calcination at 500°C for 5h, the samples were characterized by X-ray diffraction (XRD), $N_2$ physisorption (BET), temperature-programmed desorption of CO and $NH_3$, Raman spectroscopy (LRS) and diffuse reflectance infrared spectroscopy (DRIFTS) using $NH_3$ as probe molecule, while the $H_2$-de$NO_x$ efficiency was tested in a lean synthetic exhaust (200 ppm NO, 5% $O_2$, 10% $H_2O$, 2000 ppm $H_2$, $N_2$ balance).

**Results and discussion**

Fig. 1 clearly shows that promotion of bare $Pt/ZrO_2$ with Mo leads to a significantly improved low temperature activity, effective suppression of $NH_3$ emission and increased $N_2$ selectivity. The $Pt/ZrO_2$ catalyst with a Mo load of 3 wt.% shows the best performance, including $H_2$-de$NO_x$ between 80 °C and 150 °C, maximum $NO_x$ conversion of 90% and $N_2$ selectivity up to 78%. Isolated $MoO_x$ species (LRS) predominately present at Mo loads < 4 wt.% were found to act as structural promoter by stabilizing the surface area, while also providing smaller Pt particles and more active Pt sites (7.1 µmol/g, 3 wt.% Mo) compared to bare $0.25Pt/ZrO_2$ (1.8 µmol/g) as evidenced by CO-TPD. Studies on $Pt/ZrO_2$ catalysts using in-situ DRIFTS [1] and kinetic modeling [3] showed that the $H_2$-de$NO_x$ reaction occurs mainly at the Pt sites. Thus, increasing the number of active Pt sites leads to improved activity and $N_2$ selectivity. However, at Mo loadings > 4 wt.%, the Mo species aggregate and the number of Pt sites decreases, resulting in a drastic drop in $H_2$-de$NO_x$ activity and $N_2$ selectivity. Moreover, introducing Mo enhances acidity of $Pt/ZrO_2$ with formation of new Brønsted and strong Lewis acid sites ($NH_3$-TPD, DRIFTS). In particular, strong Lewis acid sites were found to improve both, activity in SCR experiments (100 ppm NO + 100 ppm $NH_3$) and $N_2$ selectivity in $H_2$-de$NO_x$ tests. These results suggest that the Mo promotion of $Pt/ZrO_2$ enables an additional SCR-related mechanistic de$NO_x$ pathway involving strong Lewis acid sites at the $MoO_x$ entities [4]. It is assumed that $NH_3$ or $NH_x$ species formed on the Pt sites during $H_2$-de$NO_x$ spill over to the strong Lewis acid sites at highly dispersed $MoO_x$ moieties, followed by a reaction with NO at the interface between the Pt sites and $MoO_x$. Thus, our study highlights the particular importance of acidity to improve the activity and selectivity of lean $H_2$-de$NO_x$ catalysts.

# Effect of Fe and Ce in a manganese titania catalyst for the low-temperature catalytic reduction of NOx with $NH_3$

Cristina I. Q. Silva[1*], Polina Lavrik[1], Mohamed Nejib Hedhili[2], Sudheesh Kumar Veeranmaril[1], Sarah Komaty[1], Javier Ruiz-Martínez[1]

**Keywords:** Low-temperature $NH_3$-SCR of $NO_x$, Mn-based metal oxides, heterogeneous catalysis.

**Introduction.** Nitrogen oxides ($NO_x$) are harmful pollutants present in combustion gases that can be emitted from stationary and mobile sources. Mn-based oxides are promising for the selective catalytic reduction (SCR) of $NO_x$ with $NH_3$ at temperatures below 200 °C, where the current commercial de$NO_x$ catalysts fall short.[1, 2] However, MnOx often suffer from low $N_2$ selectivity and low tolerance for $H_2O$ and $SO_2$, which can be improved by combining Mn with other transition metals.[1]

**Experimental/methodology.** We have developed a series of catalysts based on Mn, Fe, Ce and Ti with different compositions by a co-precipitation method designed to obtain a homogeneous dispersion to understand the effect of Fe and Ce in a MnTiOx catalyst. The catalytic activity and $N_2$ selectivity were tested for $NH_3$-SCR of $NO_x$ and the properties of these catalysts were investigated by ICP, $N_2$-physisorption, XRD, $H_2$-TPR, $NH_3$-TPD, STEM/EDX, TEM/EELS, XPS and XAS.

**Results and discussion.** We were able to determine that the addition of Fe to MnTiOx led to a catalyst composed of a rutile $TiO_2$ structure with well-dispersed amorphous Mn and Fe (Fig.1 (A, E)). The addition of Fe had a detrimental effect on the specific surface area compared to the initial MnTiOx, which had a negative effect on the catalytic activity at low temperatures (below 250 °C) of most samples, particularly in the presence of $H_2O$ (Fig.1 (C)). On the other hand, there was an overall increase in the $N_2$ selectivity (lower $N_2O$ production) across the tested temperature range (Fig.1 (D)). Based on our previous results [2], we included Ce in the catalyst formulation to improve specific surface areas and consequently catalytic activities. Adding Ce to MnFeTiOx led to a progressively more amorphous structure (Fig.1 (B, E)), higher overall surface areas, higher acidity and better $N_2$ selectivities in the presence and absence of $H_2O$. We found an optimum formulation by adding small quantities of Ce and Fe to the MnTiOx catalyst, more specifically in the $Mn_{0.31}Ce_{0.04}Fe_{0.04}Ti_{0.62}$ sample where the catalytic performance and $N_2$ selectivity were maximized at 150 °C (79% and 94% in the absence of $H_2O$ and 47% and 98% in the presence of $H_2O$, respectively), while also having a broader temperature range of application (Fig.1 (C, D)). We suggest that the addition of Fe and Ce suppresses overoxidation of reactants and thus $N_2O$ formation by reducing the MnOx ensembles on the catalyst surface.

***ges of the metal oxides. A - $Mn_{0.29}Ti_{0.71}$; B - $Mn_{0.31}Ce_{0.04}Fe_{0.04}Ti_{0.62}$; Catalytic activity presence of $H_2O$; Diffraction patterns of the metal oxides (E) (■ - $Mn_{0.29}Ti_{0.71}$; ● - $_{0.04}Ti_{0.62}$).***

# Cobalt-Manganese and Iron-Manganese Mixed Oxide Catalysts for the Total Oxidation of Dimethyl Ether in Flue Gases from Formaldehyde Production Plants

M. Smyrnioti, V. Dracopoulos, T. Ioannides*

*Foundation for Research and Technology-Hellas, Institute of Chemical Engineering Sciences (FORTH/ICE-HT), Patras, Greece*
**E-mail: theo@iceht.forth.gr*

**Introduction.** Flue gases from the industrial production of formaldehyde contain CO, methanol, dimethyl ether, $H_2O$ vapor, $O_2$, $N_2$ and traces of formaldehyde. The emission control technology applied in the process is based on the catalytic oxidation (incineration) of the flue gases. Even though the concentration of dimethyl ether in the flue gases is low, dimethyl ether dictates the final temperature required for the complete removal of the pollutants since it is the most difficult to oxidize compound compared to CO or methanol. The state-of-the-art catalysts are based on noble metal (Pt, Pd)/γ-$Al_2O_3$ washcoated on monolithic substrates. The current catalytic converter has a long lifetime, yet it has some shortcomings including its high cost due to the presence of noble metals as well as significant input energy requirements for preheating the feed stream ($T_{inlet}$>250°C). The present work refers to the development of a new emission control system (ECS) for formaldehyde production plants, based on non-noble metal catalysts; mixed cobalt-manganese oxide ($Co_xMn_{3-x}O_4$, 0<x<3) and iron-manganese oxide ($Fe_xMn_{3-x}O_4$, 0<x<3) catalysts.

