# Birth, life and aging of heterogeneous catalysts seen by the eye of a spectroscopist.

Silvia Bordiga

*Department of Chemistry, NIS Center and INSTM Reference Center, University of Turin, Via Quarello 15, 10135, Turin, Italy.*

By definition, in a reaction what is acting as a catalyst is not consumed and remain unchanged after it. However it is a commune experience to handle with birth, life and aging of our catalysts. For this reason it is crucial to be able to characterize, at the best level we can, birth, life and aging evolution of our catalysts, in order to get structure-properties correspondance aiming to improove catalysts preformances.

In this context, a selection of case studies involving zeolites as catalysts, will be illustrated showing the complementar roles of some spectroscopic techniques used in situ or following operando conditions, underlying their pros and cons.

***Acknowledgments***

Silvia Bordiga is deeply in debt with all the past and present colleagues and students that along the last 33 years have contributed to develop the research illustrated in the contribution.

Some of the presented results were financially supported by the European Union's Horizon 2020 Research and Innovation Programme under grant agreement no. 837733 (COZMOS); by Marie Skłodowska-Curie grants agreement no. 955839 (CHASS) and agreement no. 847439 and by the European Research Council (ERC), under the Horizon 2020 research and innovation program ERC-Synergy project no. 856446 (CUBE).

# Frontiers in Olefin Metathesis: Toward the Realization of a Nobel Promise

Deryn E. Fogg

*Centre for Catalysis Research & Innovation, and Department of Chemistry and Biomolecular Sciences, University of Ottawa, Ottawa, Canada K1N 6N5 and Department of Chemistry, University of Bergen, Bergen, Norway*

Olefin metathesis is an exceptionally versatile methodology for the catalytic assembly of carbon-carbon bonds. Long embraced by synthetic chemists in discovery operations in academia and industry, molecular metathesis catalysts are now beginning to see uptake in pharmaceutical manufacturing (Figure 1a).[1] This is a welcome development, as they have tremendous potential to reduce the environmental footprint associated with production of active pharmaceutical ingredients. However, this and other demanding contexts (in particular chemical biology) reveal major limitations arising from short catalyst lifetimes.

The pathways by which the important ruthenium catalysts deactivate or decompose are now coming into focus. We believe that such understanding is key to designing better processes and, ultimately, better catalysts. Insights will be described into the operation and decomposition of key metathesis catalysts, including the most recent generation of high-performing cyclic alkyl amino carbene catalysts (CAAC; Figure 1b). These will be tied to key challenges and new opportunities relating to catalyst design, synthesis, and deployment. More broadly, these studies highlight the importance of advancing the critically important science of catalysis decomposition, a little-explored frontier in molecular catalysis.

# Towards understanding catalysis at water-solid interfaces

Johannes A. Lercher

*Institute for Integrated Catalysis, Pacific Northwest National Laboratory, Richland, WA*
*Department of Chemistry Technische Universität München, Garching, Germany*

The radical changes necessary for transitioning towards a future energy and chemical industry that achieves carbon neutrality demand reconsideration of catalytic conversions under conditions previously deemed challenging. A crucial aspect involves adopting environmentally benign solvents and diluents such as water or biogenic solvents. The modifications induced by these solvents create obstacles for catalyst performance and stability, yet they also unveil new opportunities to leverage the induced excess chemical potentials of reactive substrates.

Water, along with other polar molecules, self-organizes on oxide catalyst surfaces and within microporous materials. Their presence and self-organization affect sorption and catalysis by modifying the chemical and thermodynamic properties of both the solid environment and the hosted molecules. Water forms well-structured hydrated hydronium ions at Brønsted acid sites in micropores of all dimensions. The sizes of these clusters depend on the environment and are constrained by the entropy loss relative to condensation outside the micropores. Notably, the remaining pore space is predominantly vacant in the exclusive presence of water. This inhomogeneity is not the consequence of weak interactions between the zeolite pore wall and water, but caused by the internal stabilization of the hydrate clusters.

Other molecules are adsorbed in the space among hydronium clusters, and small polar molecules may partially substitute for water in the cluster, either forming the hydrated hydronium ion or clustering around metal cations. The concentration and thermodynamic state of adsorbed and reacting molecules are influenced by the characteristics of the interacting sites, the steric environment, and the density of charged species. This complex environment leads to a pronounced (de)stabilization of both ground and transition states, thereby both augmenting and impeding the rates of catalytic pathways. This results in a maximum of catalytic activity with increasing charge density, a phenomenon absent on open surfaces and associated with the energy required to reorganize charges within the confined spaces of narrow pores.

Water layers on metal particles on the other hand induce changes by influencing the electronic surface properties and influencing binding of hydrogen on these metal surfaces. In turn, the strength of this binding determines rates of hydrogen addition reactions. Changing the binding of hydrogen by external electric potentials opens additional new pathways to enhance these reactions and also facilitates pathways involving coupled transfer of $H^+$ and electrons.

For both acid-base and metal catalyzed reactions, the lecture will show the links between these underlying physicochemical causes for the observed changes induced by water in sorption and catalysis and will discuss opportunities and limitations for developing new catalytic pathways for a circular carbon-neutral catalysis.

# Catalysis using gold containing materials

Graham J. Hutchings*

*Max Planck Centre for the Fundamentals of Heterogeneous Catalysis, Cardiff Catalysis Institute, School of Chemistry, Cardiff University, Cardiff, CF10 3AT, UK*
**hutch@cf.ac.uk*

**Keywords:** gold, palladium, oxidation, hydrogenation.

Catalysis is of crucial importance for the manufacture of the goods and infrastructure and underpins the manufacture of most goods. Hence designing new catalysts is a topic of intense research interest in the scientific community. The identification that gold in nanoparticulate or cationic form is an exceptionally effective catalyst has paved the way for a new class of active catalysts. Gold is the most active catalyst for CO oxidation and acetylene hydrochlorination and recent research on this will be described. In particular, the innovations that were required to enable the commercialization of a gold catalyst will be described. Alloying gold with palladium can enhance the activity for alcohol oxidation as well as the direct synthesis of hydrogen peroxide. However, most recently it has been found that spatial separation of Au and Pd nanoparticles on a conducting support can give a significantly enhanced activity for alcohol oxidation via a novel cooperative enhancement effect (CORE). In this lecture the following topics will be covered:

Part 1 Gold Catalysis

- Carbon Monoxide oxidation[1]
- Acetylene hydrochlorination[2,3]
- Methane oxidation[4]

Part 2 Gold Palladium Catalysis

- Alcohol oxidation,[5,6]
- Direct $H_2O_2$ synthesis[7] and use of in situ generated $H_2O_2$ for coupled reactions[8,9]

# Identification of Solids for True Design and Precise Characterization of Functional Materials

Bunsho Ohtani

*Professor Emeritus, Hokkaido University and Nonprofitable Organization touche NPO, Sapporo,Japan*
*bunshoohtani@gmail.com*

**Keywords:** electron trap, idenfication of solid materials, reversed double-beam photoacoustic spectroscopy

**Introduction.** How can we design functional solid materials, such as catalysts and photocatalysts? What is the decisive structural parameters controlling their activities, performance or properties? What is obtained as structural properties by popular conventional analytical methods, such as X-ray diffraction (XRD) or nitrogen-adsorption measurement, is limited to bulk crystalline structure and specific surface area, i.e., no structural characterization on amorphous phases, if present, and surface structure has been made so far. This is because there have been no macroscopic analytical methods to give surface structural information including possibly-present amorphous phases. Recently, we have developed reversed double-beam photoacoustic spectroscopy (RDB-PAS) which enables measure energy-resolved distribution of electron traps (ERDT) for semiconducting materials such as metal oxides [1,2].

**Experimental/methodology.** ERDT patterns were measured by RDB-PAS as reproted previously [1,2]. Brief description of the method is excitation of electrons in the valence band of semiconducting samples are excited to electron traps by wavelength-scanned (from longer to shorter) monochromatic continuous light to give photoabsorption followed by detection by photoacoustic (PA) spectroscopy using intensity-modulated LED-light beam. ERDT patterns were obtained by differentiation of the PA intesity trace and calibration to absolute value in the unit of μmol $g^{-1}$. Conduction-band bottom (CBB) energy was calculated from photoabsorption-edge wavelength maasured by conventional PA spectroscopy and shown in reference to valence-band top (VBT) energy in the unit of eV.

**Results and discussion.** For almost all the metal oxide samples, suchi as titania, in powder form, the detected electron traps (ETs) seem to be predominantly located on the surface, and therefore they reflect macroscopic surface structure, including amorphous phases. On the other hand CBB might reflect bulk structure of samples. Even if the bulk structure suggested by CBB and surface area suggested by total density (TD) of ETs are similar, different samples showed different ERDT patterns suggesting that the surface structure of samples are different among the samples of similar particle size and bulk structure. Therefore, it can be said that RDB-PAS is sole possible methodology for macroscopic detection of the surface structure of solids. Another significan point is that the activity, performance or the other properties of two samples showing resembling ERDT/CBB patterns is almost identical with each other, i.e., those samples are "identified" by ERDT/CBB patterns. As far as the author knows, this is the first result for identification of solids. In this talk, an approach of "true" material design based on the ERDT/CBB-pattern analyses is introduced [3,4].

# Catalysis and Sustainability: A Journey from Atom to Planet

Javier Pérez-Ramírez

*Institute for Chemical and Bioengineering, ETH Zurich, Switzerland*
*jpr@chem.ethz.ch*

Ensuring a sustainable future for the chemicals and energy industries is a pressing global concern that has far-reaching impacts on the environment, human health, quality of life, and the economy. Catalysis plays a crucial role in this journey, constantly pushing the boundaries of conventional design to spearhead the transition towards defossilized and circular chemical manufacturing. This talk aims to illustrate the interdisciplinary and cross-scale mindset required to design catalysts that meet the ever-evolving sustainability criteria, bridging the gap between atom and planet. Delving into the latest research from my laboratory, I will showcase how a deeper understanding of catalyzed processes is driving revolutionary technological advancements. Through case studies in key areas such as $CO_2$ valorization, polymer manufacture, and organic synthesis, I will exemplify how nanoscale engineering and the availability of increasingly powerful tools to access structural variations and mechanism under relevant conditions aid catalyst discovery. At the forefront of design, I will demonstrate the importance of precisely controlling the architecture, speciation, and dynamics of supported metals in low-nuclearity catalysts, highlighting the impact that even the smallest changes can have on performance. The presentation will touch on current frontiers in catalyst synthesis and characterization, and emphasize the critical role of quantitative metrics in guiding low-carbon strategies.

# Molecular understanding of multifunctional electrocatalysts for water and hydrogen oxidation

Xile Hu *
Ecole Polytechnique Fédérale de Lausanne (EPFL), Institute of Chemical Sciences and Engineering, EPFL-ISIC-LSCI, BCH 3305, Lausanne, CH 1015, Switzerland
* *xile.hu@epfl.ch*

**Abstract.** The development of efficient and Earth-abundant water and hydrogen oxidation catalysts is essential for the generation and use of renewable hydrogen. Real-life catalysts are typically multicomponent, with each component contributing to one or more functions. The fundamental understanding of these catalysts is still lacking, which makes the rational design of catalysts difficult. In this talk, I will first present our work in understanding nickel iron oxyhyoxides, the current benchmark catalyst for water oxidation. We use multiple operando spectroscopy, electrokinetics, and isotope labelling experiments to elduciate the active sites and mechanisms of this catalyst.[1-2] Then I will show our discovery of a novel iron nickel oxide catalysts that surpress the performance limit of conventional nickel iron oxyhydroxides, due to its cooperative mechanism.[3-4] This catalyst has found application in cutting-edge anion exchange membrane water electrolyzers (AEMWEs). In the second part I will present our work in developing hydrogen oxidation catalysts for anion exchange membrane fuel cells (AEMFCs). I will show how we achieve a low-pltatinum-group-metal AEMFCs by using a porous support to tune the electronic properties of PGM nanoparticles.[5] Then I will describe our work in developing non-PGM catalysts for hydrogen oxidation. In particular I will highlight a catalyst made of Ni nanoparticles supported on a nitrogen-doped carbon. The electronic interaction between the Ni nanoparticles and its support leads to balanced hydrogen and hydroxide binding energies, which resulted in the highest (electrochemical surface area-normalized) intrinsic activity for PGM-free catalysts.[6] This catalyst has been used in HEMFC, delivering a peak power density that is more than 6 times higher than previously best devices.

# Keynote lectures

# Renewable fuel from waste in the circular economy era

Carlo Perego

*Senior Advisor, Italy*
*E-mail address (caregoperlo54@gmail.com)*

**Keywords:** renewable fuels; advanced biofuels, biomass waste; biochemical processes; thermochemical processes.

Transition to carbon neutrality requires drastic changes to happen as summarized by the International Energy Agency in "Net Zero by 2050" report, which defines a roadmap to reach the net-zero CO2 emissions (NZE) within 2050 [1].
Decarbonization of transport sector is crucial for achieving Net Zero 2050, as this sector is responsible for around 21 % of global CO2 emissions (7670 Mt vs 36639 Mt in 2021) [2]. The transport sector is particularly challenging to decarbonize due to its fundamental reliance on the inputs of fossil feedstock (i.e. crude oil and natural gas), used both as energy source and raw materials to produce transport fuel.
To deeply decarbonize the transport sector, few action areas beside energy efficiency, have been considered [1]:

- Deployment of electricity to become the dominant fuel;
- Deployment of hydrogen-based fuels;
- Transformation of refineries in biorefineries by substituting oil and gas for biomass;
- Substitution of fossil fuels for biofuels.

The deployment of biofuel must be based on a circular economy policy, mainly utilizing as raw material biomass waste generated by agriculture and forestry, food industries and domestic waste. As a matter of fact the amount of energy potentially recoverable form waste biomass is huge (130-240 EJ/y) [3] , but only few is today utilized, in particular for biofuel production. The biofuels currently commercialized, i.e. bioethanol, biodiesel (FAME) and Hydrogenated Vegetable Oil (HVO), are mainly produced from raw materials competing with the food sector [4]. For this reason, critical issues from an ethical point of view have raised. Accordingly new legislation has evolved by promoting the introduction of renewable fuels produced from waste biomass (i.e. advanced biofuels, from agricultural waste such as wheat straw or corn stalks, agroforestry residues, biomass cultivated for energy use on marginal land such as miscanthus, aquatic biomass, the organic fraction of domestic waste, sludge from water purification plants, and livestock sewage) or from other waste not of biogenic origin like plastic waste. Despite the obvious advantages in terms of sustainability, renewable fuels have not yet reached large-scale commercialization, due to the high complexity of the technologies involved and the high production costs. From a technological point of view, the processes for the production of these fuels can be classified as biochemical processes (e.g. fermentation, aerobic biosynthesis, anaerobic digestion and CO2 biofixation), thermochemical processes (e.g. pyrolysis, gasification and hydrothermal liquefaction) and synthetic catalytic processes (e.g. hydrogenation, cracking, Fischer Tropsch synthesis) [5].
The presentation will illustrate the most salient technological aspects of this industrial sector, focusing on the catalysis issues.

# Catalysis for Sustainable Fuels

Pablo Beato

*Topsoe, Lyngby, Denmark*
*pabb@topsoe.com*

**Keywords:** Sustainable fuels, MTJet™, Hydroflex™, eREACT™, LTFT™, SAF, eFuels, eJet

Topsoe is developing and licensing process technologies and catalysts that can convert feedstocks such as renewable electricity, biomass & waste, or fossil energy into chemicals and fuels such as hydrogen, ammonia, methanol, fuels and solutions that remove sulfur. Today, Topsoe is among the top 3 in each of these market segments and no 1. in segments such as renewable fuels, hydrogen and ammonia.
The first part of this lecture will provide an overview on the status of currently available technological solutions for sustainable fuels, including an outlook into the most exciting trends and developments. In the second part the lecture will dive deeper into the actual catalytic processes behind the technologies and discuss the scientific challenges that the catalysis industry needs to master to succeed in the clean energy transition.

# Biomass as feedstock for non-food applications

C. Pinel*, V. Meille, N. Perret,

*IRCELYON, UMR 5256, CNRS, Université Claude Bernard Lyon1, Villeurbanne, France*
**Catherine.pinel@ircelyon.univ-lyon1.fr*

**Keywords:** oxygenated substrates, aqueous-phase catalytic transformation**,** fine chemicals, hydrogen.

The significant climatic upheavals and the general deterioration of the environment must lead us to step back to evaluate the impact of our anthropogenic footprint and to find quickly alternatives to the productions of essential chemical compounds. In order to reduce greenhouse gas emissions, the conversion of biomass and the derived-platform molecules into synthons for fine chemistry or specialty chemical sectors is an alternative to fossil resource use.

The development of efficient catalysts within this area of research has evolved spectacularly since the beginning of the XXI$^{st}$ century. Significant progresses have been achieved leading to the development of highly active and selective heterogeneous catalysts. While in some applications, catalysts developed for transformation of petrochemicals may be used, in many cases, considering the chemical diversity of biomass derivatives, specific catalysts have to be developed. Indeed, aqueous-phase processing is a key issue since highly oxygenated compounds are concerned in the lignocellulosic biomass. To address this issue, the design of ideal catalysts as well as appropriate processes are world-wide studied.

We have developed a range of catalytic systems active in hydrogenation, hydrogenolysis, aerobic oxidation or dehydrogenation of oxygenated substrates issued from biomass. The nature of the support (mainly oxides), of the metal (rhodium, ruthenium, copper, molybdenum…) affected the performances of the catalysts but also the stability [1]. In addition, the influence of potential residues or impurities present in the raw feed has rarely been studied while there is a need to better understand their effect [2]. Applications covered fine chemicals (solvent, monomer or chemical intermediates) as well as hydrogen production [3].