**Experimental/methodology.** The catalysts have been prepared via the citrate complexation method. $N_2$-physisorption, p-XRD, SEM, XPS, $H_2$-TPR and CO/VOC-TPD were employed for the physicochemical characterization of the samples. The catalysts have been prepared both in powder and monolithic form while their catalytic activity and long-term stability have been evaluated in the total oxidation of dimethyl ether as well as under a realistic flue gas mixture both on a lab- and a semi-pilot scale.

**Results and discussion.** The prepared Co-Mn and Fe-Mn mixed oxide catalysts were found to be among the most active catalysts for the total oxidation of dimethyl ether reported so far, with complete DME conversion being achieved at 210 °C (Co-Mn) and 240 °C (Fe-Mn) at GHSV=36000 $h^{-1}$. The citrate complexation method leads to either the formation of a solid solution (for Fe-Mn catalysts) or spinel phases (for Co-Mn catalysts) with a surface enrichment in manganese being observed throughout the whole composition range in both catalytic systems. The presence of water vapor in the feed stream inhibits the oxidation reaction, shifting the required temperature for the complete DME conversion to $CO_2$ towards higher temperatures by 20-30°C. Comparing the oxidation of the flue gas mixture with the single gases, it is concluded that the presence of VOCs inhibits the oxidation of CO and vice versa, leading to a shift of the activity curves towards higher temperatures by ~20-25 °C in both cases. The Co-Mn mixed oxide catalysts succeed in narrowing down the significant temperature gap between the oxidation of CO & $CH_3OH$, on one hand, and DME on the other compared to the prior art (the gap is 70 °C for Co-Mn vs. >160 °C for noble metal-based catalysts [1]). The optimal catalysts were scaled-up on a semi-pilot scale (50x times compared to the lab-scale catalytic tests) in order to study their long-term stability. The mixed oxide catalysts demonstrate exceptional stability retaining their initial activity with no evidence of deactivation for >500 h on-stream during non-isothermal operation of the monolithic reactor. The light-off temperature for the complete conversion of the flue gases ($X_{CO}$ and $X_{CH3OH}$=100%, $X_{DME}$=98.5-99%) is 147 °C i.e. ~100°C lower than the current situation, while the reactor outlet temperature is 235 °C due to the exothermicity of oxidation reactions.

**Keywords:** High-Throughput; $NH_3$-SCR; catalysis; mixed oxides

With the guidelines of the emission standards in the EU it is still of high concern to minimize the $NO_x$ emissions of combustion engines of automobiles which are harmful to the environment. The most common catalysts for the removal of $NO_x$ from Diesel engine exhaust gases are either zeolite-based catalysts exchanged with Cu or mixed oxide catalysts of the type $V_2O_5/WO_3@TiO_2$. They are either expensive to produce or show only a limited operational window with a high $NO_x$ conversion rate. [1,2]
Different mixed oxide catalysts based on the carrier material $CeO_2$ were synthesized via a High-Throughput (HT) approach by a co-impregnation method. Subsequently the conversion rates were measured through HT screening on a motorized linear x-y-z translational shift unit with a catalyst library on a steel sample plate [3,4,5] and gas inlet and outlet by capillaries with a total gas flow of 60 mL/min and a GHSV of 130000 $h^{-1}$ connected to a heated gas cell of a FTIR spectrometer. To validate the conversion rates of the different catalyst systems on the HT x-y-z unit, they were also tested in a conventional gas flow tubular reactor.
Synthesizing a composition spread of selected hits, the conversion rates were further optimized. Both results are shown together with the experimental setup for HT screening in Figure 2.

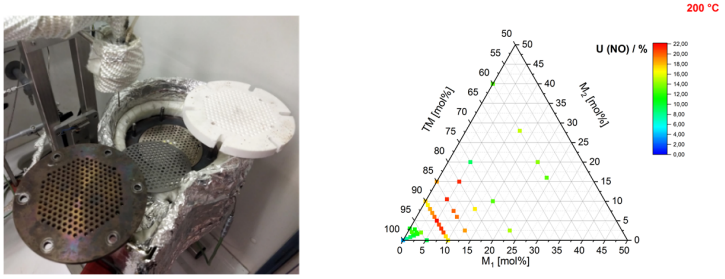

**Figure 2: Photograph of the experimental setup for the HT screening of the catalyst library on the x-y-z translational shift unit [left side] and ternary phase diagram for the optimization of selected catalyst samples [right side].**

To test the tolerance of the different catalyst systems the $NO_x$ conversion rates were compared before and after an aging procedure with either $H_2O$ or $SO_2$. The catalysts showed a good tolerance against $H_2O$ depending on the promotional elements used. $SO_2$ tolerance measurements showed a partial regeneration of the $NO_x$ conversion after a high temperature annealing at 500 °C. Furthermore, the catalysts were characterized regarding their morphology (BET/PXRD/ESEM) and in terms of reaction parameters ($NH_3$-TPD/$H_2$-TPR/DRIFTS). The characterization of the catalysts showed a high dispersion of the promotional elements on the carrier material, which also influences the surface properties, an increasing $NH_3$ adsorption rate for selected elements, different redox properties depending on the catalyst composition and the reaction mechanism showed two possible reaction routes via a Langmuir Hinshelwood or an Eley Rideal mechanism, with the latter being predominant. Through the entire process it was possible to select a catalyst system from the sample library, which could be scaled up and will be further investigated as an alternative mixed oxide catalyst for the $NH_3$-SCR in Diesel combustion engines of automobiles.

**Keywords:** Copper, Zeolite Y, Mixed Metal Oxides, $NH_3$-SCR-DeNO$_x$

**Introduction.** The selective catalytic reduction of NO$_x$ by ammonia ($NH_3$-SCR-DeNO$_x$) is the most efficient technology to eliminate NO$_x$ from stationary and mobile sources. Recently, hybrid catalysts combining components of intended functionality have attracted interest for the $NH_3$-SCR-DeNO$_x$ [1]. For example, the combination of the acidic sorption sites for $NH_3$ leading to the formation of a reservoir of ammonia molecules can be coupled with highly active metal sites for reaching sufficient activity at low temperatures. Thus, we report the preparation and experimental study of hybrid catalysts consisting of zeolite Y and Cu-containing hydrotalcite-derived CuMgAl-O$_x$ mixed metal oxides.

**Experimental/methodology.** Zeolite Y (ZY) used in this work was prepared by a dense gel method using a molar composition of $8Na_2O : 1Al_2O_3 : 10SiO_2 : 410H_2O$ [2]. The CuMgAl hydrotalcite-like precursor was prepared by using a coprecipitation method with metal nitrates [3]. For the preparation of the composites, two methods were applied, i.e., a physical and a chemical mixture (abbreviated PM and CM, respectively). All Cu-containing materials were investigated in $NH_3$-SCR-DeNO$_x$, and thoroughly physico-chemically characterized with respect to their structure and morphology (XRD, SEM), texture ($N_2$ sorption), and redox/acid properties ($H_2$-TPR, EPR, DR UV-Vis).

**Results and discussion.** The SEM images in Fig. 1a show the successful preparation of the zeolite Y / Cu-containing mixed metal oxide composites. There is no significant difference between the materials obtained *via* PM and CM methods, whereas the structure of zeolite Y is still maintained. The morphology represents a well-developed layered and plate-like structure of the CuMgAl mixed metal oxides. Pure zeolite Y reaches less than 4 % NO conversion in $NH_3$-SCR-DeNO$_x$ (Fig. 1b). The catalytic activity does not vary significantly for the samples prepared *via* PM or CM. The CuMgAl mixed metal oxides and their physical mixture with zeolite Y reveal similar catalytic activity above 300 °C due to the unselective oxidation of $NH_3$. Thus, the hybrid samples can be considered a promising catalyst for the selective catalytic oxidation of ammonia into nitrogen and water vapor ($NH_3$-SCO). The studies will be further extended for the preparation of MgAl mixed metal oxides mixed with Cu-containing zeolites.