# Materials and Mechanisms to Promote $CO_2$ Hydrogenation to Methanol

Malte Behrens[1*]

[1]*Institut of Inorganic Chemsitry, Kiel Nano Surface and Interface Science (KiNSIS), Kiel University, Max-Eyth-Str. 2, 24118 Kiel, Germany*

[*]*mbehrens@ac.uni-kiel.de*

**Keywords:** Methanol synthesis, Cu/ZnO catalyst, strong metal support interaction, catalyst promotion

**Introduction.** Co-precipitated Cu-based catalysts are among the most active and most widely studied catalytic materials in methanol synthesis with an increasing knowledge on the active site and the role of the Zn promoter. The precursor chemistry of the catalyst preparation has been studied in detail in our group[1] and found to be the basis for the synthesis of model materials that allow insight into the role of copper promotion by strong metal support interaction. For example, a series of Cu/MgO catalysts can be promoted by varying low amounts of Zn oxide enabling element-specific characterization of the dynamic state of Zn in the activated catalyst. Based on this insight, we derive a model for the active site, which was further investigated by selective poisoning with ammonia. Furthermore, the principles of the Cu-Mg-Zn system can be transferred to other metal/promoter combinations M-(Mg)-E, e.g. M = Cu, Ni and E = Zn, Ga.

**Experimental/methodology.** Catalysts were synthesized by co-precipitation from precursors such as $(Cu,Mg)CO_3(OH)_2$ with a Cu:Mg ratio of 70:30.[2,3] The promoter was added by impregnation in amounts between 0 and 20 wt%, which is low compared to the zinc content of industrial-type Cu/ZnO catalysts with a Cu:Zn ratio of ca. 70:30, which was used as a benchmark catalyst (including Al as secondary promoter).

**Results and discussion.** The Cu/MgO catalyst's activity in methanol synthesis from $CO/H_2$ was >2 times higher than that of the $Cu/ZnO/Al_2O_3$ benchmark,[2] but it was almost inactive in $CO_2/H_2$. The addition of Zn successfully promoted the $CO_2$ hydrogenation with a maximum at 10% ZnO. *In-situ* XAS at the Zn K-edge revealed the state of the promoter in the activated catalyst.[4] Together with DFT calculations, the results suggest the co-existence of reduced alloy species $Zn^{(red)}$ with partially oxidized $Zn^{(ox)}$ at the Cu surface supporting the presence of such sites also on industrial benchmark.[5] $NH_3$ is a probe molecule to affect the such promoted Cu sites by dosing pulses on the working industrial-type catalyst at high pressure.[6] $NH_3$ was found to inhibit methanol synthesis in $CO_2$-containing synthesis gas. During steady-state, isobaric trimethylamine (TMA) and $NH_3$ injections poisoned methanol formation reversibly, with the $NH_3$ poisoning being significantly stronger than TMA. Based on DFT calculations, $NH_3$ activation takes place on O* or OH* followed by the reaction with $CO_2$ forming a stable carbamate on the active site.[7] Further hydrogenation of the carbamate to methylamine exhibits high barriers, thus being rather slow, explaining stronger $NH_3$ poisoning, as TMA cannot form such carbamate species and acts only as weakly bound site-blocking species. Our contribution aims at a more detailed picture of the active site in methanol synthesis and highlights the role of the Zn promoter, which co-exists as reduced surface alloy and an oxidized form on the activated Cu catalyst. The poisoning effect of $NH_3$ on these active sites is explained by the presence of O*, likely on the $Zn^{(ox)}$ species, giving rise to $NH_3$ activation and formation of strongly bound carbamate.

# Translational Molecular Catalysis: From Challenging Catalytic Hydrogenations to Open-Loop Recycling

Jürgen Klankermayer[1*]

[1]*Institute for Technical and Macromolecular Chemistry, RWTH Aachen University, Worringerweg 2, 52074 Aachen, Germany*

[*]*jklankermayer@itmc.rwth-aachen.de*

**Keywords:** molecular catalysis, catalytic hydrogenation, carbon dioxide utilization, circular economy

Molecular catalysis has made tremendous advancements in the last few decades, and the implementation of modern computational methods has paved the way for the directed design of effective catalyst systems. This enabled, for example, the selective reduction of demanding functional groups in the field of catalytic hydrogenation and also the use of carbon dioxide as a renewable C1 building block in complex syntheses.[1,2,3] Recent developments pose a new challenge at the chemical–energy interface, which no longer requires the development of selective catalytic systems for bond formation, but rather for bond cleavage. Recently, various catalytic approaches for hydrogenolysis and selective bond cleavage have been established in a variety of polymers and biobased macromolecules, and in selected examples processes using waste materials from consumer products have already been implemented.[4,5] While current approaches largely focus on the combined use of carbon dioxide and molecular hydrogen to form C1 synthons, a novel methodology enables the synthesis of complex molecular structures with the combined direct integration of bio-based platform molecules or plastic waste, eventually leading to the concepts of bio-hybrid synthesis and open-loop recycling.[6,7]

Here, the challenges and opportunities of these new approaches to sustainable catalytic transformations and recycling approaches are presented. The general aspects are illustrated with current research results from our laboratories on the development, application and mechanistic understanding of molecular catalysts and catalytic systems.

# Science and Art of Successful Catalysts Promotion by Alkali

Andrzej Kotarba*

[1]*Jagiellonian University, Faculty of Chemistry, Krakow, Poland*
**E-mail address: kotarba@chemia.uj.edu.pl*

**Keywords:** electronic promotion, work function, surface chemistry, nanostructuration

**Introduction.**
Alkali metal compounds are widely used as promoters in many catalytic processes. The addition of alkali affects the catalysts' efficiency in many ways by increasing the activity, selectivity or prolonging the lifetime. Although the beneficial role of alkali additives is experimentally well established in catalysis, a more in-depth understanding of their action is still lacking. This is mainly due to their high reactivity, surface and bulk mobility, and difficulties in the characterization of their real surface states. Several aspects of alkali doping will be addressed such as surface states, electronic and structural effects, surface spreading, bulk and surface diffusion, and promoter loss via thermal desorption. Each of these issues will be illustrated with results referring to well-defined surfaces of active phases, as well as the model and industrial catalysts.

**Experimental/methodology.**
The investigated active phases model and real catalysts were thoroughly characterized by several traditional methods including XRD, SEM-EDX, HR-TEM/FIB, STEM/HAADF/EELS, XPS, RS, BET. The catalyst activities were measured in the laboratory (steady-state, temperature-programmed modes) and industrial conditions. In an attempt to elucidate the promotional effects of alkali and identify the decisive parameters responsible for their performance, a Species Resolved Thermal Alkali Desorption method has been developed. In tandem with work function measurements, it provides a powerful tool for the static and dynamic description of the alkali promoters in catalytic systems. The measurements were conducted in both vacuum and in near-catalytic conditions to bridge the material and pressure gap. In several cases, molecular interpretation of the results was gained by DFT modeling of the related systems.

**Results and discussion.**
The specific issues mentioned in the introduction are illustrated with the results referring to well-defined surfaces of active phases (e.g. Fe, Co, Ni, $Co_3O_4$, $Fe_3O_4$, $KFeO_2$, $K_2Fe_{22}O_{34}$, $KMn_4O_8$ $KMn_8O_{16}$), as well as the model and industrial catalysts (e.g. for ammonia synthesis, EBDH, ESR, $DeN_2O$, DeSoot). The results are discussed in terms of alkali surface state and localization (surface vs. bulk, active phase vs. support) [1, 2], electronic promotion (work function lowering) [2], structural functionalization (nanostructuration) [3], alkali dynamics (bulk diffusion, surface segregation, desorption) [4]. The effects of alkali promotion are explained at the molecular level for several investigated catalytic systems. Finally, an overview of reactivity descriptors and rational guidelines for designing, optimizing, and testing alkali-promoted catalysts are outlined.

# Sustainable Homogeneous Catalysis Using Sustainable Safer Solvents

David E. Bergbreiter

*Chemistry Department, Texas A&M University, College Station, TX 77843 USA*
*E-mail: bergbreiter@tamu.edu*

**Introduction.** Greener and/or more sustainable chemistry can involve many factors. However, a paramount issue is sustainability. That involves catalyst and solvent sustainability. Catalyst sustainability can be an issue because of the use of precious metals or complex ligands. Solvent sustainability is an issue because solvents are the major component of most reactions.

**Experimental/methodology.** In a typical experimental procedure, a PAO-soluble polyisobutylene hydrocarbon oligomer is modified by known chemistry to attach a catalyst or a ligand and a catalyst.[1] This catalyst is then dissolved in a PAO solvent, typically a $C_{20}$, $C_{24}$, or $C_{30}$ PAO.[2] A substrate is then added with a functionalized PIB or an added low molecular solvent to enhance substrate solubility. Then the catalytic reaction is carried out using the same procedure that would be used for a low molecular weight catalyst. After the reaction, the product is removed either by distillation, a solid/liquid separation (if the product precipitates), or by a liquid/liquid separation using a PAO immiscible solvent like $CH_3CN$. Subsequent cycles involve addition of fresh substrate.

**Results and discussion.** Our work has approached the problem of making homogeneous catalysis more sustainable by focusing on making recycling catalysts, ligands, and solvents as simple and as quantitative as possible. Our thesis is that a properly designed fully recyclable system of catalysts and solvents can simultaneously address issues of both catalyst and solvent sustainability. In the case of catalysts, we have focused on using polyolefins like polyisobutylene as phase anchors to recycle catalysts and ligands. For solvents, we have been exploring inexpensive safer, separable, and recyclable solvent systems that use polyolefins. Our work has shown that low viscosity commercially available the poly(alpha-olefin)s (PAOs) - fractionated hydrocarbon mixtures with 20-48 carbons - have considerable potential as solvents in synthesis and separation chemistry.[2] Such PAO solvent systems with polyolefin-bound catalysts fulfill several criteria for green and sustainable chemistry. The PAO solvent serves as a recyclable, regenerable sequestering phase. PAO phases with PAO-soluble catalysts, reagents, and sequestrants can be quantitatively recycled multiple times in catalysis, synthesis, and separation chemistry without significant contamination of the isolated organic products or of a separable polar solvent phase. Separations can most often be accomplished by liquid/liquid or liquid/solid separations. PAOs safer solvents too because of their high flash point and low volatility.[3] In moist examples, catalysts using this process can be recycled at least 5-10 times with no loss of the PAO solvent. Catalyst leaching in the separations is typically minimal. This talk will highlight these themes with examples of various transition metal and organocatalysts, pointing out both advantages and this advantages of this approach to sustainable homogeneous catalysis.

# Magnetic Catalysts and Catalytic Magnets: Never the twain?

Evgeny Rebrov[1,2*]

[1]*Department of Chemical Engineering and Chemistry, Eindhoven University of Technology, Eindhoven, the Netherlands*
[2]*School of Engineering, the University of Warwick, Coventry, UK*
[*]*e.rebrov@tue.nl, e.rebrov@warwick.ac.uk*

**Keywords:** magnetic superstructure; inductive heating; hydrogen evolution reaction (HER); magnetic catalysts, forced periodic modulation.

**Introduction.** The inductive heating of catalysts impregnated with magnetic susceptors or magnetic susceptors functionalized with catalytic active centers have been exploited for a wide range of applications, spanning from fine chemicals synthesis to electrochemistry. Whatever the application, induction heating provides unique features in comparison to conventional heating systems based on heat convection or conduction. With inductive heating, high temperatures can be reached more quickly on the active centers while the surface coverages need more time to adjust to the new conditions. This creates a possibility to run the reaction under forced periodic modulation of temperature and other parameters (flow rate, concentrations) such that the time averaged reaction rate or/and selectivity could considerably exceed those obtained at steady-state conditions [1].

**Results and discussion.** There exists two fundamentally different approaches for preparing supported catalysts operated under inductive heating. In the first approach, magnetic susceptors with excellent heating power (such as $Fe_{2.2}C$, $Co_{60}Ni_{40}$ etc.) are functionalized with a support layer ($SiO_2$, $TiO_2$) and then with catalytic nanoparticles [2]. In this approach, controlled surface engineering is vital for the design of stable catalysts. Usually, macroscopic ferromagnetic alloys are used as susceptors of magnetic field in highly endothermic transformations. In the second approach, conventional catalysts are in-situ grown around the magnetic nanoparticles [3] or magnetic nanoparticles are embedded in the catalyst support in a post-synthesis step [4]. Ferromagnetic materials (like iron oxide, nickel and cobalt ferrites) are usually employed. The control of magnetic material structure at the nanoscale is the key to increase performances and improve the energy efficiency under induction heating. Sometimes a combination of these two approaches is used when a support is coated with magnetic and catalytic materials [5]. In this respect, the development of functionalization treatments of high quality to yield magnetic catalysts with superior properties still remains a largely unexplored field, even when significant progress has been reported in the use of different organic and inorganic passivation or functionalization agents.

In this presentation, we will discuss main synthetic methods for preparation of composite magnetic catalysts, followed by their characterizations and applications in fine chemical synthesis, hydrogenation of bio-oil and electrochemistry (hydrogen evolution reaction) [6], where the reaction rate and/or selectivity was considerably increased as compared to conventional operation.

# Ceria Nanoparticles Shape Effects in Catalysis

Michalis Konsolakis*

*School of Production Engineering and Management, Technical University of Crete, GR-73100, Chania, Greece*
**E-mail : mkonsolakis@tuc.gr*

Catalysis is an indispensable part of our society, being massively involved in numerous energy and environmental processes of paramount importance. In fact, catalysis constitutes a field of diverse applications, including, among others, the production of high-commodity chemicals and fuels, refining and petrochemistry and abatement of hazardous substances, all playing a key role towards sustainability. In view of this fact, the rational design and development of cost-efficient catalyst formulations with tailored reactivity constitutes the main research pillar in the field of catalysis. Towards this direction, the fine-tuning of local surface chemistry by means of advanced synthetic and promotional routes has recently gained particular attention. In specific, the adjustment of size, shape and electronic state of multi-component metal oxide systems at the nanoscale though appropriate synthesis methods and nano-engineering strategies can exert a profound influence not only to the reactivity of metal sites, but to the interfacial activity as well, resulting in the development of highly active and stable materials for real-life energy and environmental applications [1-3].

In the present talk, the pivotal role of shape engineering in catalysis is exemplified on the basis of transition metal catalysts based on $CeO_2$. Initially, the underlying mechanism of the facet-dependent reactivity of ceria nanoparticles is discussed. A thorough characterization study of ceria-based composites of distinct nano-morphology (rods, cubes, polyhedra) is presented next, so as to gain insight into the impact of different exposed facets into key physico-chemical properties. It is clearly disclosed that shape functionalization can notably affect several key activity descriptors with direct catalytic implications. Most importantly, the combination of ceria particles with specific nano-arcitecture with late 3-d transition metals may very well induce synergistic metal-ceria interactions, thus offering extremely active and stable catalytic composites for various heterogeneous processes. Besides, from a practical standpoint, novel catalyst formulations with similar or even superior reactivity to that of noble metal-based catalyst may be obtained, such as $Cu/CeO_2$-nanorods for oxidation reactions and $Ni/CeO_2$-nanorods for $CO_2$ hydrogenation processes [4-8]. Last but not least, an overall rationale and design guidelines towards the fabrication of earth-abundant metal oxide catalysts for application in various chemical reactions of energy and environmental significance are provided.

# Size- and Composition--Selected Subnanometer Cluster Catalysts in Oxidative Dehydrogenation and Hydrogenation Reactions

Štefan Vajda

*Department of Nanocatalysis*
*J. Heyrovský Institute of Physical Chemistry, Czech Academy of Sciences*
*Dolejškova 2155/3, 182 23 Prague 8, Czech Republic*
*stefan.vajda@jh-inst.cas.cz*

The focus of the presentation will be on catalysts by supported monodisperse subnanometer clusters made of a handful of atoms, supported on technologically relevant oxide- and model carbon-based supports.

The performance of Co, Cu, Pd and CuPd clusters in the oxidative dehydrogenation of cyclohexene and cyclohexane will be discussed [1-4], where the atomic precision design of mono- and bimetallic clusters allows for the fine-tuning of their activity and selectivity by varying the composition of the clusters in an atom-by-atom fashion and by support effects.

In the second part of the presentation, the conversion of $CO_2$ on copper cluster-based catalysts to methane vs methanol or longer chain hydrocarbons will be discussed in the dependency of cluster size and support used.[5-7]

# Catalysis at the metal-support interface: about nanoparticles, clusters and single metal atoms

Emiel J.M. Hensen*

*Laboratory of Inorganic Chemistry and Catalysis, Department of Chemical Enigneering and Chemistry, Eindhoven University of Technology, The Netherlands*

Heterogeneous catalysis significantly shapes society, as it plays a crucial role in the production of fuels for mobility and base and specialty chemicals. C1 chemistry is expected to be pivotal in the transition to a sustainable reality in which renewable feedstocks and energy replace fossil resources. Typical heterogeneous catalysts for the activation of small molecules like CO, $CO_2$ and $CH_4$ consist of "metal on a support". Structure sensitivity refers to the dependence of chemical reactivity of metal nanoparticles on size and often implies low catalytic efficiency. Overcoming such limitations of structure sensitivity can be achieved by systems in which metal – metal-oxide interfaces form the active sites. These include metal oxides dispersed on metal nanoparticles as well as ultra-dispersed metal phases on redox-active support materials for the activation of reactants. Experiment and theory will be combined in this lecture with $CO_2$ hydrogenation as a model reaction relevant to renewable energy storage.

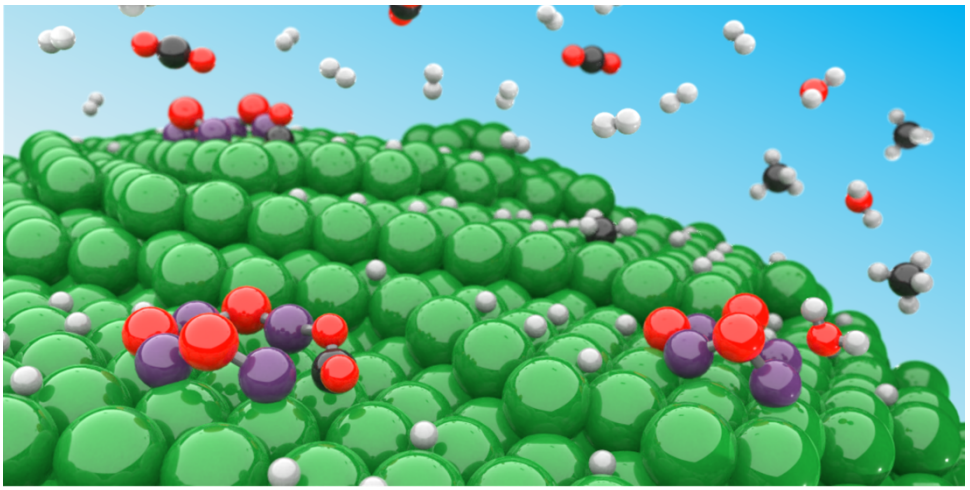

**Figure 1:** Structure sensiitivity guides the design of metal nanopartticle catalysts for sustainable catalysis.

# Engineering of Catalytic Cycles in Redox Reactions

De Chen

[1] Department of Chemical Engineering, Norwegian University of Science and Technology, Trondheim, 7491, Norway. *de.chen@ntnu.no*

**Keywords:** redox cycley, operando kinetic study, rational design of catalysts

**Introduction.** Redox reactions play a critical role in the chemical industry and are used in numerous industrial processes, including the production of chemicals, fuels, and metals, as well as environmental applications. Understanding the mechanisms of these reactions and developing efficient and sustainable catalysts is essential for the continued growth and advancement of the chemical industry. The oxidation state of metal plays a crucial role in determining the activity, selectivity, and stability of catalytic redox reactions, which are essential in many industrial processes. The engineering of the catalytic cycle of redox reactions requires a deep understanding of the redox mechanisms involved and the ability to control the oxidation state of the metal. In this context, the Mars and van Krevelen mechanism provides a simplified approach to understanding redox cycles in selective oxidation reactions. Many redox reactions involving C, Cl, N, and S follow similar simplified mechanisms on metal carbide, chlorides, nitrides and sulfides.

**Experimental/methodology.** A new approach for kinetic analysis and rational design of the redox reaction cycle, as well as a new tool for predicting the catalyst's oxidation state, were developed. The approach involves the oprando transient kinetic study and modeling of individual reduction and oxidation steps following a kinetic synthesis of the redox cycle at the steady state . The operando kinetic study was carried out in a fixed bed reactor coupling with in-situ UV-Vis-Near IR and mass spectroscopies

**Results and discussion. The** approach can help in optimizing catalyst performance and predicting catalyst behavior in industrial reactors. The control of the oxidation state of the metal can be achieved through the selection of appropriate catalysts, the use of promoters or inhibitors, and the manipulation of reaction conditions. The engineering of the catalytic cycle of redox reactions provides a new tool for the rational design and fine-tuning of the metal oxidation state for the development of efficient and sustainable chemical processes. Applications of the approach in cases of ethylene oxychlorination and methane selective or total oxidation will be discussed.

*The University of Messina and the European Research Institute of Catalysis aisbl, Messina/Italy and Brussels/Belgium*
** E-mail: siglinda.perathon@unime.it*

**Keywords:** electrocatalysis, photoelectrocatalysis, renewable energy, artificial leaf, electrocatalytic cells

**Introduction**. Defossilization of chemical production to meet targets such as net-zero emissions by the year 2050 is a challenge influencing research directions [1]. Electrochemistry has been known for over a century. Still, the interest in electrocatalysis raised recently, with exponential growth over the last two decades reaching over 600 publications and 25000 citations per year. Notwithstanding this impressive number of publications and reviews, the reactions investigated are mostly restricted to the conversion of small molecules (CO2, N2, H2O) and a few biomass intermediates. Regarding reactors and experimental conditions, literature studies are often quite far from those necessary for possible industrial exploitation [2,3]. Addressing the challenge of creating new fossil-free chemistry requires exploring novel solutions and approaches by identifying the limiting factors for exploitability and studying how to overcome them [4].

**Discussion**. This study highlights the contribution and discusses recent research projects in this area of (photo)electrocatalysis, which are relevant case examples to explore new directions but are characterised by a little background research effort. It is organized into two main sections, where selected examples of innovative directions for electrocatalysis and photoelectrocatalysis are presented.
The areas discussed include (i) new approaches to green energy or $H_2$ vectors, (ii) the production of fertilisers directly from the air, (iii) the decoupling of the anodic and cathodic reactions in electrocatalytic or photoelectrocatalytic devices, (iv) the possibilities given by tandem/paired reactions in electrocatalytic devices, including the possibility to form the same product on both cathodic and anodic sides to "double" the efficiency, and (v) exploiting electrocatalytic cells to produce green $H_2$ from biomass. The examples offer hits to expand current areas in electrocatalysis to accelerate the transformation to fossil-free chemical production. The role of the design of the cell and electrodes, and critical factors determining the behavior are also discussed.
The final part of the lecture will discuss the recent results as part of the EU project A-LEAF of the development of an artificial leaf device built with earth-abundant materials for combined $H_2$ production and storage as formate with efficiency >10% [5].

# Metal-organic Frameworks as versatile solar photocatalysts for overall water splitting

Hermenegildo García

*Instituto Universitario de Tecnología Química, Consejo Superior de Investigaciones Científicas-Universitat Politecnica de Valencia, Universitat Politecnica de Valencia, Av. de los Narnajos s/n, 46022 Valencia, Spain*
**E-mail: hgarcia@qim.upv.es*

**Keywords:** Photocalysis, Solar Energy Conversion, Overall Water Splitting, Hydrogen Generation, Metal-Organic Frameworks.

**Introduction.** Sunlight can provide enough energy to power the planet. However, several issues including intermittency and low power density have to be overcome. One possibilities is the storage and concentration of solar energy into chemical compounds that can be used as fuels (*solar fuels*).

**Results and discussion.** The fundamentals of the mechanism of the photocatalytic overall water splitting will be presented together with a short introduction on the properties of metal-organic frameworks (MOFs) that make these porous crystalline inorganic-organic materials suited for their use as photocatalysts. The main emphasis of the presentation will be on the recent contribution of the Valencia group to the field of hydrogen generation from water that has been recently summarized in Chem. Rev.[1] It will be shown how the structure of the MOF can be optimized by selection of appropriate linkers,[2, 3] metal nodes,[4] presence of co-catalysts,[5] and on-purpose generation of defects,[6] resulting in enhancements of the photocatalytic efficiency. Fig. 1 shows the structure of one of the most active materials reported so far, denoted as IEF-11.[7] IEF-11 is constituted by 2D layers of three different types of $TiO_6$ octahedra that are coordinated with squarate ligands in the perpendicular direction. Due to its color, squarate introduces visible light photoresponse and upon light absorption, this aromatic cycle injects electrons onto the $TiO_2$ layer, leading to charge separation. As result, IEF-11 exhibits a productivity in overall water splitting of 550 micromoles of $H_2/g_{catalyst}$ with the corresponding half the amount of $O_2$. The solid was reused ten times reproducing the same temporal profile for $H_2$ and $O_2$ evolution. Furthermore, no changes in the XRD of the solid after extensive use was observed, implying that the MOF structure remains unaltered during the photocatalytic reaction. Further improvements on the efficiency are expected upon modulation of the MOF structure. Current target is to produce over 1 mmol $H_2/g_{IEF-11}$ under natural light irradiation, bringing photocatalytic hydrogen generation closer to TRL 5.

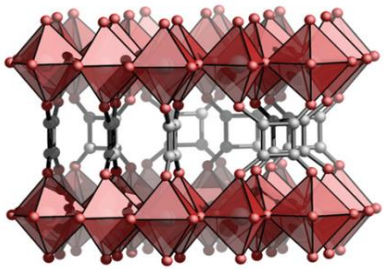

**Fig. 1**. Cross sectional view of IEF-11 showing the 2D TiOx layers connected by perpendicular squarate linkers (taken from ref. 7)

# Cleaning emissions from vehicles using catalysis

L. Olsson*

*Chemical Engineering, Competence Centre for Catalysis, Chalmers University of Technology Gothenburg, Sweden*

*louise.olsson@chalmers.se

**Keywords:** NOx removal, ammonia selective catalytic reduction, passive NOx adsorbers, catalyst aging

**Introduction.**

Exhaust from gasoline engines can be treated using a three-way catalyst, that operates in stoichiometric conditions and effectively can remove CO, hydrocarbons, and NOx. However, the exhaust aftertreatment system (EATS) for diesel and lean burn engines are much more complicated due to the difficulty in removing NOx in oxygen excess [1]. Ammonia selective catalytic reduction (SCR) is a key technology in this respect, where ammonia selectively reacts with NOx. However, there are challenges with this technique such as sulfur poisoning for example [2]. In addition, the ammonia is produced from urea decomposition and urea cannot be dosed at low temperature due to issues with deposits. An interesting technique is therefore passive NOx adsorbers, where NOx is adsorbed at low temperature and released at higher temperatures where the urea can be dosed. However, also this technique has challenges such as deactivation in the presence of high CO concentrations.

**Experimental/methodology.**

Different copper and palladium based zeolites were prepared. The activity, selectivity and deactivation were measured using flow reactors equipped FTIR. The catalysts were characterized in detail before and after poisoning using for example BET, XRD, XPS, TEM, TPR, TPD, DRIFTS and NMR.

**Results and discussion.**

An overview will be given regarding cleaning emissions from vehicles. A special focus will be given to the removal of NOx during oxygen excess. Sulfur poisoning is a large issue for Cu/zeolites that are used for ammonia SCR. In Cu/zeolites there are different types of copper species, where $[Cu(OH)]^+$ and $Cu^{2+}$ are very important. We have found that $[Cu(OH)]^+$ is more sensitive to $SO_2$ poisoning than $Cu^{2+}$. Moreover, Cu/LTA can store larger amount of $SO_2$ compared to Cu/SSZ-13, which could be due to that the interaction of $[Cu(OH)]^+$ with the framework in Cu/LTA is much weaker as suggested by $H_2$-TPR. This results in a slower deactivation during SCR conditions [2]. Another degradation mode is phosphorus poisoning, where $[Cu(OH)]^+$ in Cu/SSZ-13 were poisoned significantly, resulting in low temperature deactivation. Moreover, the extent of phosphorus deactivation was influenced by the choice of zeolite, where Cu/BEA even exhibited increased activity due to phosphorus. XPS characterization revealed that most of the phosphorus on Cu/BEA was in the form of $P_2O_5$, and we suggest that $P_2O_5$ enhanced the redox ability [3]. Another issue with ammonia SCR is that the urea cannot be dosed at low temperatures due to deposits. Passive NOx adsorption is an interesting concept where NOx is stored at low temperature and released thermally at higher temperature when the SCR system is operating. However, there are challenges with this system, especially deactivation induced by high CO concentration. We have developed a kinetic model that can describe this CO-inducted degradation [4]. Moreover, we have developed an improved Pd/SSZ-13 catalyst, by changing the synthesis procedure which resulted in a catalyst more resistant to CO deactivation [5].

# Green asymmetric organocatalysis

Radovan Šebesta

*Comenius University Bratislava, Faculty of Natural Sciences, Mlynska dolina, Ilkovičova 6, 842 15 Bratislava, Slovakia, e-mail: radovan.sebesta@uniba.sk*

Climate change and enduring need for the synthesis of chiral compounds present new challenges to organic chemistry and catalysis. Efficient synthesis of chiral compounds necessary for medicines, materials, or crop protection need not only be highly stereoselective but must comply with stringent environmental criteria. The ideal synthesis should abide by principles of green chemistry such as the elimination of dangerous compounds, decrease waste production but also time and financial effectivity. Asymmetric organocatalysis, that is the use of small chiral organic molecules as catalysts, offers excellent opportunities in the synthesis of critical chiral compounds and, at the same time, enables the implementation of green chemistry principles [1].

Enantioselective organocatalytic reactions, such as Michael additions of aldehydes to nitroalkenes, aminoxylation, and hydrazination of aldehydes can be performed in aqueous media or under solventless conditions using a ball mill [2]. We have found out that these reactions proceed with high yields and highly enantioselective. The solventless methodology also allows for more effective catalysis using organocatalysts, which employ non-covalent interactions for activation [3]. Chiral thioureas and squaramides, in some cases, proved to be more enantioselective catalysts for Michael additions under solventless conditions than in solvents [3]. Ball-milling was highly effective in promoting diastereodivergent oxa-Diels-Alder reaction of unsaturated ketones with enoates [4]. Chiral squaramides were very effective for enantioselective domino Mannich reaction with fluorination [5]. We have used acidic ionic liquids and microwave irradiation to release unstable alkyloxyacetaldehydes from the corresponding acetals in situ. This idea improved the organocatalytic synthesis of antiviral drug oseltamivir [6]. Greener solvent alternatives, such as 2-methyltetrahydrofurane allow highly enantioselective warfarin synthesis [7].

# Intensification of Catalytic Processes for the Synthesis of Hydrocarbons from Renewable Feedstocks

S. Escolástico[1], M. Balaguer[1], L. Almar[1], J.M. Serra[1], A. Martínez[1*]

[1]*Instituto de Tecnología Química, Universitat Politècnica de València-Consejo Superior de Investigaciones Científicas (UPV-CSIC), Valencia, Spain*
[*]*amart@itq.upv.es*

**Keywords:** Renewable fuels and chemicals, intensification, membrane reactor, tandem catalysts.

**Summary.** The European Commission has recently adopted new net emission targets for 2030 and 2050 as part of the European Green Deal plan towards climate neutrality. Two key strategies for reaching the ambitious goal of net-zero carbon emissions include the use of renewable energy to displace fossil energy and the implementation of *Carbon Capture and Utilization* (CCU) technologies. CCU brings potential to mitigate carbon emissions by using $CO_2$ captured from fossil- and bio-based industries or directly from the air as a carbon feedstock for the production of value-added products. Among the available CCU options, the thermocatalytic conversion of $CO_2$ via hydrogenation to fuels and chemicals using green $H_2$ and renewable electricity is especially appealing as it provides an effective means to store and transport surplus renewable electricity in the form of chemical energy. However, most current $CO_2$-to-hydrocarbons conversion technologies rely on multi-step approaches involving several separation and catalytic processes (e.g., water electrolysis, conversion of $CO_2$ to intermediate products, transformation of the intermediates to final products) that result in low overall energy efficiency and high cost. In this respect, process intensification can provide an effective solution to these drawbacks and could thereby help to lay the ground towards their industrial implementation.

In this Keynote, the application of the process intensification concept for the synthesis of valuable hydrocarbons (e.g., fuels, chemicals) from $CO_2$ will be discussed from two perspectives: 1) the use of advanced multifunctional catalysts enabling the one-step hydrogenation of $CO_2$ to specific hydrocarbons via tandem catalysis (Figure 1), and 2) the use of electrochemical catalytic membrane reactors (e-CMRs) combining chemical reaction and separation (Figure 2). The benefits of both intensification approaches will be illustrated for the synthesis of different renewable hydrocarbons as proposed, for instance, in the two ongoing EU-funded eCOCO2 and CO2SMOS projects.

# Nano-imaging chemical properties of zeolite catalysts

M.B.J. Roeffaers[1*]

[1]*cMACS, KU Leuven, Leuven, Belgium*

**Keywords:** fluorescence microscopy, correlative microscopy, Raman microscopy, nanoscale structure-function-activity relation

**Introduction.**

Fluorescence microscopy is a recent addition to the toolbox for in situ study of solid catalytic materials. It combines ease of use with non-invasiveness, high sensitivity, and temporal resolution.[1,2] In this presentation, I will explain how fluorescence-based assays can be used to map catalytic reactions inside individual zeolite particles down to the single turnover level. Such measurements, in combination with structural and functional information from correlative Raman and electron microscopy, enable to generate nanoscale activity images of working zeolite catalysts.[3,4] Next to significant intraparticle heterogeneities, the data also reveal important interparticle heterogeneities, which have often been overlooked so far, and this both for lab-scale and industrially produced catalyst batches.

**Results and discussion.**

Fluorescence microscopy is widely used in biomedical research, however, its use in materials research is much less explored. In contrast to biological (single molecule) fluorescence studies, that rely on large polycyclic substrates, the widespread application in catalysis research critically depends on identifying relevant reagent molecules that are converted into strongly fluorescent reaction products that are detectable with single-molecule sensitivity.[1,2] By recording the fluorescence signal generated by every single catalytic conversion and by accurate image reconstruction, a nanoscale activity map can be generated. Overlaying such information on the corresponding electron micrographs enables to precisely pinpoint the zones of enhanced catalytic activity.

Next to the direct observation of catalytic conversions, a detailed understanding of catalytic site distribution and accessibility is critical. Rather than looking at the inorganic compositions, as in electron and X-ray microscopy, we employed advanced Raman-based assays with organic probe molecules similar to those used in infrared spectroscopy to visualize the 3D acid site distribution in acid zeolite catalysts.[4]

In this contribution, information on single zeolite crystals obtained from different types of optical microscopy will be combined to generate a detailed picture of working zeolite catalysts (ZSM-5[5,6], MOR[4,7] and USY [8]) at the single particle level and ultimately with single-molecule sensitivity. The presented approach enables unraveling the complex interplay between diffusion, catalytic site distribution, and reactions at the single particle level. Furthermore, next to significant intraparticle heterogeneities, the data also reveal important interparticle heterogeneities which have often been overlooked so far.