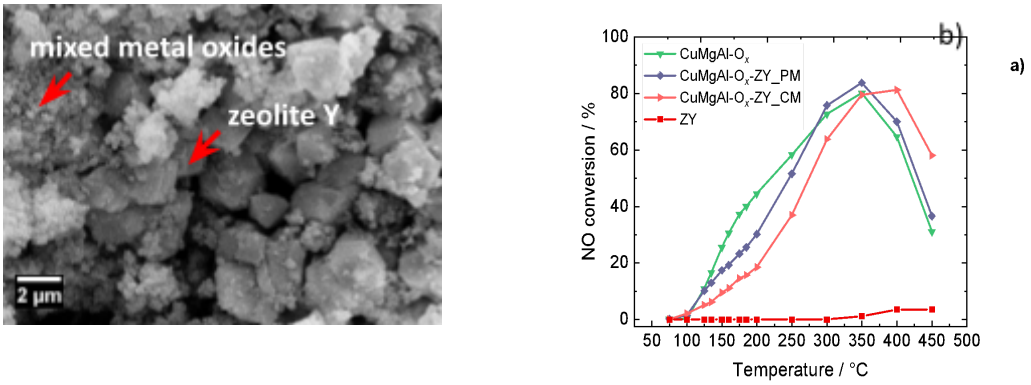

**Figure 1. SEM images of CuMgAl-O$_x$/ZY_CM (a) and NO conversion in $NH_3$-SCR-DeNO$_x$ over CuMgAl-O$_x$/ZY (b).**

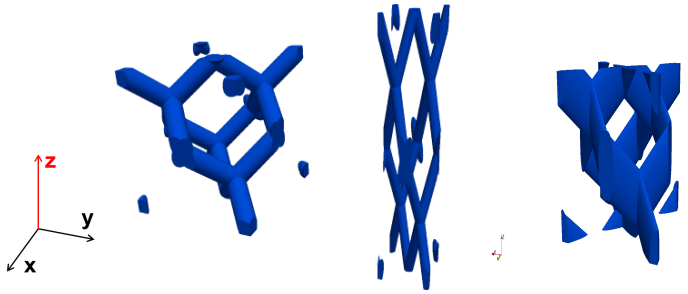
# Intensified POCS supports with optimized strut geometry for catalytic reactors

Claudio Ferroni[1], Mauro Bracconi[1], Matteo Ambrosetti[1], Matteo Maestri[1], Gianpiero Groppi[1] and Enrico Tronconi[1*]



[1]*Laboratory of Catalysis and Catalytic Processes, Department of Energy, Politecnico di Milano, Via La Masa 34, 20156 Milano, Italy*

**Keywords:** Catalytic Reactors, Process Intensification, Structured Catalysts, Lattice Supports

**Introduction.** 3D printed Periodic Open Cellular Structures (POCS) with Diamond unit cell [1-3] are regarded as promising structured supports to intensify catalytic reactors where the trade-off between gas-solid mass transfer and pressure drop is crucial, like in many important Environmental Catalysis applications. These systems usually employ honeycomb monoliths as reference catalyst supports [3]. Previous investigations revealed that the increment of mass transfer granted by POCS comes along with significantly higher pressure drop. To overcome this drawback, we propose a new geometry that adopts streamlined elliptical struts along the flow direction to reduce the pressure drop.

**Experimental/methodology.** Reactive CFD simulations are exploited as synthetic experiments for the investigation of transport properties and pressure drop of POCS [3]. Periodic boundary conditions at the domain side boundaries are applied to evaluate asymptotic transport properties as a function of geometrical and operating conditions, neglecting entrance effects and solid wall constraints. The performances are assessed by considering the Merit Index (M.I.), a dimensionless trade-off index relating the mass transfer coefficient with the pressure drop [3].

**Results and discussion.** Based on the Diamond unit cell ((Figure 1 *(a)*)), the new geometry (Figure 1 *(b)*) is obtained by replacing the cylindrical struts with streamlined elliptical struts along the flow direction (z). Figure 1 *(c)* compares POCS with a honeycomb monolith (HC) 900 CPSI/2.5 mils. The standard Diamond offers poorer performance than the HC due to the greater pressure drop [3]. Conversely, the optimized structure provides up to 25% higher M.I. granted by the reduced pressure losses. Consequently, these structures grant higher conversions than honeycombs for the same pressure drop on a wide range of flowrates. This increment may pave the way towards intensified catalytic reactor solutions.

**Keywords:** Selective Catalytic Reduction, SCR, NOx, deNOx, $SO_2$, Sulphur, ammonium bisulphate, ABS

**Abstract-**
Selective Catalytic Reduction (SCR) is an important tool for reducing NOx in flue gases. In particular, the use of vanadium oxides on titania is widely utilized and successful owing to relatively good resistance to sulphur poisoning. Industrial flue gases *eg.* those from cement factories, waste incinerators *etc.* inherintly have trace amounts of $SO_2$ of varying concentrations. $SO_2$ is oxidised to $SO_3$ and subsequently reacts with $NH_3$ to form ammonium bisulphate (ABS). ABS condenses as a liquid in the pores of said catalyst, inhibiting the ability of active sites to function as normal. This results in activity loss and ultimately, deactivation of the SCR catalyst. The ability to perform SCR at low temperatures is importortant for industrial flue gases to mitigate heating costs but ABS fouling poses a significant barrier to deoployment. In this study we will reveal how we have employed intelligent catalyst design and assesment using high throughput screening and performance modelling including Artificial Neural Networks (ANN) and Partial Least Squares (PLS) regression to predict catalyst activity and fouling resistance and how our findings might guide the development of novel SCR catalysts.

# Role of Ionic Liquids as Promoters to Enhance $CO_2$ Capture Performance of Methyldiethanolamine

**Keywords:** $CO_2$ Capture, Dual Funtionalized Ionic Liquid, Kinetics Study

**Introduction.** $CO_2$ containing industrial flue gas effluent streams are a potential cause of air pollution. $CO_2$ capture utilising benign, low-cost solvents is an important unit operation not just in the process sector for $CO_2$ separation and recovery from industrial off-gas streams, but also for direct capture from air to clean the environment. Researchers have found many solvents with excellent $CO_2$ capture efficiency owing to their attractive chemical and physical characteristics, $CO_2$ interaction mechanism, and low regeneration energy cost. However, alkanolamines, such as Monoethanolamine (MEA), Diethanolamine (DEA), and Methyldiethanolamine (MDEA), are the most often utilised solvents for CO2 capture. These solvents have a number of drawbacks, including limited thermal stability, the generation of heat-stable salts, and the fact that they are highly degradable. To address these difficulties, a new type of solvent need be developed. These constraints may be circumvented by dual functionalized ionic liquids (DFILs). Hence, this work a new class of dual functionalized ionic liquids (DFILs) synthesized by the acid-base neutralization reaction using polyamine as cation and cyclic amines as anions.

**Experimental/methodology.** In this work, the $CO_2$ absorption was performed using a VLE setup, and the mass balance method was used to calculate the $CO_2$ loading at different temperatures, pressures, and DFILs concentrations. Further $^{13}C$ NMR was used to understand the $CO_2$ interaction with $CO_2$, which was also validated with DFT results. Additionally, non-linear regression and machine learning methods were used and described to predict the $CO_2$ loading using 54 data points of $CO_2$ loading in the DFILs blend MDEA system. Furthermore, specific energy consumption and productivity for all absorbents were calculated, and a comparative study was conducted to select the best promoter.

**Results and discussion.** Initially, crucial properties such as viscosity and density were measured for these absorbents, and results showed that with increasing wt% of DFILs, viscosity and density slightly increased. $CO_2$ absorption was also performed, and it was discovered that the $CO_2$ loading and rate of absorption increased significantly with increasing wt% of DFILs. For the prediction of $CO_2$ solubility in MDEA blend systems, machine learning methods have been used and predicted. Here, five different methods are applied for prediction, with the MLR, RF, and DTR methods showing high accuracy while the KNN and SVM methods predict with slightly lower accuracy. Further, specific exergy consumption and productivity were calculated for all absorbents, and based on these values, a superior promoter was selected, and it was noticed that [T-Im] and [D-Pz] blend absorbents provided optimum conditions for efficient $CO_2$ absorption.