# Heterogeneous catalysts under pressure

Jeroen A. van Bokhoven[1,2]

[1]*ETHzurich, Zurich, Switzerland*
[2]*Paul Scherrer Institute, Villigen, Switzerland*
[*]*j.a.vanbokhoven@chem.ethz.ch / jeroen.vanbokhoven@psi.ch*

**Keywords:** heterogeneous catalysis, characterization, pressure gap, materials gap

**Introduction.**

The continued quest for novel and better catalysts is helped by providing an understanding of the relationship between structure and properties. The obvious difficulties to obtain such relationships are, on the one hand, the complexity of the heterogeneous catalyst and, on the other, the demanding conditions under which catalytic reactions are performed. One understandable approach is to make use of model systems and to employ milder reaction conditions. Oppositely, doing so may lead to erroneous conclusions when extrapolating results to actual catalysts and conditions.
Methanol synthesis from synthesis gas is done over archetype $Cu/ZnO/Al_2O_3$ catalyst, the structure of which is debated since decades. There is renewed interest in the catalyst, given its activity in methanol synthesis from carbon dioxide and renewable hydrogen. Such green route with methanol as intermediate towards fuels and chemicals may play a future role in chemicals and fuels production. There are multiple catalytic functions that the catalyst must fulfill. Through characterization at various pressures, a very complex relationship between catalyst structure and condition is identified.

**Experimental/methodology.**

Through systematically varying the pressure of hydrogen on the one hand and of $CO_2/H_2$ mixtures on the other, the complex interplay between structure and pressure is identified. The combination of high-pressure isotope exchange experiments, joint by simultaneous infrared spectroscopy, and operando XAS at the Cu and Zn K edges, the reaction mechanism and its relation to catalyst structure emerge.

**Results and discussion.**

The conditions at which alloy formation occurs are identified, as well as the roles of surface adsorbates and the structures that copper and zinc adopt under various conditions. Based on these data will activity - performance relations be drawn. In addition, including simple considerations the limitations of such conclusions will be discussed, which will be positioned into a general perspective to what extend we have achieved actual understanding of functioning heterogeneous catalysts.

# Catalysis for sustainable chemical production

A. Kirilin[1]

[1]*Dow Benelux B.V., Corporate R&D, Terneuzen, the Netherlands*
*akirilin@dow.com*

**Introduction.**

Climate changes, energy and feedstock cost and availability are among major global challenges that are vital to our society. The chemical industry is at the front end of innovation [1] to develop more sustainable, energy efficient and cost competitive solutions [2] with purpose to meet ambitious recycling, circularity and decarbonization goals and deliver a sustainable future for the world.

Catalysis plays a critical role in enabling chemical transformations that otherwise would not be possible. Catalytic technologies can provide energy advantaged solutions with reduced $CO_2$-footprint compared to non-catalytic routes.

**Results/Discussion.**

To illustrate the role and importance of heterogeneous catalysis and innovation in the industrial sector, two examples of catalytic chemistries will be discussed. The first example is the use of synthesis gas (mixture of CO and $H_2$) as versatile platform enabling use of recycled carbon for the production of feedstocks and platform chemicals (ethylene, propylene) via catalytic routes. In particular, a hybrid catalyst approach for syngas conversion will be highlighted. Hybrid catalysts comprise a mixed metal oxide (MMO) and a zeolite component that are working in tandem. The aspects of rational catalyst design with respect to catalyst selectivity and stability will be discussed [3].

Another example covers a novel route for synthesis of methyl propionate (MP), an important chemical used as solvent, additive in coatings and used in production of other industrial chemicals. One of the commercial technologies to produce MP today is liquid phase process that uses a homogeneous palladium-based catalyst. Use of expensive homogeneous catalysts, need for handling and purification of solvent as well as separation costs make the overall process energy intense.

Dow has envisioned a more sustainable and energy efficient route for methyl propionate production based on C2 feedstock platform in a gas-phase process using a heterogeneous catalysis. A single-step transformation of ethylene, CO and methanol directly to methyl propionate is enabled thru metal sulfide catalysts [4] without a need to use noble metals. A combination of catalytic approach, high selectivity to target product and ability to efficiently recycle unconverted feedstock results in reduction of energy intensity and increase in overall process efficiency compared to the traditional Pd homogeneous catalytic process.

# Electrophotocatalysis: Combining Light and Electricity to Promote Reactions

T. H. Lambert[1*]

[1]*Cornell University, Ithaca, NY, USA*
[*]*tristan.lambert@cornell.edu*

**Keywords:** electrophotocatalysis, photocatalysis, electrochemistry

**Introduction.** Visible light photocatalysis and electrocatalysis have emerged as two prominent approaches for driving chemical reactions. However, the combination of these modalities, known as electrophotocatalysis, has remained relatively unexplored until recently. In the past few years, a growing number of studies have showcased the immense potential of harnessing both light and electrical energy to enable novel catalytic transformations. Electrophotocatalysis eliminates the need for large amounts of chemical oxidants or reductants by utilizing an electrochemical potential as an electron source or sink, thereby enabling efficient photoredox reactions. In addition, electrophotocatalysis also readily enables the use of open-shell photocatalysts, which typically possess very high redox potentials, leading to powerful redox reactions under mild conditions. This lecture will describe some of our work in the area of electrophotocatalysis, especially using trisaminocyclopropenium (TAC) ions.

**Experimental/methodology.** We have shown that a trisaminocyclopropenium ion ($TAC^+$) can serve as a powerful oxidative electrophotocatalyst.[1] Mechanistically, the TAC cation ($TAC^+$) can be oxidized at a relatively low anodic potential (1.26 V vs. Standard Calomel Electrode, SCE) to produce the deep red TAC radical dication ($TAC^{\bullet 2+}$). When photoexcited, this species becomes a powerful oxidant ($TAC^{\bullet 2+*}$, 3.33 V vs. SCE). Thus, irradiation of an electrochemical cell containing $TAC^+$ can oxidize even poorly reactive substrates via single electron transfer (SET) to generate the corresponding radical cations, which are highly reactive intermediates that can lead to a number of advantageous reaction outcomes.

**Results and discussion.** TAC electrophotocatalysis has enabled a range of transformations, including the oxidative functionalization of unactivated arenes, the regioselective derivatization of ethers, C–H aminations, vicinal C–H diaminations and dioxygenations, olefin dioxygenations and aminooxygenations, and carbonyl olefinations. These results, along with insights into catalyst stability and operation, will be discussed.

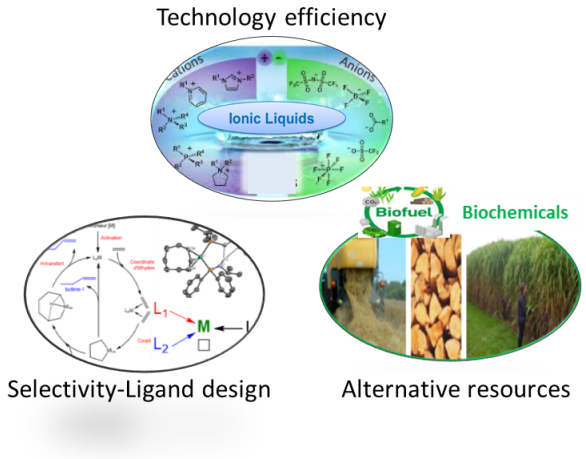
# Adventure in Homogeneous catalysis : from laboratory to industrial applications



Hélène Olivier-Bourbigou

IFP Energies nouvelles, 1&4 Avenue de Bois-Préau, 92852 Rueil-Malmaison, France
*helene.olivier-bourbigou@ifpen.fr*

**Keywords:** petrochemistry, ionic liquids, biomass conversion

Petrochemistry is an essential part of the chemical industry today. The production of petrochemicals and their derivatives which are integral to modern societies and found in many parts of the modern energy system, absorbs an increasing proportion of the world's oil and gas (approximately 14%) with a global demand growth faster than oil's. What could be the research and innovation contribution to make petrochemistry more sustainable ?

In this context, the presentation will particularly focus on 3 parts. The first one will concern the technology efficiency. The development of ionic liquids will be discussed for olefin transformation (metal-catalyzed and acid-catalyzed oligomerization and hydroformylation) with new developments of catalytic systems that bridge the gap between homogeneous and heterogeneous catalysis [1]. The second part will focus on how to improve feedstock efficiency in increasing selectivity for the production of on-purpose alpha-olefins with ligand oriented catalyst design approach [2-3]. In the third part we will outline the possible alternatives to fossil resource for the production of fuels and chemicals [4]. Non-edible biomass chemistry is considered to represent a realistic option with bio-ethanol as an interesting platform molecule that can bridge the gap between biomass fuel production and traditional petrochemical engineering.

**Keywords:** catalysis, high throughput experimentation, artifical intelligence, sustainability

Catalysis plays a crucial role as core technology in helping achieve the United Nations' sustainability goals, particularly in reducing greenhouse gas emissions, integration of secondary biomass and promoting recycling of various waste forms. This is because catalysts can help improve the efficiency of chemical processes, reducing energy consumption and emissions of greenhouse gases such as carbon dioxide, methane, and nitrogen oxides and therefore promote circular economy. Additionally, catalysts can be used to convert greenhouse gases into valuable chemicals, helping to remove them from the atmosphere.

A massive change is at the horizon for development workflows in catalysis, which is in at large driven by the availability of Big Data in catalysis in harmonized formats and the ability to analyze these data and to predict system behavior down to the molecular scale.

Development workflows in the field of catalysis are likely to evolve in the future in several ways:

-Increased use of artificial intelligence (AI) and machine learning in predicting behavior on molecular scale for materials and molecules: AI and machine learning algorithms will play an increasingly important role in catalyst discovery, optimization, and design, automating many tedious and time-consuming tasks. AI

-Integration of computational simulations: Computational simulations, particularly high throughput simulation augmented by AI, will therefore become increasingly integrated into development workflows, allowing for the prediction and optimization of catalytic behavior before synthesis and experimentation. Simulation results can easily be democratized and shared. A culture of sharing is also already better embedded in the community of practice in the field of theoretical chemistry.

-High-throughput experimentation plays an increasingly pivotal role in these development cycles: hte methods are becoming more widespread, enabling the rapid screening of large numbers of catalysts and reaction conditions and will be the most valuable resource of trusted experimental data – available as Big Data.

Several approaches which can lead to new materials using Big Data generation and analysis and high precision modelling and prediction will be presented and discussed in this lecture.[1]

[1] This text has been generated using AI based methods with minimal human curation exercise and editing. This exercise has been concluded within the framework on an internal project around the topic “AI in Chemistry”. The presentation of the result seeks not to offend the organizers and participants of the conference but should be seen as a general view on where AI in Chemistry stands today.

# On the structural sensitivity of platinum electrocatalysts

Federico Calle-Vallejo[1,2,*]

[1] *Nano-Bio Spectroscopy Group and European Theoretical Spectroscopy Facility (ETSF), Department of Polymers and Advanced Materials: Physics, Chemistry and Technology, University of the Basque Country UPV/EHU, Av. Tolosa 72, 20018 San Sebastián, Spain.*
[2] *IKERBASQUE, Basque Foundation for Science, Plaza de Euskadi 5, 48009.*

*federico.calle@ehu.es*

**Keywords:** platinum, generalized coordination numbers, coordination-activity plots, selectivity maps.

**Introduction.** Simultaneously, platinum is one of the scarcest and most promising electrocatalysts for several reactions of industrial and technological interest, which calls for the design of optimal Pt electrocatalysts. To do so, the most active sites for each reaction ought to be unambiguously determined and exploited. A computational tool for that purpose are "generalized coordination numbers" (GCNs).

**Results and discussion.** In my talk, I will first show that GCNs are able to describe adsorption-energy trends for unstrained Pt sites on extended surfaces and nanoparticles of different shapes and sizes with higher accuracy than conventional descriptors.[1, 2]

Subsequently, I will illustrate the use of "coordination-activity plots" based on GCNs to outline the geometric configuration of optimal Pt sites for three important reactions: oxygen reduction,[3, 4] CO oxidation,[5] and hydrogen evolution.[6] Besides, GCNs can be used to elaborate selectivity maps that help rationalize the intriguing selectivity of acetone electroreduction depending on the structure of Pt electrodes.[7]

Finally, I will show that GCNs and the plots based upon them can be extended to strained Pt electrodes,[8] Pt alloys[9] and other transition metal catalysts.[3, 10, 11]

## Pressure and temperature dependence of metallic zinc and partially reduced zinc oxide formation in copper-zinc-alumina catalysts – Limits of X-ray spectroscopy

A. Beck[1,2], M. Zabilskiy[3], M. A. Newton[2], O. Safonova[3], M. G. Willinger[2]*, J. A. van Bokhoven[2, 3]*

[1]University of California, Santa Barbara [2]ETH Zürich, [3]Paul Scherrer Institute

Rational catalyst design requires understanding of the structure of the catalyst in its working state. Such understanding is made possible by *in situ* and *operando* characterization. The wealth of new insights that these methods provide into catalysis has, at the same time, created numerous strong controversies and often studies on the same catalytic system have reported contradictory results. A prime example for such a system are Copper-zinc-alumina (CZA) catalysts:

CZA catalysts are the industrially-used formulation for methanol synthesis from carbon monoxide and carbon dioxide. The superior performance develops from synergies between its components. This important catalytic system has been intensively investigated, however, no comprehensive agreement has emerged as to the fundamental source of its high activity. One potential source of the disagreements is the considerable variation in pressure used in studies to understand a process that is industrially performed at pressures above 20 bar. Here, a systematic X-ray absorption spectroscopy study of the catalyst state during temperature-programmed reduction and under carbon dioxide hydrogenation is presented. The evolution of the catalyst over four orders of magnitude in pressure (1 mbar – 10 bar) shows how the state is defined by its environment [1,2,3]. In the light of the new systematic findings, existing controversies on the copper-zinc-alumina catalysts can be explained by considering the pressure regimes under which many previous studies have been conducted. Secondly, the talks shines light on the difficulty to differentiate between two central species using X-ray absorption spectroscopy, which debated for the reaction mechanism: the formation of a copper-zinc alloy containing metallic zinc and oxygen vacancy rich – partially reduced – zinc oxide.

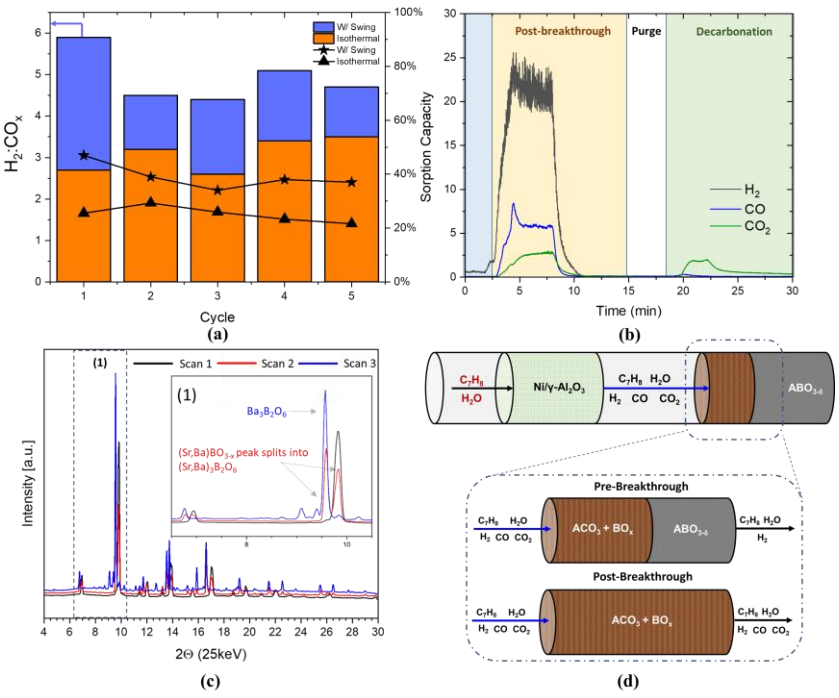
# Biomass to chemicals and fuels

# Sorption-enhanced steam reforming of toluene using multifunctional perovskite phase transition sorbents in a chemical looping scheme



L. Brody[1], R. Cai[1], M. Rukh[1], K. Yang[1], M. Bekheet[2], S. Praetz[2],

[*]*fli5@ncsu.edu*

**Introduction.** Sorption-enhanced steam reforming of toluene using catalytic $CO_2$ sorbents is a promising route to convert the aromatic tar compounds found in lignocellulosic biomass into hydrogen ($H_2$) or $H_2$-rich syngas. Commonly used sorbents are effective at capturing $CO_2$ initially but are prone to lose their sorption capacity (mole of $CO_2$/mole sorbent) over repeated cycles due to sintering at reaction temperatures. Herein, we present a demonstration of sorption-enhanced steam reforming of toluene using A- and B-site doped $Sr_{1-x}A'xFe_{1-y}B'_yO_{3-\delta}$ (A' = Ba, Ca; B' = Co) perovskites in a chemical looping scheme.

**Experimental/methodology.** The perovskite PTSs were synthesized using a modified Pechini method. Wet impregnation was used to introduce Ni to the surface. Redox catalysts' surface and bulk characterizations were conducted with XRD, XAS/XANES, XPS, and TGA. Reactive performance testing was conducted in a fixed bed quartz U-tube reactor containing 1.0 g of PTS (and 0.3 g of commercial NiO/ γ-$Al_2O_3$ when the sequential configuration was adopted) with liquid feeds controlled by programmable syringe pumps and gases delivered via a panel with automated cyclic valve switching. Mass spectrometry (MS) was employed to quantify conversion and sorption capacities. Additionally, two sorbents with different observed soprtion capacities were analyzed using synchrotron *in-situ* powder XRD analysis.

**Results and discussion.** We have extended the use of A-and B-site doped perovskite oxides to SESR of toluene under isothermal reaction conditions, both as stand-alone multifunctional catalytic sorbents as well as in a sequential packed bed configuration downstream of a commercial Ni-based catalyst (Ni/γ-$Al_2O_3$). We found that initial attempts to make an all-in-one multifunctional material via surface impregnation of 5-10 mol% Ni on the perovskite PTS succeeded in increasing activity for toluene conversion but is not a long-term solution due to undesirable Ni migration into the bulk as revealed by XRD analysis and Rietveld refinement. We solved this issue by adopting a sequential bed configuration with NiO/γ-$Al_2O_3$ upstream of $Sr_{0.25}Ba_{0.75}Fe_{0.375}Co_{0.625}O_{3-\delta}$ (SBFC-2635) and compared performance results for both isothermal and thermal swing experiments. While SESR was achieved isothermally for this material, the best results occurred when a 100 °C thermal swing was deployed, resulting in an average sorption capacity of ~38% and $H_2$:$CO_x$ > 4.0 across five cycles. Additionally, the *in-situ* XRD patterns revealed a complex series of solid-state reactions that proceed once the sorbents are reduced and carbonated.