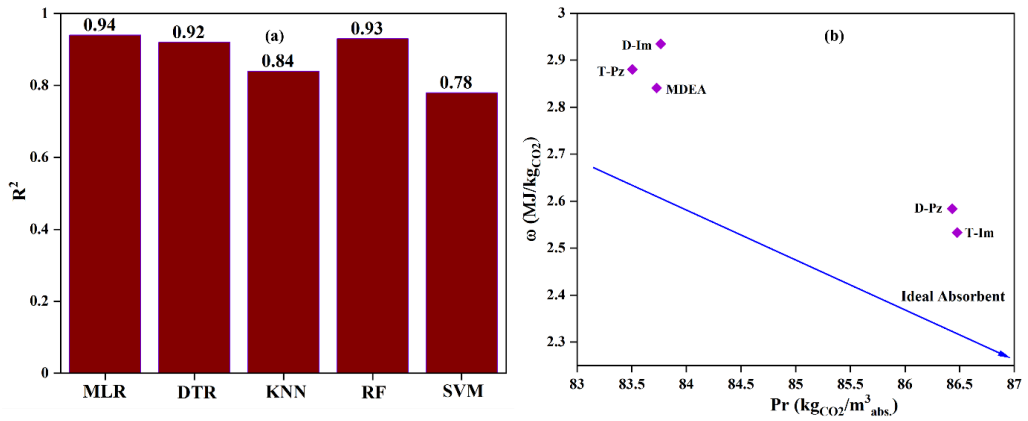

**Figure 1. Comparative study for capturing performance: (a) Machine learning methods for CO2 solubility prediction; (b) Economic point of view comparative study of MDEA and MDEA blend MDEA system**

**Keywords:** Cu-doped ceria, nanoneedle, oxygen vacancy, CO oxidation reaction

The presence of oxygen vacancies in the $CeO_2$ crystal lattice, which are participating in the gas adsorption, plays a critical role in the catalytic performance [1, 2]. Thus, an optimized crystal design would help to expose more surface oxygen vacancies, resulting in the enhancement of catalytic activity. Herein, a series of Cu-doped $CeO_2$ needle-shaped nanocatalysts were synthesized. The oxygen vacancy content was studied and the influence of Cu amount on the CO conversion activity was also investigated. The relationship between the crystal structure and the catalytic activity are discussed.

The as-prepared $CeO_2$ particles are needle-like shaped with high crystallinity, and the inserted schematic diagram illustrates the assumed nanoneedle grow along the [110] direction (Fig. 1a). When Cu was doped into $CeO_2$, the distribution of Cu tends to form clusters (Fig. 1b). The detailed mapping image was taken from the surface of $CeO_2$ (Fig. 1c). The $Ce^{3+}$ are mostly distributed on the surface, while the $Ce^{4+}$ are in the bulk, indicating the present of amounts of oxygen vacancies. By calculating the ratio of $Ce^{3+}/Ce^{4+}$ from the Ce 3d XPS spectrum (Fig. 1d), it can be obtained that the incorporation of 10% Cu formed the most oxygen vacancies on the surface. The CO conversion temperature is in line with the trend of oxygen vacancies concentration (Fig. 1e), suggesting that the vacancies act as active sites for CO adsorption. The DRIFTS result indicates that the 10% Cu doped $CeO_2$ exhibits rapid CO absorption at room temperature (Fig. 1f).

**Keywords:** EXAFS; $N_2O$ decomposition; Cobalt Oxide; Mesoporous materials; catalysis

**Introduction.**

Compared to $CO_2$, the most common green house gases, $N_2O$ has 300 times effect for global warming for a 100-year timescale.[1] Although agriculture is considered as the major source of $N_2O$ due to human activities, the $N_2O$ emission from transportation sector cannot be ignored with 56mg of $N_2O$/km for on-road vehicles travelling.[2] One of the best $N_2O$ removal ways is catalytic $N_2O$ decomposition. The catalytic process involves breaking N-O bond and forming O* with $O_2$ as final product, which is a redox reaction. Although nobal metal shows good activity in low temperature, the development of non-noble metal catalytic with excellent redox properties and thermal stability is more important. Our studies use copper and cobalt as materials to design the experiment of how to improve the $N_2O$ conversion.

**Experimental/methodology.**

We developed a bifunctional catalyst contains both Cu and Co. 1) **Optimizing the loading of Cu.** We have designed five catalysts: $Co_3O_4$, 10CuCo, 25CuCo, 50CuCo and 90CuCo. The number indicate the concentration of copper loading on Cobalt. With the adding of small amount of Cu, the $N_2O$ conversion was improved significantly especially at low temperature. Most of them show better decomposition ability than pure $Co_3O_4$ (Fig. 1a). 25 wt% $CuO$-$Co_3O_4$ gives 3.5 times higher $N_2O$ conversion than $Co_3O_4$ at 350 °C, and $N_2O$ can be completely converted at 400 °C. 2) **Maximizing the reactive surface.** We have further improved the activity by synthesizing mesoporous meso-$Co_3O_4$ and meso-25CuCo that maximize the reactive surface. Meso-25CuCo is by far the best catalyst for $N_2O$ decomposition, surpassing all the reports in the literatures, achieving almost 80% conversion already at 350 °C (Fig. 1b,c).

3) **Reduction of Cu and Co species.** In addition, we performed *in-situ* $H_2$-TPR XAFS study at spring-8 for meso-$Co_3O_4$ and meso-25CuCo. For pure $Co_3O_4$, the reduction starts at 250 °C and to pure $Co_3O_4$ at 400 °C (Fig. 1e). For meso-25CuCo, the reduction starts at 200 °C and forms majority of metal Co at 250 °C (Fig. 1f). The addition of Cu significantly promotes the reduction of $Co^{3+}$ to $Co^0$, which is a complete surprise to us.

**Figure 1 a,b** The conversion of $N_2O$ from 200°C to 550°C. **c,** The comparison of $N_2O$ conversion between non-porous and mesoporous catalysts at 350 °C. **d,** *in-situ* XANES spectra at 300°C under $H_2$. The LCF(Linear combination fitting) of **e,** meso-$Co_3O_4$; **f,** meso-25CuCo under $H_2$ at different temperatures.

**Results and discussion.**

For $N_2O$ decomposition process, we achieve high surface area *via* templated synthesis; and we also maximize the $CuO/Co_3O_4$ interfaces by varying the Cu and Co ratio. The templated $CuO$-$Co_3O_4$ has a surface area of 91 $m^2/g$ and shows 2.5 times $N_2O$ conversion to that of normal $CuO$-$Co_3O_4$ *via* co-precipitation methods. The 25% CuO loading achieves the best $N_2O$ conversion at low temperature. Then we did in-situ XAS study in $H_2$ atmosphere to confirm that Cu promotes and accelerates the $Co^{3+}$ reduction. Such study is very rare to the $N_2O$ chemistry and will help understand the $N_2O$ decomposition mechanism.

# Catalytic oxidation of propane over Pt-Pd bimetallic nanoparticles supported on $TiO_2$

R. Camposeco, A. E. Torres, V. Maturano, R. Zanella*
*Instituto de Ciencias Aplicadas y Tecnología, Universidad Nacional Autónoma de México, C. U., 04510, Ciudad de México, Mexico*
**rodolfo.zanella@icat.unam.mx*

**Introduction.** The internal combustion engines in vehicles and stationary sources using diesel and gasoline cause harmful pollutants such as carbon monoxide (CO), un-burned hydrocarbons (HCs), nitrogen oxides ($NO_x$), sulfur oxides ($SO_x$), and particulate matter (PM). In contrast, liquefied petroleum gas (LPG) is a cleaner alternative to burning fuel in internal combustion engines. Propane is the most abundant light alkane among the organic compounds emitted from combustion of LPG. Noble metals have been found to be highly effective but expensive in the total oxidation of VOCs. Platinum and palladium are some of the most active materials for hydrocarbon oxidation, however, there is debate in the literature about how platinum particle size or shape affects the catalyst activity. In this context, some studies have shown that the reaction rate per platinum atom does not significantly change with the particle size or dispersion, the reaction rate per surface platinum atom increases with larger platinum particle sizes. Up to now, several catalysts have been applied for total propane oxidation and noble metal catalysts have been reported to show better catalytic performance than transition-metal-oxide catalysts.

**Experimental/methodology.** The mono and bimetallic platinum and palladium catalysts were prepared by the sol-gel method. They were characterized by XRD, ICP-OES, $N_2$ adsorption/desorption isotherms using the BET method, Pyridine thermo-desorption, $H_2$-TPR, HRTEM and HAADF, XPS and CO-DRIFTS. The catalytic activity for both reactions was evaluated by temperature programmed experiments using a flow reactor at atmospheric pressure. The reactor output gases were analyzed with an on-line gas chromatograph equipped with TCD and FID detectors and a methanizer to detect $CO_2$ and/or CO.

**Results and discussion.** The results show that the catalytic properties of the bimetallic Pt-Pd/$TiO_2$ catalyst in the propane oxidation reaction are better than the ones displayed by monometallic Pd/$TiO_2$ and Pt/$TiO_2$ catalysts, achieving $T_{50}$ values of 220, 280 and 300 °C, respectively. In fact, the reaction rate and TOF values show a synergistic effect by the combination of Pt and Pd, which was confirmed by the Pd and Pt interaction with $TiO_2$, following the order: Pt-Pd/$TiO_2$ > Pt/$TiO_2$ > Pd/$TiO_2$; likewise, the activation energy showed the sequence Pd/$TiO_2$ > Pt/$TiO_2$ > Pt-Pd/$TiO_2$. The Pt, Pd, $Pt^{2+}$ and $Pd^{2+}$ species and the outstanding Brönsted and Lewis acidity type induced the activation of adsorbed oxygen species, which participated in the propane oxidation. In this line, the computational results showed that Pt tends to increase the Brönsted acidity of the interface, thus favoring oxygen adsorption through a dissociative mode. While the bimetallic system presented a unique behavior in that hydrogen (even abstracted from propane) is less bound to the oxidized site; then, a more Lewis acidic site is attained. Interestingly, the predicted Lewis acidity (Pt-Pd/$TiO_2$ > Pt/$TiO_2$ > Pd/$TiO_2$) through hydrogen adsorption energies, for the single oxidized site, exhibited the same trend as that determined for the catalytic activity, suggested as a possible chemical reactivity descriptor for the oxidation of propane. The stronger acidity of the bimetallic system might also improve the catalyst water tolerance compared to monometallic analogue systems.The relatively high surface area of the synthesized $TiO_2$ with highly reactive bimetallic Pt-Pd nanoparticles did not allow high accumulation of carbonates on the surface of the Pt-Pd/$TiO_2$ catalyst, displaying moderate thermal stability and resistance to deactivation. Moreover, in-situ DRIFTS characterization revealed that propane was dehydrogenated and then, surface adsorbed oxygen oxidized propane to $CO_2$ and $H_2O$ on the Pt-Pd/$TiO_2$ catalyst.

# Outstanding synergistic effect of Au-Ir/$Al_2O_3$ catalysts on the total oxidation of propane

R. Camposeco, R. Zanella*
*Instituto de Ciencias Aplicadas y Tecnología, Universidad Nacional Autónoma de México, C. U., 04510, Ciudad de México, Mexico*
**rodolfo.zanella@icat.unam.mx*

**Introduction.** Volatile organic compounds (VOCs) are emissions generally coming from industrial processes and transport. There are two types of catalysts that can be used to eliminate VOCs: noble metals supported on oxides and metal oxides mainly supported on $TiO_2$, $Al_2O_3$, and $SiO_2$. Earlier studies have evidenced that Pt/$Al_2O_3$ presents activity in the catalytic oxidation of toluene and propene, likewise, it has been reported that γ-$Al_2O_3$ possesses specific surface properties that allow the achievement of good dispersion (up to 70%) of metallic active phases. Previous studies have reported that iridium atoms donate electrons with more facility than gold atoms when both metal atoms interact as nanoparticles; this interaction can modify the capability of gold to donate electrons. However, Au-Ir has not been reported as a catalytic system for the total oxidation of propane. Inspired by the previously mentioned and because gold catalysts are not stable in the total oxidation of $C_3H_8$, Au/$Al_2O_3$, Ir/$Al_2O_3$ and bimetallic Au-Ir/$Al_2O_3$ catalysts were synthesized and approached from the highlights of metal loading, dispersion, gold and iridium species on the catalyst surface and their adsorption capacity, as well as their surface acidity type.

**Experimental/methodology.** The synthesis of γ-$Al_2O_3$ was performed by the sol-gel method. Au/$Al_2O_3$, Ir/$Al_2O_3$ and bimetallic Au-Ir/$Al_2O_3$ catalysts were synthesized by the deposition precipitation with urea metod. A sequential deposition of iridium and gold on $Al_2O_3$ was carried out for the bimetallic samples. The synthesized materials were characterized by XRD, HRTEM-HAADF, $H_2$-TPR, UV-vis, and pyridine thermo-desorption, followed by FTIR and XPS, showing distinct characteristics that were correlated with their catalytic activity. The catalytic activity was evaluated by temperature programmed experiments using a flow reactor at atmospheric pressure. Flow mass controllers were used to set the flow of a gas mixture at 5000 ppm of $C_3H_8$ and 2% of $O_2$ in $N_2$ with a total flow rate of 100 mL $min^{-1}$. $CO_2$ concentration in the effluent gas was monitored online using a gas chromatograph Agilent Technologies system equipped with a methanizer

**Results and discussion.**

The monometallic Ir/$Al_2O_3$ catalysts turned out more active than the Au/$Al_2O_3$ ones. The addition of iridium to $Al_2O_3$ suppressed the crystal growth, resulting in more defects on its surface and high surface area. The superior performance of the Ir/$Al_2O_3$ catalysts may be associated with $Ir^{2+}$ species, oxygen vacancies and adsorption oxygen sites on their surface. The bimetallic materials displayed outstanding synergistic performance in the propane oxidation reaction compared to their gold and iridium monometallic counterparts at low reaction temperatures. Outcomes revealed a strong interaction among the gold and iridium particles when the catalysts are activated in $H_2$ and that the thermal treatment atmosphere (hydrogen or air) modifies the active sites; likewise, gold–iridium and monometallic iridium catalysts supported on γ-$Al_2O_3$ showed considerable endurance to activity loss because they hardly presented metal sintering at high reaction temperatures. Moreover, XPS results revealed electron transfer between Au-Ir. Only the bimetallic system presented Lewis and Brönsted acidity, which may have been responsible for enhancing the total oxidation of $C_3H_8$. The superiority of bimetallic catalysts was confirmed by the use of a GHSV of 41,000 $h^{-1}$ and the addition of 5 vol. % water. Additionally, the 3Au-5Ir/$Al_2O_3$ catalyst exhibited considerable stability in cycling and long-term stability tests in the $C_3H_8$ oxidation, setting it as a potential candidate to be used in real VOC removal processes.

**Keywords:** methane combustion, Pd-MeOx/$Al_2O_3$ catalysts

**Introduction.** Catalytic combustion of methane has been extensively investigated for emission control and power generation during the last decades. The alumina-supported palladium catalyst is widely accepted as the most active catalysts for catalytic combustion of methane. The activity of Pd/$Al_2O_3$ decreases during time on stream, especially under water vapor. The following order of activity in the reaction of complete oxidation of methane was established: $Co_3O_4$> CuO>NiO> $Mn_2O_3$> $Cr_2O_3$ [1]. It may be expected that the combination between Pd and these oxides could lead to the promising catalysts in reaction of complete methane.