**(a) Sequential bed results for isothermal and thermal swing; (b) MS profile detailing the chemical looping SESR cycle; (c) in-situ XRD patterns detailing rapid phase transitions during reduction/carbonation; and (d) a schematic of the sequential bed detailing pre-breakthrough phenomenon.**

# Vanadium-based catalysts for the sustainable production of formic acid from glucose

Débora Álvarez, Maria Isabel Dominguez Leal, Marcela Martínez T, S. Ivanova, Miguel Angel Centeno*

Instituto de Ciencias de Materiales de Sevilla, Centro mixto CSIC- Universidad de Sevilla, Avda. Americo Vespucio 49, 41092 Sevilla, Spain

**Keywords:** formic acid, glucose, biomass

**Introduction.**

Hydrogen is the most promising energy vector able to participate in the green future in which fossil fuels are not involved. However, the difficulty and cost of its storage and transportation, limits its effective implantation. The use of formic acid as liquid organic hydrogen carrier can help to solve these drawbacks. The commercial industial production of formic acid is based on the CO reaction with methanol to produce methyl formate which is later hydrolyzed to formic acid, and CO is normally produced from coal or natural gas. Then, more sustainable and green routes for formic acid production are mandatory to be developed and one of them is the catalytic oxidation of residual biomass.

In this work, the catalytic performance of a series of $V_2O_5/TiO_2$ catalysts in the oxidation of glucose, as molecule representative of the cellulosic biomass, is evaluated.

**Experimental/methodology.**

$V_2O_5/TiO_2$ catalysts were prepared by wet impregnation and calcined at 450°C, starting from $VOSO_4$ and Titania P25. For the reaction, 400 mg of glucose dissolved in 20 mL water were introduced in presence of catalysts in a Parr reactor under pressure using $O_2$ as oxidant. The liquid products were analysed by HPLC. The influence of the catalyst charge (100-400 mg), time, temperature (100-170°C) and $O_2$ pressure (20-30 bar) was studied. All catalysts were characterized by TPR, XRD, UV-Vis, SEM, Raman and XPS.

**Results and discussion.**

All synthesized catalysts are able to produce formic acid as major liquid product. Fructose, produced by glucose isomerization, and traces of lactic, glycolic and acetic acids were also detected. Total glucose conversion and formic acid yields up to 45% were achieved when high reaction times and/or high temperatures were applied. However, incomplete carbon balances occur in these cases, pointing to the production of gaseous $CO_2$. The use of mild temperatures drives to lower formic acid yields (around 10%) but with total selectivity to formic acid. Concerning the catalysts, best results are obtained with those with the theoretical monolayer of vanadium species on the titania support, pointing out the importance of the nature of the surface vanadium species on the catalytic properties. Moreover, monolayer vanadium species are the most interacting with the titania surface, minimising the lixiviation of the active phase during the catalytic reaction.

**Keywords:** acetaldehyde, ethanol, selective oxidation, pillared clay, vanadium catalysts.

**Introduction.** Acetaldehyde (AcH) is an industrially important solvent and an intermediate for the synthesis of a wide range of organic compounds [1]. Gas phase catalytic oxidation of ethanol (EtOH) from biomass by molecular oxygen (from air) is an economical and environmentally friendly process to produce it. Supported transition metal oxide catalysts, notably those of V, are effective for this reaction, but their perfomance depend on good oxide dispersion, that requires high specific surface area (SSA) supports. For instance, MCM-41 as support is efficient for this purpose [2], but its synthesis requires expensive reagents and generates wastes. Natural clays are an interesting alternative due to their low cost, great availability in nature, and ease to modify their properties by simple procedures. As the dispersion and nature of the supported V species depends on the nature of the support surface, we explored the use of titania pillaring to get efficient catalysts for this reaction, and investigated the effect of V content on their performance.

**Experimental/methodology.** The starting support (Ti-PILC) was synthetized from an Argentinian bentonite, that was purified and pillared by exchange with an acid $Ti(OBu)_4$ pillaring solution. Catalysts x%V/Ti-PILC (x=0.5-2 wt.% V) were prepared by wet impregnation, drying at 100ºC and calcination in air (450ºC, 3h) and characterized by BET, XRD, ICP-OES, Raman and DR UV-Vis spectroscopies and XPS methods. They were tested for EtOH selective oxidation in a fixed-bed continuous flow reactor (250-350ºC, W/F=1.55 $g_{cat}$.h/mol EtOH, EtOH:$O_2$=1) with on line analysis of reactants and products by GC.

**Results and discussion.** XRD showed the loss of regularity of the laminated structure of the Ti-PILC during catalyst synthesis and no peaks related to $V_2O_5$ phase, pointing to high V dispersion, which was confirmed by XPS. Though SSA of Ti-PILC decreased progresively with increasing V loading, all catalysts kept similar mesoporosity and high SSA (≥87 $m^2/g$). XPS spectra showed the V $2p_{3/2}$ peak for catalysts with V content >0.75 % wt. Its intensity increased with the V loading but with no shift the peak BE. The peak was composed by two contributions at 517.3 and 516.5 eV assigned to $V^{5+}$ and $V^{4+}$ respectively, with a ratio $V^{5+}/V^{4+}$>1 in all cases. All catalysts were active and very selective in EtOH oxidation. EtOH conversion increased with increasing V content and temperature, with a maximum of 87% at 350 ºC on 2%V/Ti-PILC, with 82% AcH selectivity. However, for all temperatures, productivity per V atom increased up to 1 wt.% V (equivalent to *ca.* 1 V atom/$nm^2$), with no change with the further increase of V content. Such V surface density is close to the reported value for the monolayer [3], which could indicate that most of the additional V content in the 2 wt.% V sample forms V oxide agglomerates, thus inhibiting their accessibility to the substrate.

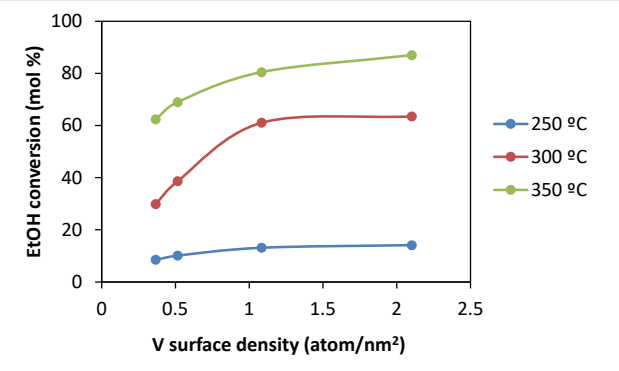

**Figure 1. Effect of V surface density on EtOH conversion**

**Keywords:** glucose, fructose, solid base, leaching, salt effect, solvent

Transition from fossil feedstocks to renewable resources is accompanied by an increasing importance of heterogeneous catalysis in liquid phase. Design of heterogeneously catalyzed processes for liquid-phase transformations is hampered by the significantly less developed knowledge on processes at liquid-solid interfaces than understanding the widely used in petrochemistry solid-gas reactions. In this work, isomerization of D-glucose into D-fructose was considered focusing on influence of leached species, solvent, catalyst nature, and electrolytes onto reaction rate and selectivity.

The reactions were performed in batch reactors in the temperature range of 40 to 110 °C. Solid bases, such as MgO, CaO, SrO, $Ba(OH)_2$, $Li_2CO_3$, $MgCO_3$, $CaCO_3$, $SrCO_3$, $BaCO_3$, $Li_3PO_4$, $Mg_3(PO_4)_2$, and Mg-Al hydrotalcites, were tested as catalysts. NaOH was applied as a soluble reference catalyst at constant pH values in the range of 9.5 to 11.5. Molecular amines, such as triethylamine or TBD, were tested under similar conditions for isomerization of fructose in various solvents, such as water, MeOH, DMF, and DMSO.

We explored contribution of leached $OH^-$ species into catalysis of glucose-fructose isomerization by solid bases. The hydroxide ions are generated *in situ* through partial dissolution of bases with low solubility. Plotting initial rate of isomerization against concentration of $OH^-$ in logarithmic scale suggested catalysis by leached $OH^-$ species. Our studies indicate a limited applicability of a frequently used "filtration test" or a "contact test" to estimate contribution of homogeneous catalysis to the isomerization catalyzed by solid bases. Kinetic studies coupled with monitoring the concentrations of leached $OH^-$ and metal ions proved to be significantly more informative. Interestingly, catalyst composition influences the product selectivity. For instance, improved selectivity for fructose was observed for catalysis by Mg-Al hydrotalcites or $MgCO_3$.[1, 2]

We observed a significant acceleration of the isomerization rate, up to x6, in the presence of soluble neutral salts, such as NaCl or $Na_2SO_4$. The salt effect was observed in the presence of soluble base NaOH as well as solid catalysts $Li_3PO_4$, MgO, and Mg-Al hydrotalcites. We found out that the observed salt effect is caused by a dependency of a thermodynamic acidity constant of glucose on concentration of electrolytes.[3]

Solvent nature impacts isomerization selectivity. Thus, conversion of fructose in the presence of amines gives rise to glucose in water and to allulose in DMSO or DMF. The selectivities are in good correlation with the concentrations of the tautomers, suggesting fructopyranose as substrate for formation of glucose and fructofuranose as substrate for allulose. Thus, changes in tautomeric equilibrium for different solvents result in change of selectivities.[4]

In summary, our results on base-catalyzed isomerization of glucose and fructose suggest that catalysis on the liquid-solid interface presents a complex phenomenon with contributions of catalyst nature, leached species, solvent, and electrolytes.[5]

# Efficient conversion of polysaccharides to glucose in water using a heterogeneous ionic polymer catalyst

K. A. Abhyankar[1], R. J. Somerville[1], F. Fadei Tirani[1], Z. Fei[1] and P. J. Dyson[1]*

[1]*Institut des Sciences et Ingénierie Chimiques, Ecole Polytechnique Fédérale de Lausanne (EPFL), 1015 Lausanne, Switzerland*

**Keywords:** biomass valorisation, polysaccharide hydrolysis, ionic polymer, solid acid

**Introduction.** Catalytic polysaccharide hydrolysis is a key step in the valorisation of cellulosic and starchy biomass, as glucose is a key intermediate in potential biorefineries[1] for the production of fuels and platform chemicals (e.g. dimethylfuran, levulinic acid, γ-valerolactone)[2]. Carrying out this hydrolysis with heterogeneous catalysis in water is desirable as it improves catalyst separation and avoids organic solvents. We report the systematic design of vinylimidazolium salts containing pendant carboxylic acid groups and their use in cellulose and starch depolymerisation in water. The most promising vinylimidazolium salt was polymerised resulting in a cross-linked weakly acidic polymer network that heterogeneously catalyses starch depolymerisation to glucose in water.

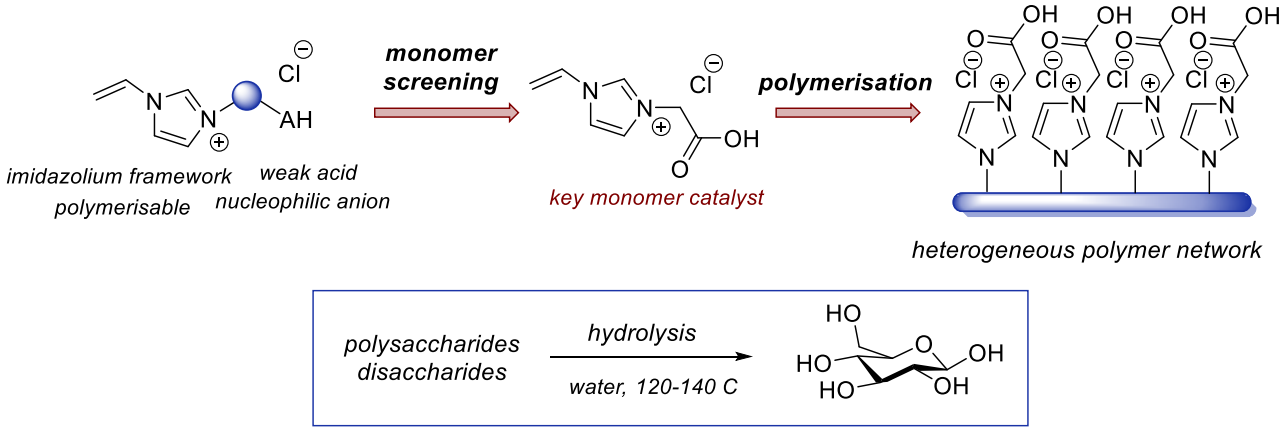

**Figure 1: Design of weakly acidic ionic polymer for polysaccharide hydrolyis**

**Experimental/methodology.** The series of vinylimidazolium monomers was screened against the model compounds cellobiose and maltose (which are homogeneous models of cellulose and starch, respectively). Glucose was quantified by HPLC-RID. The most effective monomer was next tested against polysaccharides cellulose and starch. This monomer was then polymerised to create a cross-linked insoluble acidic polymer network for the heterogeneous cleavage of saccharides. The heterogeneity of the polymer catalyst and the hydrothermal stability of the polymer was investigated and humins deposition onto the polymer surface proposed as a possible catalyst poisoning pathway. Monomer catalysts were characterised by NMR spectroscopy, mass spectrometry and X-ray crystallography. The polymer catalyst was catalysed by solid state NMR spectroscopy, differential scanning calorimetry, and thermogravimetric analysis.

**Results and discussion.** With the most active monomer, good yields of glucose were obtained from model saccharides, cellulose, and potato starch. Subsequent polymerisation resulted in a heterogeneous ionic polymer catalyst which was active for the conversion of model saccharides and potato starch to glucose in water. Gratifyingly, the yields obtained with the polymer catalyst mirrored those obtained with the monomer catalyst in most cases and were obtained in water at relatively mild temperatures (120 –140 °C). Importantly, catalysis with the polymer network was found to be heterogeneous and the catalyst remains active even at low (1:10 catalyst:potato starch, by mass) loadings.

**Keywords: lignocellulose fractionation, lignin depolymerization, RCF, magnetic catalyst**

**Introduction.** Fractionation of lignocellulosic biomasses is an essential step for biorefinery strategies to isolate and fully exploit cellulose, hemicellulose and lignin for the production of materials, fuels and chemicals[1]. Conventional pre-treatments usually involve loss of mass or functionalities due to the different effects of process conditions on different structural components. In particular, lignin faces irreversible structural modification because of the lability of ether linkages (C-O-C), and re-condensation reactions of unstable intermediates (i.e. aldehydes) forming novel C-C bonds which confer higher recalcitrance to the "processed" lignin structure leaving few prospective of valorisation[2]. One of the most promising strategies aimed to the valorisation of the lignin fraction is based on the extraction, depolymerisation and simultaneous stabilisation of lignin fragments towards the production of low molecular weight lignin oil through the so called Reductive Catalytic Fractionation (RCF)[3]. RCF is a catalyst dependant process capable of producing phenolic compounds and lignin oils while preserving the carbohydratic pulp in the presence of a reducing agent, generally hydrogen[4]. Noble metal catalysts supported over active carbons were found to be active for the target process; however, one major issue, often underestimated, is represented by the inefficient catalyst recovery from the fibrous cellulose solid pulp which limits catalyst recyclability thus impacting the economic sustainability of the entire process[5].

**Experimental/methodology.** Catalytic tests were performed in a batch reactor (autoclave) loading either raw poplar wood or an actual urban pruning waste residue, with the desired amount of catalyst and a binary water/1-butanol mixture already known to be efficient for the extraction of lignin as well as for the simplification of the downstream separation procedures (i.e. hemicellulose polyols retained in water phase while lignin derived products are readily solubilized in butanol)[6]. An innovative Ru/γ-$Fe_2O_3$ was synthesized via Incipient Wetness Impregnation of a commercial magnetite and calcination at 400°C.

**Results and discussion.** Considering all the problems described in the introduction section, we developed a novel magnetic catalyst based on 5wt% Ru/γ-$Fe_2O_3$ active for RCF and easily recoverable through the application of an external magnetic field with high recovery yield (around 90%). In particular, we focus on the comparison between our catalytic system and a commercial 5wt% Ru/C catalyst in terms of delignification of cellulose, lignin oil yield and catalyst recovery. The magnetic catalyst is characterized by lower surface area compared to Ru/C, this feature probably affecting Ru dispersion finally limiting lignin depolymerisation efficiency to monomers (i.e. phenolics), nonetheless we were able to get both higher cellulose delignification and lignin oil yield. Furthermore, preliminary recyclability test have proven the stability of our catalyst for at least 3 cycles of reaction. This catalyst shows great potential thanks to its good stability and recyclability, its ability to produce high quality cellulose pulp together with relatively low MW lignin oil without affecting the economic sustainability of the process. Future work will be devoted to the improvement of the phenolic monomers yield as well.

**Keywords:** chitin, oligosaccharides, carbon catalyst, depolymerization, hydrolysis

**Introduction.** Chitin-oligosaccharides, trimer to hexamer of *N*-acetylglucosamine (NAG), can activate the immune systems of plants as biostimulants, and the oligosaccharides may facilitate the growth of plants. However, the oligosaccharides are in short supply, because their selective synthesis is difficult. We have been studying the depolymerization of chitin to NAG and conversion of NAG to organonitrogen compounds [1-4]. Herein, we demonstrate the selective synthesis of chitin-oligosaccharides from chitin over a carbon-based solid catalyst named AC-Air (Equation). Using a planetary ball-mill, weak acid sites on the catalyst show high activity toward the hydrolysis of chitin to the oligosaccharides [5].

**Experimental/methodology.** AC-Air was prepared by heating steam-activated carbon (AC) in air at 425 °C for 10 h. Chitin powder was milled with a catalyst for 12 h with alumina balls in an alumina pot at 500 rpm by a planetary mill. After the milling process, the products were analyzed by HPLC.