**Experimental/methodology.** In the present work, we investigate the activity of Pd/$Al_2O_3$ catalysts promoted with metal oxides (MOx; M= Ni and Co). The Pd-based catalysts modified by metal oxide were prepared by sequential impregnation of $Al_2O_3$ with aqueous solutions of $Me(NO_3)_2.6H_2O$ and $Pd(NO_3)_2.6H_2O$ and next calcination. All samples were characterized by XRD (X-ray diffraction), TPR (temperature-programmed reduction), EPR (electron paramagnetic resonance) and XPS (X-ray photoelectron spectroscopy).

**Results and discussion.** According to the XRD data finely dispersed palladium particles were formed on the surface of all samples. XPS analysis shou the present ff both $Pd^{2+}$ and $Pd^{4+}$ on the surface of the fresh catalysts modified with Co and Ni only. The EPR data also suggest the existence of $Pd^{+}$ or $Pd^{3+}$ forms on the surface of the monocomponent Pd/$Al_2O_3$ and the exchange interactions between paramagnetic palladium species and nickel ions in Ni-Pd/$Al_2O_3$. Concerning Ni, EPR suggests the presence of $Ni^{2+}$ ions located in partly dehydrated $Al(OH)_3$, orthorhombic $Ni^{+}$ species and a $Ni^{+}$ species in axial symmetry. The reduction behavior of the synthesized catalysts was investigated by means of TPR (Figure 2). Several reduction maxima were observed. The hydrogen consumption in the interval 70-103 °C is attributed to the reduction of PdO [2]. The peak at 350 °C in Ni modified catalyst is ascribe to the reduction of finely divided NiO particles [2]. The reduction peaks at 387 and 500 °C in Pd/Co/$Al_2O_3$ catalysts are ascribed to the two-step reduction of $Co_3O_4$. The hydrogen consumption above 500 °C in all samples is attributed to the reduction of Ni-Al or Co-Al oxide phases [2, 3].

An improvement of activity was observed after modification with cobalt and oxides. We suggest that occurrence of Co-Al and Ni spinel phases plays a significant role for the stabilization of the palladium as PdO, leading to high activity and stability in methane combustion.The Pd+$CoO_x$/$Al_2O_3$ sample demonstrates remarkable stability after ageing thus the Pd/$Al_2O_3$ catalysts modified with Co exhibit the most promising catalytic activity for methane oxidation.

**Keywords:** urea polymer support, palladium catalyst, microreactor, carbonylation

**Introduction.**

Palladium supported catalysts belong to the most efficient catalytic systems for the reductive carbonylation, carbonylative reduction and formation of organic carbonates, particularly via cross-coupling reactions [1]. Based on our previous results with homogeneous palladium catalysis [2,3] and activity enhancement by crosslinked supports containing amide groups [4], we have developed new original catalysts using biologically degradable urea polymer supports. The prepared catalysts were tested in the Heck type aminocarbonylation of aryl halide and morpholine.

**Experimental/methodology.**

Pentamethylene diisocynate trimer (Desmodur® eco N 7300, Covestro), 1,5-pentanediamine (cadaverine, Merck) as a crosslinker and 2-picolylamine (Merck) for derivatizing of NCO groups, were used for the preparation of polymeric support (UBPS). Palladium catalysts (Pd(0)@UBPS) were prepared by the absorption of palladium acetate and its subsequent reduction employing either $NaBH_4$ or $H_2$ or $Et_3N$ in dioxane. The carbonylation reaction (example is in Scheme 1) was carried out in a two chamber (vial) system using $FeBr_2(CO)_4$ as an *ex-situ* CO source. The NMR, HPLC and GC-FID techniques were used for the analysis of reaction mixtures.

*Scheme 1.* Carbonylation reaction using the Pd@UBPS catalyst.

**Results and discussion.**

4-Haloanisoles (bromo- and iodo-) were tested in the carbonylation reaction according to Scheme 1. The best result was obtained using 4-iodoanisole (*IAnis*) and 1 mol % of Pd in the Pd@UBPS catalyst (reduced with $Et_3N$). The reaction proceeded with 99 % conversion of *IAnis* and (4-methoxyphenyl)(morpholin-4-yl)methanone) was obtained in 96 % isolated yield. Three recycling of the catalyst with a minimum loss of its activity showed the efficiency of this catalyst in the studied carbonylation reaction. The reaction of 4-bromoanisole *(BrAnis*) proceeded only with a low conversion (about 1.5 %), and chloro derivative (*ClAnis*) exhibited virtually zero activity under similar conditions. Achieved results are promising for a facile route to various aroyl amide derivatives – important intermediates for biologically active substances.

**Introduction**

The growing interest in the production of fine chemicals, pharmaceuticals and agrochemicals by continuous process technology is reflected by several studies found in open literature. The main obstacle for adopting continuous processes as a standard technology for Mizoroki-Heck reaction usually lies in its specific reaction mechanism. Here we present an important step forward answering the challenges unraveled through a comprehensive study that provides deeper understanding on the Mizoroki-Heck reaction, in particular the case when iodobenzene and butyl acrylate react in a continuous packed bed reactor in the presence of a Supported Ionic Liquid Catalyst (SILCA) containing Pd. A simple continuous flow process was proposed resulting in a high catalytic activity (up to 1470 $mol_{ArI}$ $mol_{Pd}^{-1}h^{-1}$) thus competing with the performance of commercial catalysts. For the production of pharmaceuticals, carbon–carbon couplings are very important branch of reactions, often they are the key step in formulating more complex molecules for the synthesis of fine chemicals and active pharmaceutical ingredients (APIs). Nowadays it is widely accepted that the reaction is based on the $Pd^0$ catalysis and throughout the reaction cycle, palladium alternates between the oxidation states $Pd^0$ and $Pd^{2+}$. The real nature of the palladium is more dynamic (the release-and-catch mechanism).

**Experimental**

A simple packed bed reactor system was designed and used to investigate the catalyst performance in the presence of triethanolamine base. The main goal was minimizing metal leaching and promoting SILCAs as suitable catalysts for C–C coupling reactions in flow. Catalysts with palladium loaded on propyl imidazolium bromidetetramethylguanidinium pentanoate $SiO_2$ allowed a localised catalytic cycle within the ionic liquid layer. All the experiments were performed in a designed tubular reactor with 0.7 cm internal diameter and 15 cm length. The temperature was monitored with four thermocouples in order to control the temperature in the bottom, middle and top segment of the catalyst bed. The catalyst bed length was 9 cm. Outlet of the reactor was passed throughout the UV–VIS analyzer, while the system of valves allowed collecting GC aliquots before and after reactor and the UV–VIS analyzer.

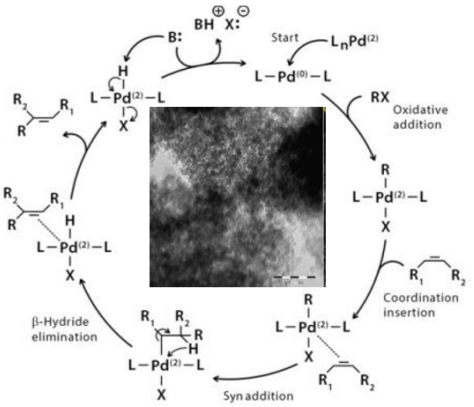

**Figure 1.** Heck Reaction: Definition, Example, Mechanism, & Application, (n.d.). https://www.chemistrylearner.com/heck-reaction.html (accessed April 2, 2021)

**Results and discussion**

For studying the Mizoroki-Heck reaction under continuous flow conditions, a simple tubular reactor with 7 mm internal diameter of the tube and 9 cm length of the diluted catalyst bed was applied. Exploring the impact of the individual compounds on the palladium leaching from the catalyst surface in a continuous reactor system unravelled the catalyst stability. Agglomeration can be suppressed with the use of ligands, while in case of pseudo-heterogeneous systems (release-and-catch mechanism) ligandlike species must be permanently anchored to the surface of the catalyst. Thus, the obtained insights together with the information received with ICP-OES, TEM and XPS led to expanded understanding of the catalytic cycle, deactivation mechanism and to the hypothesis that the reaction is proceeding in the ionic liquid layer. All this served to design an efficient continuous process with low Pd loading and leaching, activity as high as 1470 $mol_{ArI}$ $mol_{Pd}^{-1h-1}$, reaching productivity in the range of 12,000 to 16,000 $mol_{ArI}$ $mol_{Pd}^{-1}$ and competing commercially available catalysts.

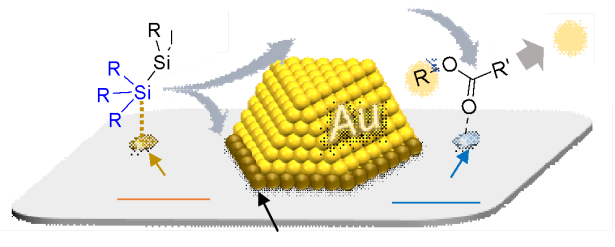
# Supported Gold Nanoparticles as Single-Electron Transfer Catalysts for Cross-Coupling Reactions



H. Miura[1,2*], M. Doi[1], Y. Yasui[1], K. Ameyama[1], and T. Shishido[1,2]

**Keywords:** Gold nanoparticles,cross-coupling, single-electron transfer catalysts

**Introduction.** Supported gold nanoparticles (Au NPs) exhibit excellent catalytic activity in a wide range of chemical reactions. Detailed studies mainly based on electron paramagnetic resonance (EPR) spectroscopy have revealed the harmonic interaction between Au NPs and organic radicals. These findings led us to reconsider whether several catalytic organic transformations under the influence of Au NPs might include single-electron transfer. In this study, we report that supported Au NPs function as a heterogeneous single-electron transfer catalyst to promote cross-coupling reactions for synthesizing various alkylsilanes[1] and alkyl boronates[1,2].

**Results and discussion.** $Au/ZrO_2$ catalyst promoted efficiently the cross-coupling of alkyl acetate with disilanes to give the corresponding alkylsilane in high yield. The heterogeneous Au catalysts were effective for the silylation of $C(sp^3)$–O bonds in various alkyl esters and alkyl ethers to afford the corresponding alkylsilanes. In addition, this reaction could be applied to the upcycling of polyesters, i.e., the degradation of polyester and the synthesis of organosilicon compounds were realized concurrently by the unique catalysis of $Au/ZrO_2$. Mechanistic studies corroborated the notion that the generation of alkyl radicals is involved in $C(sp^3)$–Si coupling and the cooperation of gold and an acid-base pair on $ZrO_2$ is responsible for the homolysis of stable $C(sp^3)$–O bonds.[1] On the other hand, Au/C catalysts efficiently catalyzed decarboxylative cross-coupling of *N*-hydroxy phthalimide (NHPI) esters with disilanes to give the corresponding alkylsilane. Furthermore, the Au/C catalyst was also effective for decarboxylative C–B coupling to afford alkyl boronates. A detailed mechanistic investigation revealed that single-electron transfer mediated by supported gold nanoparticles enabled the generation of an alkyl radical and silyl radical, thereby enabling radical cross-coupling.[2]

**Introduction.** Acylation reactions play an important role in fine chemical industries [1] and are tradionally carried out using inorganic compounds such as $AlCl_3$, $ZnCl_2$ and $BF_3$, posing serious environmental and economic issues [2]. Thus, the development of heterogenous catalysts able to replace these compounds is of paramount importance. Starting from these premises, in the present work, the potential utilization of different Ion exchange resins as catalysts for the acylation of 1,3-benzodioxole (MDB) to 3,4-Methylenedioxypropiophenone (MDP1P, used in drugs and insecticides) were investigated.
**Experimental/methodology.** The reactions were carried out in a round 2-neck flask connected to a reflux condenser. The reagent mixture (with no solvent) together with the catalyst were heated to the reaction temperature under stirring and maintained at this temperature for 1 h. The products were analyzed by GC and identified through GC-MS tecnique. The characterization of the catalyst before and after reaction was carried out using SEM, IR, BJH and TG analyses.
**Results and discussion.** The acylation of MDB, using propionic anhydride (AP) as acylating agent, over acid macroreticular-type resins such as Purolite and Amberlite, showed that the best results in terms of MDP1P yield and selectivity were achieved at 120°C, hitting yields of ≈ 45% but with a high by-products formation. Conversly, Aquivion PW-87 (a perfluorosulfonic acid/gel-type resin) can efficiently catalyze the reaction at 80°C, showing a higher MDB conversion (53%) and a MDP1P selectivity of 79% (Figure 1a). The overall efficiency can be futher boosted by encapsulating the resin into a $SiO_2$ matrix via a one-pot, sol gel synthesis. Moreover, It was found that, although the PW87/$SiO_2$ ratio drives the MDB and AP conversion, the yields in by-products can be nearly halved using the new composite.

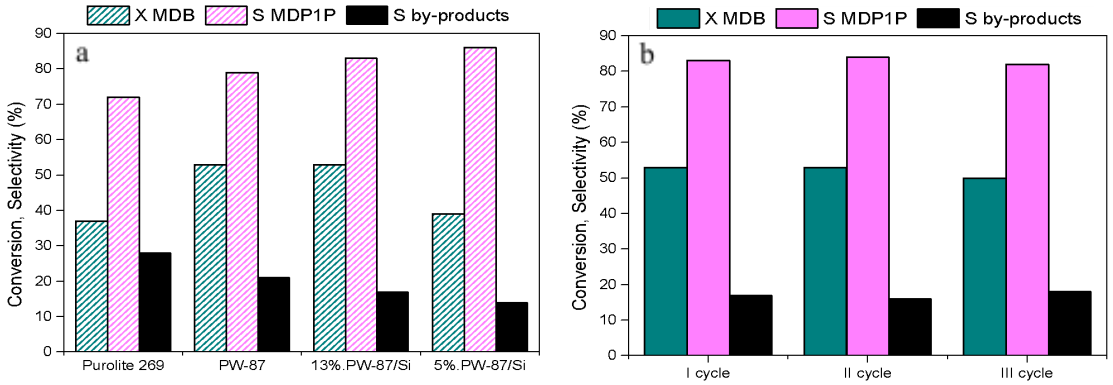

Figure 1: a) catalyst activity in terms of MDB conversion (X), MDP1P and By-products selectivity (S) and b) catalytic activity of 13%.PW-87/Si after each regerenation step with 20% $HNO_3$ (aq). Reaction conditions: 80°C, 500 rpm, MDB:AP = 1 mol/mol, 1h, mol $H^+$/ mol MDB = 0.007.

The study of the catalyst deactivation, revealed that the transformation of AP into heavier compounds over the catalyst surface is the main phenomenon that led to the blockage of the active sites during reaction. The regeneration of the resin can be obtained through a fast oxidation of the catalyst surface using an aqueous solution of $HNO_3$ (20%) or $H_2O_2$ (20%) at 100°C. In this way, after drying, the PW87-based catalysts can be efficiently reused for several cycles (Figure 1b) without significant activity drops.

# [MnBr(CO)$_5$] as a Precatalyst for the Selective Oxidation of Silanes into Silanols with Water

Emanuele Antico[1,2], Markus Leutzsch[3], Niklas Wessel[1,2], Thomas Weyhermüller[1], Christophe Werlé[1,4] and Walter Leitner[1,2]

**Keywords:** Homogeneous catalysis, manganese, hydrogen, silanols, water, mechanistic studies.

**Introduction.** Silanols have many applications, ranging from materials science and polymers[1] to medicinal chemistry.[2] Traditional procedures to synthesize silanols proceed via the wasteful hydrolysis of chloro- or alkoxysilanes with a stoichiometric amount of base, consequentially generating stoichiometric amounts of waste.[3] An appealing alternative resides in the oxidation of silanes using $H_2O$ as a green oxidant: hydrogen is produced as the only valuable byproduct, but the reaction often shows significant selectivity issues.