**Results and discussion.** We observed high activity of AC-Air in the hydrolysis of chitin in a planetary milling system, in which the selectivity for the chitin-oligosaccharides reached over 90% (Table 1). As shown in entry 1, the non-catalytic reaction gave low yields of NAG and the oligosaccharides in 12 h. AC-Air increased yields of NAG to 2.8 %C and oligosaccharides to 32 %C (entry 2). The selectivity for oligosaccharides was as high as 94%. The oligomer fraction contained not only dimer (4.7 %C) but also larger oligomers (trimer 5.9%C, tetramer 6.5 %C, pentamer 5.2 %C, hexamer and larger 9.7%C). Notably, this reaction produced no acetic acid, indicating no hydrolysis of the amide groups in chitin. This feature is in sharp contrast to aqueous-phase reactions that hydrolyze both glycosidic and amide bonds. The yield of oligosaccharides increased to 66 %C by extending the reaction time to 48 h, while maintaining 92% selectivity (entry 3). The catalyst was reusable after washing with dilute HCl to remove the adsorbed amines originally contained in chitin. For comparison, we performed a mechanocatalytic hydrolysis of chitin with $H_2SO_4$ (entry 4). This reaction gave a 95% solubilization ratio and 62 %C yield of oligomers, but the selectivity for oligomers was only 65%. The by-product formation was verified by NMR analysis. We analyzed the time course of the mechanocatalytic hydrolysis, and applied Monte Carlo simulations that virtually hydrolyzed a chitin molecule. These results show that AC-Air can cleave glycosidic bonds of chitin molecules without influence of the molecular size. Consequently, the mechanocatalytic system can reduce the successive hydrolysis of small oligomers, thus giving a high yield and selectivity of oligosaccharides.

**Table 1. Mechanocatalytic hydrolysis of chitin with solid catalysts.**

| Entry | Catalyst | Yield of products /%C | | Solubilization ratio /% |
|---|---|---|---|---|
| | | NAG | Oligomers (Selectivity /%) | |
| 1 | - | 0.1 | 1.2 (15) | 8.2 |
| 2 | AC-Air | 2.8 | 32 (94) | 34 |
| 3 | AC-Air | 8.3 | 66 (92) | 72 |
| 4 | $H_2SO_4$ | 7.3 | 66 (65) | 95 |

**Keywords:** Catalytic upgrading - Biofuel – Ni(Mo)W Sulfide – NiMo Nitride – Ni Phosphide - GC×GC

**Introduction**

Global energy demand and environmental concerns about limiting $CO_2$ emissions and carbon footprint have been growing recently. In this context, fuel production from renewable resources has become a priority, especially for aviation. Among sustainable bio-resources, microalgae represent an attractive alternative to provide carbon molecules due to their fast-growing rate and the potential high lipid content. In addition, microalgae can be easily transformed into oil by the hydrothermal liquefaction (HTL) process. The microalgal oils still contain a large quantity of O-, N- or S- compounds that have to be reduced to be used as fuel. Particularly, the main components of HTL microalgal oil are the C16-C18 fatty acids issued from the lipids conversion during the HTL process. Those acids, in addition to other components like amides, alkenes, esters, or alcohols are not compatible with transport fuels and need to be upgraded to hydrocarbons. In this work, we propose catalytic upgrading, including deoxygenation, denitrogenation, and desulfurization of an HTL oil obtained from *Chlorella vulgaris* microalga [1] with various supported catalysts having hydroconversion ability.

**Experimental/methodology.** Supported catalysts ($Ni_2P/Al_2O_3$, $Ni_2P/SiO_2$, and $NiMoN/Al_2O_3$) were prepared on the various oxide supports following published works [2,3] and compared to benchmark sulfided catalysts ($NiW/Al_2O_3$, $NiMo/Al_2O_3$, $NiWS/SiO_2$-$Al_2O_3$). HTL oil of *C. vulgaris* was provided by CEA Liten. The catalytic tests were performed in a batch reactor under $H_2$ pressure. Typically, algal oil (3 g) was mixed with 0.6 g of supported catalyst in 25 g of heptane and heated under 1 MPa of $H_2$. When reaching the reaction temperature (375°C), the reactor was filled with $H_2$ to reach 10 MPa pressure. Afterward, the mixture was filtered to recover the catalyst, and the heptane was removed by evaporation.

**Results and discussion.** The main compounds in *C. vulgaris* HTL oil were the C16 (9.3 wt%) and C18 (24.2 wt%) fatty acids. During the upgrading, they were converted readily to the corresponding alkanes by hydrodeoxygenation (HDO) or decarboxylation/decarbonylation (DCO) [4]. The refractory compounds are fatty amides, nitriles, and the various heterocyclic nitrogen molecules coming from proteins. Supported $Ni_2P$ catalysts promoted the DCO route, while $NiMoN/Al_2O_3$ promoted the HDO pathway. Among sulfide catalysts, $NiWS/SiO_2$-$Al_2O_3$ showed low performances, probably due to the inhibition of acid sites by the nitrogen compounds of the bio-oil. Alumina-supported NiWS catalyst was the most performant solid for the studied reaction, producing a hydrotreated oil with the best higher heating value (HHV), the lowest aromaticity degree, and the lowest average molar mass. The most refractory remaining are cyclic nitrogen compounds such as indoles, pyrroles, and carbazoles. The biofuels obtained with the various catalysts fall mainly in the diesel and jet-fuel ranges as observed by SimDist. For instance, for $NiWS/Al_2O_3$ catalyst, 66 wt% of the liquid is recoverable as traditional fuels. Moreover, with this catalyst, a higher reaction temperature (400°C) allowed increasing the jet fuel and diesel fraction, reaching a total of 80 wt%. The screening of catalysts has thus revealed the alumina-supported NiWS catalysts as a robust and performant system to upgrade micro-algal oils into biofuels. The heavier fraction might be hydrocracked in a second step to obtain an even higher light fraction yield.

Lignin, one of the three major components of lignocellulosic biomass, is a cross-linked amorphous phenolic biopolymer that gives plants their structural strength and shape. It contains highly functionalised aromatic units that makes them a potential renewable and sustainable feedstock to produce aromatics and has the potential to replace fossil-fuel based feedstock in producing fuel and base chemicals.[1] To valorise lignin, it is crucial to break both the C – O and C – C inter unit linkages, to make biorefining economically viable and sustainable. Depending on the biomass, 25-34% of the inter-unit linkages are C – C linkages and they are more recalcitrant compared to the C – O inter-unit linkages. The bond dissociation energies of C – C and C – O linkages are 226 – 494 kJ $mol^{-1}$ and 209 – 348 kJ $mol^{-1}$ respectively. Consequently, most of the reported valorisation strategies focus on the cleavage of C – O linkages resulting into *ca.* 60 wt.% of un-valorised lignin fraction having predominantly C – C inter-unit linkages. Here we employ the ruthenium ion catalyzed oxidation (RICO) for the oxidative cleavage of the most recalcitrant C – C inter unit linkages found in lignin: the 5-5' bond linking two aromatic rings (BDE 481 – 494 kJ $mol^{-1}$). We use biphenyl and custom made model hemaxer for this study [Figures 1 & 2].[2] All the reactions were carried out in a glass flask at 295 K using a mixture of water and acetonitrile as the solvent. $RuCl_3$ was used as the Ru source and $NaIO_4$ was used as the oxidant and $RuO_4$ was generated *in situ* during this oxidative depolymerisation reaction. Qualitative and quantitative analyses of the reaction mixture were done using $^{1}H$, $^{13}C$ NMR spectroscopy methods along with GC-MS and Gel Permeation Chromatographic (GPC) methods. Advanced 2D NMR spectroscopic methods such as HSQC, HMBC and $^{31}P$ NMR spectroscopy after phosphitylation of the mixture were employed to quantitatively analyse the breaking of the β-5, 5-5' [Figure 2] and β-O-4 linkages and to identify the products. Density functional theory (DFT) with the hybrid B3LYP functionals were used to calculate energies of intermediates and transition states using the Gaussian09 package.

**Keywords:** $NH_3$/$SO_2$ adsorption microcalorimetry, acid-base sites, isopropanol dehydration, propylene

**Introduction.**

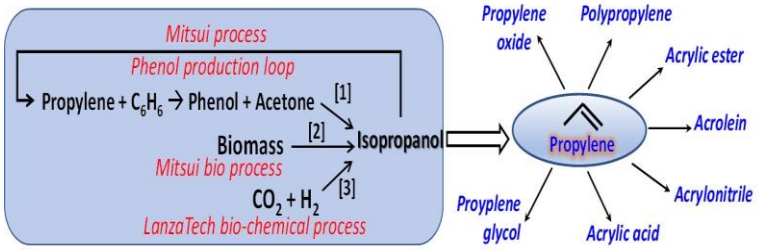

**Figure 1.** Novel isopropanol production routes and the commercial interest towards isopropanol dehydration to propylene

Propylene (PEN) is considered as a versatile building block in most of the petrochemical industries to produce valuable chemical intermediates such as polypropylene, acrylonitrile, acrolein, acrylic acid etc. Currently, PEN is primarily produced as a by-product during the ethylene in the naphtha steam crackers and fluid catalytic cracking (FCC) units, but also through MTO/MTP and metathesis. Considering the recent trends in the production of isopropanol using environmentally friendly processes, for *e.g.*, Mitsui and LanzaTech processes, the commercial propylene production from isopropanol dehydration is gaining more attention (see figure 1) [1-3]. Isopropanol (IPA) dehydration to propylene (PEN) is not new to the catalysis world but the formation of side products, particularly, di-isopropyl ether (DIPE) and acetone makes it still a tricky reaction that requires very fine catalysts tuning/selection criteria (amount and distribution of the active sites) in attaining polymer grade PEN.

**Results and discussion.** In this study, the adsorption microcalorimetry investigation using $NH_3$ and $SO_2$ probe molecules helped us to finely tune and classify different solids such as Alumina, Silica Alumina, Bentonite (clay type) etc. based on their acid-base properties (figure 2). The adsorption isotherms and their corresponding differential heats obtained for some of the selected solids revealed their entirely different acid/base behavior, *i.e.*, the alumina exhibiting amphoteric nature, the silica-alumina being predominantly acid with very low basicity and the bentonite possessing only acid sites (figure 2). The IPA dehydration was then performed to study the reaction kinetics and further to draw correlations between catalytic sites and reaction products. Correlations have been established between the ratio of acid to basic sites and the PEN/acetone formation. These correlations helped us to further optimize the catalysts and reaction conditions for attaining very high PEN selectivity. The high temperature and low pressures favored PEN while low temperature and high pressure resulted in the by-product DIPE [4]. However, too much increase in the temperature can result in the issues such as PEN polymerization and coking. Employing sufficiently high gas linear velocity and large pore catalysts can avoid the problems due to diffusion limitations [4].

# Furfural manufacture at high yield

J.-P. Lange
*Shell Global Solutions International B.V., Amsterdam, The Netherlands*
*Sustainable Process Technology, University of Twente, Enschede, The Netherlands*
*e-mail: jean-paul.lange@shell.com*

**Introduction.**
To mitigate climate change and decrease society's reliance on fossil resources, the industry must develop new routes to produce fuels and chemicals from renewable carbon resources. Some of them include furfural as platform molecule to valorize the ~20 wt.% xylose present in hard wood and grasses. Present furfural production processes valorize only half the xylose and use the rest of the biomass (85-90wt%) as energy source for powering the process. This lecture will present novel furfural manufacturing routes that promise high biomass utilization by extracting the xylose for furfural production and leaving the rest for alternative valorization options.

**Results.**
A first approach integrates biomass fractionation with biphasic xylose dehydration and recycling of the acidic aqueous phase [1]. The resulting furfural yield of ~70 mol% (based on xylose) can further be lifted to ~90 mol% by applying microwave heating and adjusting the medium composition [2].

A second approach integrates the biomass fractionation with novel two-step processes to produce furfural with 90% yield and low energy demand. This is achieved by selectively extracting the dilute xylose as boronate ester and, subsequently, dehydrating it to furfural either in a water-organic homogeneous phase or under biphasic saline conditions (Fig. 1, [3,4]). These process concepts are designed for efficient recycling of all components, i.e., the boronic acids, the organic solvents and/or the saline solution. Dedicated kinetic study assigned the high furfural selectivity to the balance between the rates of boronate hydrolysis and xylose dehydration [5].

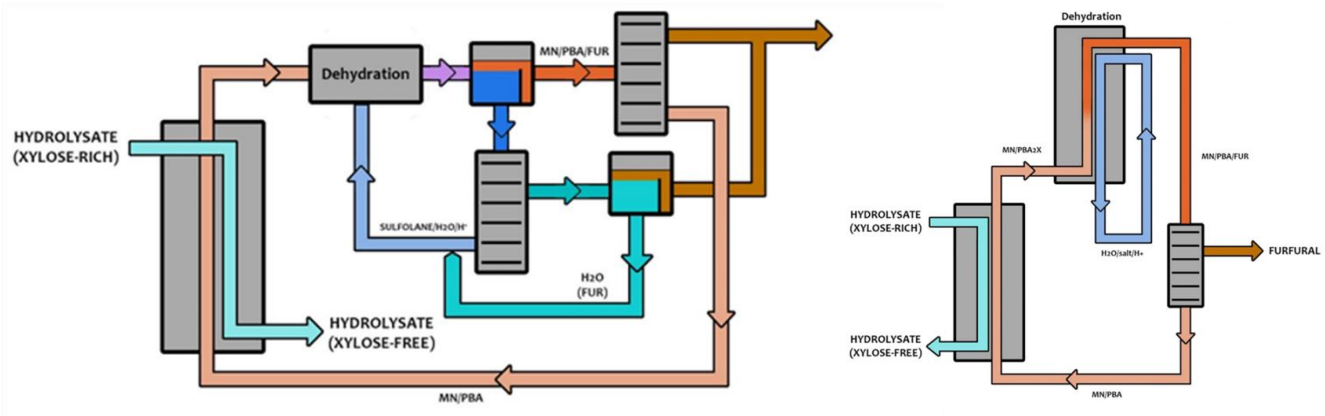

Figure 1. Process concepts for converting diluted Xylose hydrolysate to furfural with 90% selectivity, via extraction as boronate ester and subsequent dehydration in monophasic medium (left, [3]) or in biphasic saline medium (right, [4]).

**Introduction.** 5-hydroxymethylfurfural (HMF) derived from the lignocellulosic biomass feedstock is considered as a versatile platform molecule that can be converted into a wide span of desirable chemicals ranging from fuels to plastics. Among them, 2,5-dimethylfuran (DMF) and 2,5-dimethyltetrahydrofuran (DMTHF) are pivotal molecules of high value, with applications as biofuels or biofuel additives.

One of the most efficient metals in the hydrogenation and hydrogenolysis of many biomass-derived oxygenates is ruthenium, mainly owing to its outstanding performance that rely on the decrease of the energetic span of the reaction pathway in the presence of a protic solvent [1]. Its very high activity is however an obstacle for obtaining high selectivity, as it is a challenge to tune its properties in order to avoid overhydrogenation reactions or other secondary reactions.

**Methodology**. The $TiO_2$ supported Ru and Ru-Ni catalysts were prepared according to a solar light photon-assisted synthesis method [2] over a broad range of Ru:Ni ratios. Catalysts were characterized by numerous surface and bulk techniques including HRTEM, ToF-SIMS, XPS, XRD, TPR. Catalysts were tested in the liquid phase 5-hydroxymethylfurfural hydrodeoxygenation (30 bar $H_2$ in 160°C for 4 h).

**Results and discussion.**

Regardless of the Ru:Ni ratio in the bimetallic Ru-Ni/$TiO_2$ catalyst, the photon-assisted synthesis leads to small size Ru nanoparticles homogeneously dispersed at the surface of the $TiO_2$ support with a narrow particle size distribution, and no aggregates were observed. What is more, the presence of nickel favoured the reduction of the mean Ru nanoparticle size, that decreased from 1.1 nm for the monometallic Ru catalyst down to 0.6 nm for the bimetallic Ru-Ni catalysts. The Ru/$TiO_2$ reference catalyst led to moderate performances, with a HMF conversion and a DMF selectivity of 46% and 72%, respectively. We evidenced that the increase of the Ni/Ru bulk ratio favoured the HMF conversion, that reached 100% for a Ni/Ru molar ratio of 1.5. By contrast, the DMF selectivity pattern exhibited a volcano-like shape, with a maximum selectivity of 96% being achieved for a Ni/Ru molar ratio of 1.0. Thanks to this novel sustainable method, highly selective and stable Ru-Ni catalysts have been developed, with an activity that can be easily optimized through the tuning of the Ru:Ni ratio.

# Design of Aluminum Phosphate Catalysts for Selective Valorization of Biomass-derived Furfural

W. Fang[1], A. Riisager[1*]

[1]*Centre for Catalysis and Sustainable Chemistry, Department of Chemistry, Technical University of Denmark, Kgs. Lyngby, Denmark*
[*]*ar@kemi.dtu.dk*

**Introduction.** Furfural (FF) is a lignocellulosic biomass-derived precursor molecule, which can be converted into numerous value-added chemicals [1]. The aldehyde group of FF can undergo important transformations, including reduction, reductive etherification, acetalization, and aldol condensation (Figure 1). Aluminum phosphate (APO-5) is a zeotype material possessing an AFI structure with 12-membered rings with large pore size (7.3 Å) [2], which is suitable for conversion of FF [3]. Catalytically active sites (acidic sites) can be created in the theoretically neutral APO-5 structure by different routes and the resulting catalysts applied for various acid-catalysed reactions.

**Experimental/methodology.** APO-5 catalysts with different Al/P ratios were prepared by hydrothermal synthesis. Alkali earth metals (AEMs)-loaded and Zr-doped APO-5 catalysts were prepared by corresponding impregnation and isomorphous substitution.