**Results and discussion.** Herein, we present [MnBr(CO)$_5$] as a highly active and selective precatalyst for this reaction.[4] To our knowledge, this constitutes the first example of using manganese for this specific reaction. [MnBr(CO)$_5$] operates under neutral conditions and avoids the undesired formation of siloxanes (a standard limitation of this reaction). A broad scope of silanols was synthesized in yields up to 98%. The scope includes silanediols and silanols bearing unsaturated functionalities such as allyl- or vinyl-, that can have potential applications in the synthesis of Si-based polymeric materials and are incompatible with traditional synthetic procedures. Moreover, the activation of the Si–H bonds by [MnBr(CO)$_5$] was elucidated studying the reaction kinetics on $PhMe_2SiH$ as a model substrate (including KIEs of $PhMe_2SiD$ and $D_2O$). The initial activation of [MnBr(CO)$_5$] was clarified, and the experimental data are most consistent with a catalytic cycle comprising a cationic tricarbonyl Mn(I) unit as the active framework. Altogether, these insights offer some catalyst design criteria for future catalytic systems capable of activating σ-bonds (such as Si–H, B–H, and H–H bonds) based on the widely available and earth-abundant manganese.

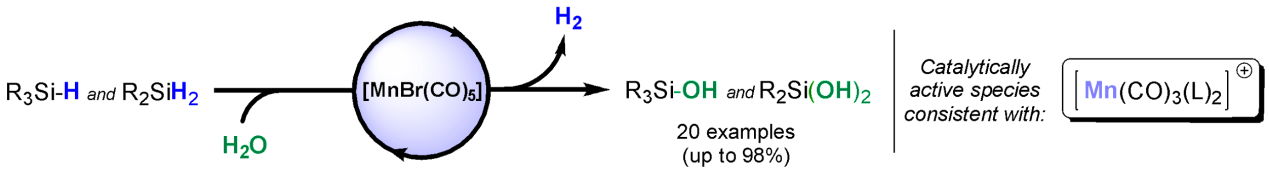

**Figure 1:** Schematic representation of the work, including the plausible active species mediating the catalytic cycle

**Experimental/methodology.** Several spectroscopic techniques (FT-IR, $^1$H-, $^{29}$Si-, $^{13}$C-, and $^{19}$F-NMR), Single crystal XRD, and GC-TCD were used to study the activation mechanism of the [MnBr(CO)$_5$] in the presence of silanes and to perform the kinetic studies used in the elucidation of the overall reaction mechanism. $^1$H-, $^{29}$Si-, $^{13}$C-, and $^{19}$F-NMR were also utilized to determine the nature and purity of the obtained products.

# Transaminase-membrane reactor for intensified chiral amines synthesis

Hippolyte Meersseman[1*], Tom Leyssens[1], Patricia Luis[1], Francesca Paradisi[2], Damien P. Debecker[1]

[1] *UCLouvain, Louvain-La-Neuve, Belgium*
[2] *University of Bern, Bern, Switzerland*
[*] hippolyte.meersseman@uclouvain.be

**Introduction.** Chiral amines are essential building blocks for the pharmaceutical industry. Their synthesis often involves multi-step processes requiring costly organometallic homogeneous catalysts [1]. Amine transaminases (ATAs) may provide greener routes to produce chiral amines with excellent enantioselectivity. Yet, industrial applications of ATAs remain restricted to batch processes in which ATAs are employed as free enzymes (non-reusable). One can thus design more versatile heterogeneous biocatalysts able to operate in flow, by immobilizing ATAs on solid supports [2]. Importantly, most targeted transaminations are limited by unfavourable thermodynamics. One strategy to shift the equilibrium towards high chiral amine yields, is the set-up of combined reaction-purification processes. Hence, coupling transaminases with membrane technology in an enzyme membrane reactor is of particular interest, as it could allow the removal of products during operation.

**Experimental/methodology.** As a proof of concept, we present the immobilization of an ATA from *Halomonas elongata* (HeWT) onto polypropylene (PP) and polyacrylonitrile (PAN) membranes and its application to catalyze the enantioselective synthesis of a model chiral amine in batch (**Fig. 1**). Briefly, PAN surface was chemically modified and coated with polyethyleneimine (PEI) to attract HeWT *via* electrostatic interactions. Glutaraldehyde (GA) was then used to cross-link the loosely attached HeWT and prevent their leaching from the membrane surface. On PP membranes, a covalent grafting strategy was adopted. PP surface was coated with polydopamine (PD) which provided amine functions for further functionalization. The subsequent addition of glycerol diglycidyl ether (GDE) enabled a strong grafting of the enzyme, especially when it was partially derivatized with PEI prior to immobilization.

**Results and discussion.** The obtained heterogenized ATAs are robust and recyclable, as they successfully performed successive catalytic cycles without deactivation, and with negligeable leaching (as confirmed by hot filtration test). They also showed good (30 %) activity recovery and enhanced stability compared to their soluble counterparts. Thus, we demonstrate the use of novel immobilized ATA carrier materials well-suited for upcoming flow operations, paving the way to intensified processes for chiral amines production.

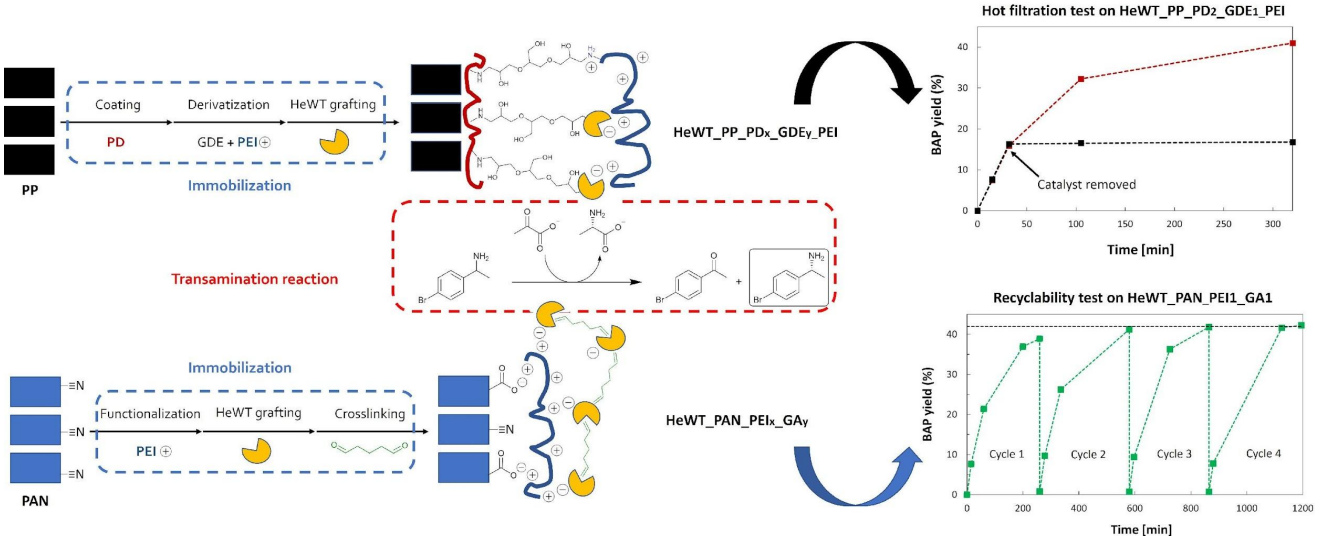

**Fig. 1. Left: Representation of the HeWT immobilization procedure on PP and PAN, and of the studied transamination. Right: Hot filtration and recyclability tests of the obtained heterogeneous biocatalysts.**