**Results and discussion** Highly selective and durable APO-5 catalysts were designed for various valorization reactions of FF at mild conditions (i.e. 120-150 °C). As shown in Table 1, weakly acidic APO-5 (Al/P = 1) showed excellent catalytic performance for the acetalization of FF with ethylene glycol to obtain **1** due to co-catalysis of adsorptive and acidic sites [4]. More acidic APO-5 (Al/P = 1.5) catalyzed both catalytic transfer hydrogenation and subsequent etherification of FF in 2-propanol with good yield of **2** besides ring opening and hydrogenation products [5]. Introduction of alkali-earth metal oxides, e.g. calcium oxide, in Ca/APO-5 (Al/P = 1.5) allowed to modify the acidity and basicity of the catalyst, which improved the selectivity to hydrogenation product **3** and further suppressed side reactions, e.g. etherification, acetalization and ring opening reaction [5]. Furthermore, introduction of Zr into the framework enhanced the adsorption for C=O bond and created suitable acidic and basic sites, promoting the aldol condensation of FF with cyclohexanone to obtain **4** [6]. Notably, all the APO-5 catalysts also displayed high catalytic activity in the conversion of other bio-derived aldehydes.

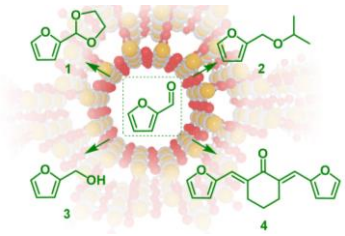

**Figure 1. Furfural valorization**

**Table 1. Furfural valorization with APO-5 catalysts**

| Catalyst | Acidity (mmol/g) | FF Conv. (%) | Product Yield (%) |
|---|---|---|---|
| APO-5 (Al/P = 1) | 0.001 | 97 | 96 (**1**) |
| APO-5 (Al/P = 1.5) | 0.40 | 95 | 55 (**2**) |
| Ca/APO-5 (Al/P = 1.5) | 0.25 | 97 | 90 (**3**) |
| ZrAPO-5 (Zr/Al/P = 0.2/1/1) | 0.52 | 99 | 79 (**4**) |

Overall, the work demonstrates a simple approach to design heterogeneous APO-5 catalyst systems for the efficient and highly selective valorization of biomass-derived FF to value-added chemicals.

**Keywords:** catalytic transfer hydrogenation, alkyl levulinates, ethanol, zirconia, continuos-flow, gas-phase

**Introduction.** Levulinic acid (LA) and its esters (LE) are important, polyfunctional molecules that can be obtained from lignocellulosic biomass through hydrolysis or alcoholysis respectively. The most applied strategy for their valorization is the chemical reduction toward valuable compounds (e.g. fuel additives and intermediates). Hydrogenations in the presence of high pressure molecular hydrogen has been widely investigated and, in most cases, leads to the effective and selective formation of γ-valerolactone (GVL), a promising, innovative, bio-based solvent and fuel additive.[1] Nonetheless, GVL may be obtained also through the catalytic transfer hydrogenation (CTH) of LA/LE, using alcohols as reducing agents for the carbonyl group. Most of the studies published for the CTH of LA and its esters have been performed in liquid phase using batch reactors, secondary alcohols (i.e. 2-propanol) as H-donor and $ZrO_2$ as heterogeneous catalyst.[2] However, very long reaction time and high autogenic pressures are needed in order to work in the liquid phase at high temperature with light alcohols. Recently, we reported on the possibility to enhance the CTH of alkyl levulinates with ethanol (and bio-ethanol) in a continuous-flow, fixed bed, gas-phase reactor using a relatively high-surface-area tetragonal $ZrO_2$. In this way, by working at 250°C and atmospheric pressure with a contact time of just one second over the catalyst, methyl levulinate (ML) was completely converted promoting GVL formation with yield up to 70%.[3,4] Unfortunately, our catalyst undergoes to a progressive deactivation, due to the deposition of heavy carbonaceous compounds over the Lewis acid sites, finally promoting unwanted alcoholysis and transesterification reactions. Therefore new efforts have been made to strongly limit the deactivation rate and push our selectivities beyond GVL, in this way trying to assess the versatility of this gas-phase, continuous-flow approach.

**Experimental/methodology.** Zr-based mixed oxides have been synthesised through co-precipitation or hydrothermal synthesis depending on the case. Catalytic tests have been performed in a fixed-bed, tubular glass reactor and the desired mixture of ML and ethanol has been continuously fed in a heated line together with nitrogen in order to obtain an instant vaporisation and mixing before the reaction section.

**Results and discussion.** We proved that the deactivation rate is strongly affected by the surface acid-base properties of the catalyst (sites strenght and density) and these can be effectively modulated either by changing zirconia crystalline phase, the monoclinic one being the most affected by deactivation, promptly promoting parasite oligomerization reactions of the intermediate angelica lactones and acetaldehyde, or by promoting the synthesis of Zr-based mixed oxides (e.g. by the inclusion of Ti or Si). The latter strategy allows us not only to improve catalyst stability but also enhance consecutive reactions on GVL toward the efficient production of C5 esters (e.g. ethyl pentenoates and ethyl pentanoate) with a minor contribution of C7 due to the inclusion of ethanol in the final molecule via aldol condensation.

**Keywords:** catalysis, supercritical ethanol, BTX, lignin, EXAFS

**Introduction.**

This study unveils the key structural features and compositional aspects of several molybdenum hemicarbide-based catalysts using a combination of synchrotron techniques, X-ray diffraction and elemental mapping in conjunction with electron microscopy [1] as well as their catalytic performance in the conversion of lignin to BTX using supercritical ethanol and base. [2]

**Experimental/methodology.**

The molybdenum hemicarbides as well as a molybdenum carbo-nitride composite material were prepared by thermal decomposition of a molybdenum–melamine polymer in the presence of titanium nitride at 650 °C under a reducing atmosphere. The catalytic reactions were performed in supercritical ethanol at between 280 and 330 °C and the samples anaylsed using a variety of spectrocopic and chromatographic techniques.

**Results and discussion.**

The composite was shown to be more effective than either $Mo_2C$ or $Mo_2N$ for the hydrodeoxygenation of lignin to single-ring arenes in supercritical ethanol. Extended X-ray absorption fine structure experiments at 330 °C, under a stream of ethanol vapor to approximate in situ conditions, elucidate the importance of the interaction of the titanium nitride support with the molybdenum carbo-nitride phase. The titanium nitride and molybdenum carbide phases are intimately mixed and, surprisingly, the result of the EXAFS analysis is consistent with the incorporation of terminal Mo≡N motifs.

Supported molybdenum hemicarbide catalysts were prepared and employed for the depolymerization and deoxygenation of waste lignins to aromatics in supercritical ethanol. Titanium nitride appears be a particularly beneficial support material. Depolymerization at 330 °C led to a higher yield and selectivity for arenes than at 280 °C. Base is essential for efficient substrate conversion: the basic constituents inherent in waste lignins are suitable, as is added sodium hydroxide. Without base, depolymerization is poor, the yield of aromatics is very low, and substrate defunctionalisation does not occur. A significant proportion of aromatic products is formed from supercritical ethanol itself, including benzene, which is likely to be present in all catalytic runs due to ethanol aromatization. Hence the total arene content produced is actually higher than has been widely reported. Catalytic cracking of ethanol leads to C1-units, which add to reaction intermediates to give aromatics containing odd numbers of carbons (e.g. toluene).

**Keywords:** Hydrodeoxygenation, dispersion, catalyst synthesis, biocrude, Jet-A1, BTX Biomass, zeolites, redox, acidity

**Introduction**

For small or negative carbon footprint liquid fuels and commodity chemicals from unconventional renewable and sustainable sources new technological approaches have to be developed. In particular moving away from low oxygen content fossil hydrocarbon feedstocks requires the development of new chemical processes and possibly decentralisation of fuel production. Some energy carriers like air transportation fuels and also commodity chemicals will be important in the foreseeable future. To decarbonise these products, renewable sources can be used. In this lecture, new developments in controlling selectivity and productivity of hydrodeoxygenation and (de)aromatisation with an emphasis on valorisation of biomass to fuels and chemicals is presented. In particular, the emphasis will be on a new method to increase dispersion in transition metal catalysts and its application in biomass hydrotreatment.

**Results and discussion**

We have developed heterogeneously catalysed reaction technology that is highly selective to desired products The detailed properties of catalysts play an important role in oxidation and reduction as well as cracking reactions over heterogeneous catalysts. In particular redox activity plays an important role in tuning the selectivity of the catalyst towards hydrogenation [2] [3-5] and acidity [6] plays an important role in ring opening, cracking and deoxygenation of the biocrude feedstock originating form lignocellulosic sources. High catalyst dispersion, i.e., available metal surface atoms influence selectivity significantly [4] and reduces catalyst cost. In this paper we report a novel method that is applicable to a number of transition metals to increase metal dispersion. Herein, we present a novel facile method (vacuum-heating) which employs a specific thermal vacuum processing protocol of catalysts to promote the decomposition of metal precursors. The removal of coordinated $H_2O$ by controlling the atmosphere and heating cycles restricts the formation of intermediates (metal-bound OH species), resulting in catalysts with a uniform, metal nanocluster distribution. *In situ* FTIR, temperature-programmed decomposition and XAS measurements were used to characterise the structure of and chemistry of the intermediate species[1]. We demonstrate how the development of a fundamental understanding of acidic and redox properties of catalysts leads to the improvement of heterogeneous catalytic processes for industrial applications.

# Extending catalyst lifetime of Sn-Beta through a tandem reduction/oxidation

J. S. M. Espin[1]*, A. Katerinopoulou[1], S. Tolborg[1], E. Taarning[1]
[1]*Topsoe A/S, Haldor Topsøe Allé 1, Kgs. Lyngby, Denmark (*jsme@topsoe.com)*

**Keywords:** Lewis acidic catalysts, Sn-Beta, biomass conversion, regeneration.

**Introduction.** The lewis acidic catalyst Sn-Beta has been found useful in the conversion of sugars to functional chemicals with potential for industrial application.[1] However, some challenges still slow down the industrial implementation of this tin-based catalyst. The high reactivity of bio-based oxygenated reactants limits the operational conditions to low temperature and liquid phase employing mostly polar solvents.[2] Zeolites are known to suffer under these harsh conditions leading not only to reversible deactivation from carbonaceous build-up but also leads to a re- and destructuring and thus loss of activity during use.[3, 4] In this work, we present insight into the operation of Sn-Beta during sugar conversion and implementing a way of recovering lost catalyst activity on spent by forcing the redistribution of tin into active position after use.[5]

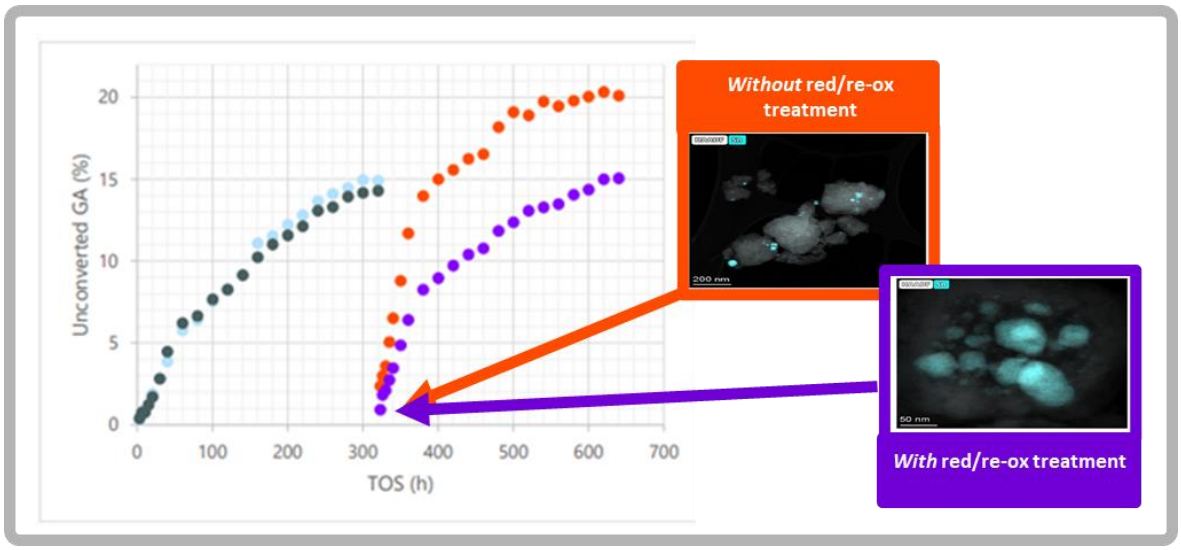

**Figure 1. Unconverted glycolaldehyde (GA) as a function of TOS in hours showing the difference between employing a simple oxidative regeneration (orange) or a tandem reduction/oxidation treatment in-between cycles.**

**Experimental/methodology.** Sn-Beta catalysts were prepared using the methodology described in [1]. The catalyst were deactivated in a GA-containing feed (PFR, 160-180°C) and the spent catalysts were treated in different gas compositions at varying temperature and subsequently tested and characterized by spectroscopic and microscopic methods to compare recovery of activity and material differences.

**Results and discussion.** By implementing a tandem reduction-reoxidation treatment in the regeneration protocol of Sn-Beta during use in-between cycles, catalytic activity can be recovered as shown by a cycle-to-cycle comparison in Figure 1 to yield similar deactivation profiles in the 1$^{st}$ and 2$^{nd}$ use of the same catalyst. The recovered activity can be related to changes to the material after treatment as observed by microscopy, where lost and trapped tin – observed as tin oxide agglomerates – disappear and redistribute following the tandem treatment with spectroscopic data indicating what is likely the re-creation of active tin sites otherwise lost. This recovery and reforming of tin sites will significantly extending the catalyst lifetime.

# Ceria-supported Bimetallics as Catalysts for Upgrading of Lignin to Marine Fuel

Alexandra Radu[1], Savvas Kavoukis[1], Panos D. Kouris[1], Michael D. Boot[1], and Emiel J.M. Hensen[1]
[1]Eindhoven University of Technology, 5600 MB Eindhoven, The Netherlands

**Keywords:** hydrodeoxygenation, bimetallic catalysis, biomass, bio-oil

Anthropogenic greenhouse gas emissions are expected to more than double in 2050 for the maritime sector in a business-as-usual scenario.[1] While petroleum-derived fuels are dominant, the potential of lignin as a source of renewable maritime fuels with a considerably lower environmental impact remains relatively untapped.[2] Moreover, delivering lignin derived drop-in fuels would significantly contribute to the economics of future biorefineries. Upgrading lignin by hydrodeoxygenation (HDO) has been proven difficult due to the recalcitrance of this aromatic biopolymer against depolymerization and the harsh conditions required for hydrotreatment. The product composition in terms of monomers, dimers and oligomers determines to a large extent the viscosity, which is a key specification for acceptance as marine fuel. To decrease the polarity mismatch with conventional marine fuel, oxygen needs to be removed. A novel approach is transition metal doping of reducible supports, which leads to oxygen vacancies.[3] In this work, a mild HDO route is presented involving synergetic effects between Fe and Ni on reducible supports such as ceria. A comparison is made to conventional supports. GPC shows that bimetallic transition metal catalyst lowers the molecular weight of various lignin feedstocks by two orders of magnitude in comparison to a Pd/C reference. The deoxygenation performance is determined via model compound studies, showing a 96% selectivity towards hydrogenated products. Structure-activity relations of the developed systems are investigated by XRD, XPS, STEM EDX, H2-TPR, N2-physisorption and Mössbauer spectroscopy. Products were analyzed with GC-FID/MS and 2D-HSQC NMR.

**Keywords:** HVO, hydroisomerization, green fuels.

**Introduction**

Nowadays energy generation plays a critical role in our society, developing new processes to obtain clean and renewable energy, to decrease the $CO_2$ emissions mainly caused by the use of fossil fuels. Green fuels appear as good candidates for this goal, they can be obtained from biomass residues and drop-in in the current infrastructure, transport, and storage [1].

This research's purpose is related to the hydrotreating of vegetal oil (HVO)/hydroisomerization (HISO) process for obtaining green diesel and kerosene. The HVO unit yields a mixture of lineal hydrocarbons that cannot be employed directly as fuel, because several properties are not adequate, especially cold behavior. In the second step, HISO, the mixture of a part of lineal hydrocarbons is converted into branched hydrocarbons, this new mixture has exceptional properties as fuel. The catalysts and the operational conditions in each stage were picked with the aim of maximizing the conversion, the selectivity to desired products and the yield of both reactions, having into account the scalability of the process.

**Experimental/methodology.**

Nickel-based catalysts on alumina-supported tungsten oxides (15 wt. % W) with different loadings of nickel (0.5-10 wt. % Ni) were synthesized to study the role of Ni loading on the hydroisomerization of n-dodecane. The catalysts were prepared by wetness impregnation method on the supports to introduce W and Ni.

The hydroisomerization performance of each catalyst was tested in a trickled-bed mode reactor, worked in parallel flow, at 300ºC and high pressure (20 bar) [2].

**Results and discussion.**

The nickel particles were deposited over $Al_2O_3$ support, which has been modified with $WO_x$ to increase its acidity. The activity results reveal an optimum balance between metal and medium-strength acid centers, which favors a fast desorption rate of the intermediates involved in the isomerization reactions, being the catalyst that contains a 6 wt. % Ni the best candidate (Figure 1). The employ of large nickel particles (> 6 wt. % Ni) favors the cracking reactions instead of isomerization reactions, due to a less Ni dispersion and higher acidity, corroborated by XRD, XPS, and $NH_3$-TPD analysis, decreasing the yield of the reaction.

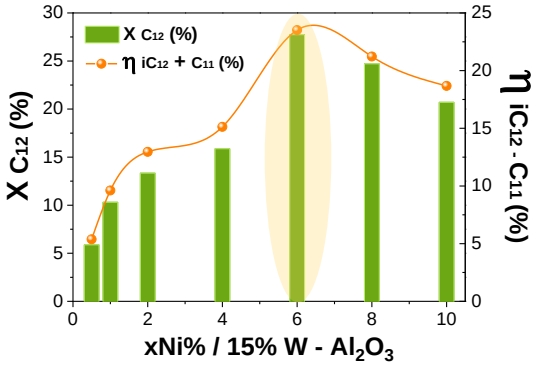

**Figure 1.** Conversion and yield obtained with xNi/15%W-$Al_2O_3$ catalysts for the hydroisomerization of n-dodecane.

The results confirmed the use of nickel-based catalysts for n-alkane hydroisomerization is a possible alternative for reducing the cost of the catalyst and the availability of the metal, compared with platinum-based catalysts usually employed.

# Emulsion templated unsupported micropsherical catalysts for slurry phase hydrotreatment of lignocellulosic bio-oils

A. Reznichenko *, T. Viertiö, A. Tuisku, E. Högnabba, J. Kihlman, J. Lehtonen

*VTT Technical Research Center of Finland, Espoo, Finland*
**alexander.reznichenko@vtt.fi*

**Keywords:** slurry hydrotreatment, bio oils, hydrodeoxygenation, emulsion, microsphere synthesis

**Introduction.** Thermochemical liquefaction of residual lignocellulosic biomass results in sustainable bio-oils which can in turn be further upgraded to fossil-free chemicals and fuels via hydrotreatment approach [1]. Slurry hydrotreatment allows for a robust upgrading of lignocellulosic bio-oils via continuous addition, circulation and removal of catalyst and unreacted feed [2]. In this light, development of low cost, high activity hydrotreatment catalysts compatible with slurry process and catalyst recovery operation is an important challenge to be solved for successful commercialization of pyrolysis oil upgrading to transportation fuels and biochemicals.

**Experimental.** Unsupported Co-promoted molybdenum sulfide based catalysts for slurry hydrotreatment of bio oils were prepared via emulsion templated synthesis. Broad range of synthesis conditions including type and amount of surfactant, nature of dispersed and continuous phases as well as emulsion solidification conditions were explored. Liquid-liquid emulsion precursors were characterized with laser scattering technique to determine stability and droplet size distribution. Solid catalysts were characterised with XRD, physisorption, XPS, ICP-AES and SEM-EDS. Both emulsions and ex situ solidified catalysts were tested in the hydrotreatment of the model compound isoeugenol in a batch reactor at 300 °C and 30 bar. Furthermore, the catalysts were tested in semi-batch hydrotreatment of fast pyrolysis bio-oil to compare the performance and evaluate the conclusions drawn from model compound experiments.
Catalyst performance was benchmarked against traditional supported sulfided hydrotreatment catalysts.

**Results and discussion.** Emulsion concentration, agitation regime, nature and amount of surfactant were all found to affect droplet size distribution of the stable water-in-oil emulsions containing catalyst precursors components in dispersed phase droplets. Droplet size range can be effectively adjusted in a broad range of 1-30 microns, producing dispersions with narrow size distributions and low content of fines and agglomerates. Such emulsions were found to be suitable for a direct application as catalysts in model compound and bio oil hydrotreatment. Ex situ solidification of emulsions was used to study the effect of solidification conditions on the morphology, composition and catalytic performance of the microspherical catalyst particles. More details on the catalyst preparation, characterization and catalyst performance tests will be given in the final presentation.

**Keywords:** FeNi catalysts, hydrodeoxygenation, lignin derived, catalytic support, renewable fuels

**Introduction.** The current interest in lignocellulosic biomass as a source of renewable liquid fuels and chemicals is due to depletion of fossil feedstock and environmental problems associated with fossil fuels. Hydrodeoxygenation is one of the promising methods for production of fuel components by upgrading of crude oil from fast pyrolysis .

**Experimental/methodology.** In this work, eight low-cost bifunctional metal-acid catalysts were investigated in hydrogenation of the lignin-derived model compound dihydroeugenol in a continuous mode. As a support, materials with different porosity and acidity were selected, namely: $SiO_2$, $\gamma$-$Al_2O_3$, and a range of zeolites H-Y-5.1, USY-30, H-ZSM-5, H-Beta-300, H-Beta-38, H-MCM-48. The incipient wetness impregnation method with two impregnation steps and nominal loading 5 wt% for each metal was used to synthesised FeNi containing catalysts. Iron and then nickel were subsequently introduced using aqueous solutions of $Fe(NO_3)_3 \cdot 9H_2O$ and $Ni(NO_3)_2 \cdot 6H_2O$, respectively.

Fresh and spent 5-5 wt% FeNi catalysts were characterized by a range of physico-chemical method such as SEM-EDX, TEM, ICP-OES, FTIR with pyridine, TPR, TGA, $N_2$-physisorption, Mössbauer spectroscopy, X-ray absorption in terms of XANES and EXAFS, and soluble coke extraction with $CH_2Cl_2$ analyzed by GC-MS.

**Results and discussion.** The results clearly demonstrated that the catalyst support has significant effect on the physico-chemical properties as well as on Fe-Ni interactions directly influencing catalytic results in dihydroeugenol hydrodeoxygenation in a continuous mode. Rapid deactivation due to coke formation was obtained for all catalysts except FeNi/H-Y-5.1. Overall, the most active and selective towards desired oxygen-free compounds was FeNi/$\gamma$-$Al_2O_3$. More details on the catalyst preparation, characterization and catalytic tests will be given in the final presentation.

**Keywords:** Lignin, HDO process, lignin models, supported Ru-catalysts, metal oxides.

**Introduction.** Lignocellulosic biomass, mainly composed of cellulose, hemicellulose and lignin (15-25 wt%), is the biggest renewable source for the production of biofuels and biomaterials; lignin being the major source of renewable aromatic compounds. Its highly complex amorphous structure is formally derived of the co-polymerization of sinapyl, coniferyl and *p*-coumaryl alcohols. However, it is possible to find a series of specific linkages which are repeated more or less frequently in its structure; among those, the more predominant is β-O-4´.[1] For lignin-derived biofuel production, hydrodeoxygenation (HDO) process is required to produce hydrocarbons through oxygen removal, as well as to cleave C-C/C-O bonds present in lignin through hydrogenolysis reactions. Conversion of well-defined and chemically pure lignin model compounds was used as reference to study the role of different supported Ru catalysts, a metal known for its notable activity in HDO reactions,[2] for the cleavage of the most representative chemical linkages in lignin oligomers. Based on these results, the most appropriate catalysts for HDO of real lignin feeds can be designed. Different lignin model compounds have been considered in this study, including: 1-(3,4-dimethoxyphenyl)-2-(2-methoxyphenoxy)propane-1,3-diol as representative model for β-O-4´ lignin linkages, and 2,3-dihydrobenzofuran as representative model for β-5´ linkages, respectively.

**Experimental/methodology.** A set of Ru catalysts supported on different metal and lanthanide oxides (γ-$Al_2O_3$, $TiO_2$, $ZrO_2$, $CeO_2$) and mixed oxides thereof ($TiO_2$·$Al_2O_3$, $ZrO_2$·$Al_2O_3$, $TiO_2$·$ZrO_2$, $CeO_2$·$ZrO_2$; prepared by co-precipitation method) were developed. Catalysts with a theoretical loading of ≈2wt% of Ru were synthesized by deposition-precipitation method and characterized by ICP-OES, XRF, XRD, $N_2$ adsorption isotherms, SEM and TEM, $NH_3$-TPD, and TPR, among other. The catalysts were activated under $H_2$ flow at 250 ºC for 4 h prior to their use in reaction. A 12 mL stainless steel autoclave reactor with a PEEK-reinforced with graphite wire vessel was used for catalyst evaluation in the conversion of lignin models via hydrogenation/HDO. Typically, the reactor was charged with a suspension of the catalyst (20wt% respect to lignin model) and lignin model in 2 mL of EtOH as solvent. The reactor was hermetically closed and pressurized with 40 bar of $H_2$. Then, the reaction mixture was heated to 240 ºC at 1000 rpm during 5 hours. Kinetics of reaction were followed by GC-FID (Agilent 7890A instrument equipped with a 30 m HP-5 capillary column), while product identification was made by GC-MS.

**Results and discussion.** From the different studied Ru-based catalysts, which were benchmarked against a commercial Ru/C, Ru/γ-$Al_2O_3$ and Ru/Ti-Al-O showed superior catalytic activity (i.e. TON) for both lignin models as well as superior HDO activity in view of the product distribution achieved. This developed Ru/γ-$Al_2O_3$ catalyst will be tested on a real lignin feed, a sugar-containing methanol-based crude lignin oil (CLO) derived from the processing of raw lignin in the IDEALFUEL Horizon Europe project, and compared to the commercial Ru/C, under HDO operational conditions previosuly established for benchmark catalysts.

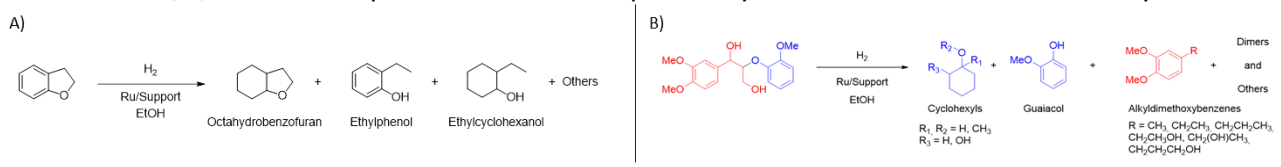

**Figure 1.** HDO reactions of Ru-supported catalysts studied in this work: A) of β-5' lignin model 2,3-dihydrobenzofuran and B) of β-O-4' lignin model 1-(3,4-dimethoxyphenyl)-2-(2-methoxyphenoxy)propane-1,3-diol.

# Influence of Sulfation on Activity & Stability of Metal oxide Catalysts for Vapor-phase Ketonisation of Volatile Fatty Acids

G. Deshmukh[1], M. Delarmelina[2], A. Goguet[1], R. Catlow[2], and H. Manyar[1,*]

**h.manyar@qub.ac.uk*

**Introduction.** The depletion of fossil fuels coupled with increasing demand for renewable carbon-neutral energy is amongst the top global challenges, and development of alternative biofuels is one of the potential solutions [1]. In this context, aqueous streams also called process waters, obtained after the biomass treatments (hydrothermal liquefaction, pyrolysis, and fermentation) are important feedstock. Aqueous streams contain up to 10% w/w carboxylic acids (chain length $C_1$ to $C_6$), which are generally referred as the volatile fatty acids (VFAs). VFAs can be upgraded to produce long chain alkanes ($C_8$-$C_{14}$) through a series of catalytic processes. The current VFA upgrading process involves ketonisation of VFAs to produce $C_5$-$C_{11}$ range ketones, followed by aldol condensation of ketones to elongate the chain length. A final hydrogenation produces fuel range alkanes. In ketonisation, two molecules of carboxylic acids are condensed to form long chain ketone with the loss of one molecule of $CO_2$ and $H_2O$ each (**Figure 1a**). Ketonisation of VFAs has been widely studied, but the reaction mechanism and the role of active sites such as surface acid-base pairs is not clearly understood. In this study, by combining experimental and Density functional theory (DFT) studies, we have established the reaction mechanism and the role of sulfated species on the surface of metal oxides in enhancing the catalyst activity, minimising the byproduct formation, and increasing the catalyst stability and longevity [2]. Herein, we show that upon sulfation, Brønsted and Lewis acid strength increased significantly, whereas Lewis basicity decreased. Such changes in the interplay between acid−base sites resulted in an improvement of the selectivity toward the ketonisation process, by suppressing the side reaction of acetone self-condensation. We report a detailed DFT investigation of the putative surface species on sulfated zirconia, including the possible formation of dimeric pyrosulfate ($S_2O_7^{2-}$) species. Our results show that the formation of such a dimeric system is an endothermic process, with energy barriers ranging between 60 and 70 kcal mol$^{-1}$, and which is likely to occur only at high $SO_4^{2-}$ coverages (4 S/nm$^2$), high temperatures, and dehydrating conditions. Conversely, the formation of monomeric species is expected at lower $SO_4^{2-}$ coverages, mild temperatures, and in the presence of water, which are the usual conditions experienced during the chemical upgrading of biofuels.

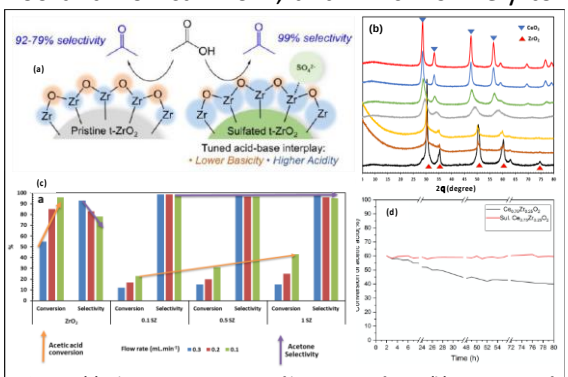

**Figure 1. (a)** Schematic representation of ketonisation of VFAs, **(b)** XRD patterns of different sulfated $Ce_xZr_{1-x}O_2$ catalysts, **(c)** The effect of space velocity on % conversion of acetic acid and % selectivity to acetone for pristine and sulfated $ZrO_2$, and **(d)** Time on stream for catalyst activity and stability.

**Experimental/methodology.** A series of sulfated and as synthesized $Ce_xZr_{1-x}O_2$ catalysts with varying Ce/Zr mole ratios were prepared using co-precipitation method. The ketonisation was performed in custom designed packed-bed reactor. Periodically, reaction samples were analysed using gas chromatography.

**Results and discussion.** The efficacy of all pristine and corresponding sulfated $Ce_xZr_{1-x}O_2$ catalysts showed that the sulfation improved the selectivity to acetone by prohibiting subsequent self-condensation of acetone. Decreasing the feed flow rate, over as synthesized $Ce_xZr_{1-x}O_2$ catalysts, enhanced the acetic acid conversions, but lowered the acetone selectivity. All sulfated $Ce_xZr_{1-x}O_2$ catalysts, showed high selectivities to acetone (95-98%). The XRD patterns of all catalysts calcined at 500 °C, reflected $ZrO_2$ in tetragonal phase and ceria in cubic phase (**Figure 1b**). Both sulfated and pristine $Ce_{0.75}Zr_{0.25}O_2$ catalysts showed better activity and selectivity to acetone compared to the corresponding parent metal oxides of $CeO_2$ and $ZrO_2$ (**Figure 1c**). Sulfation of the catalysts also helped to enhance the catalyst stability (**Figure 1d**). The scope of the ketonisation was successfully extended to a range of $C_4$-$C_6$ VFAs in individual and mixture of feedstocks.

# Glycerol derivatives as bio-based $C_1$ building blocks for N-formylation of amines to formamides with $O_2$ as the oxidant

Xingchao Dai[1*], Angelika Brückner[1], Feng Shi[2], Jabor Rabeah[1]

**Introduction**

The rising production of biodiesel creates a surplus of glycerol which must be valorized to turn waste into treasure. One way is selective oxidation of glycerol to 1,3-dihydroxyacetone (DHA), glycolic acid or glyceraldehyde being platform molecules for further syntheses.[1] Recently, we have demonstrated that DHA can be used as a $C_1$ carbonyl source instead of highly toxic CO to convert amines to formamides with $H_2O_2$ as oxidant.[2-4] Unfortunately, an excess of $H_2O_2$ was needed, due to its low utilization efficiency, partial decomposition and detrimental byproduct formation. To make these reactions more sustainable, $H_2O_2$ should be replaced by gaseous oxygen as a clean and cheap oxidant. In this work, we show for the first time that all carbon atoms in DHA can be utilized to convert amines to the respective formamides in the presence of molecular oxygen and a ligand-modified $Cu/C_3N_4$ catalyst.

**Experimental**

Different $Cu/C_3N_4$ catalysts (Figure 1) were prepared using copper nitrate and melamine as the $C_3N_4$ precursor by one-pot pyrolysis in the absence and presence of amino ligands such as 1,10-phenanthroline (phen) and 2,2-bipyridine (bpy). The prepared catalysts were comprehensively chracterized by different analytic and spectroscopic techniques. N-formylation of amines with DHA was performed at 150 °C with 0.5 MPa $O_2$ in an autoclave.

**Results and discussion**

Activity test results showed the highest catalytic performance for $Cu(phen)_2/C_3N_4$ in N-formylation of aniline with 90% yield of the desired formanilide (Figure 1a). With this catalyst, a range of amine substrates including aromatic, aliphatic, benzylic, primary and secondary amines can be converted into valuable formamides in good yields. Combined ex-/in-situ characterization techniques revealed that the active catalyst $Cu(phen)_2/C_3N_4$ contained a higher amount of surface Cu species and exhibited a faster $Cu^I/Cu^{II}$ redox cycle, which may be the reason for the better catalytic activity (Figure 1b-c). Investigations of the reaction mechanism by in-situ EPR and control experiments revealed that singlet oxygen is formed by activation of $O_2$ on the catalyst, which may be the real oxidant (Figure 1d) and that HCOOH is the possible $C_1$ reaction intermediate in the formation of formamide products.

# Catalytic conversion of biobased ketones to renewable aromatics: Influence of solid acid catalysts and reaction engineering

Phillip Reif[1], M. Rose[1*]
[1]*Chemical Technology II, Technical University of Darmstadt, Darmstadt, Germany*
[*] *marcus.rose@tu-darmstadt.de*

**Introduction.** Aromatics such as benzene, toluene and xylene (BTX) are important precursors for versatile industrial applications.[1] Annually more than 103 Mio. t (2012) are produced globally mainly via catalytic reforming of naphtha.[2] But limitation of fossil resources demands for sustainable routes from renewable resources such as biomass. Current approaches for bio-based aromatics focus on biomass-derived furan derivatives as raw material and pyrolysis of lignocellulosic biomass. However, these processes are based on multiple reaction steps which often lack selectivity and require complex separation. Herein, we present a one-step, solvent-free direct production of 1,3,5-substituted C6-aromatics by cyclotrimerization of biomass-derived alkyl methyl ketones which are accessible from chemocatalytic or biotechnological biorefinery processes,[3] e.g., acetone from ABE-fermentation. We proof the potential of this route using stable solid acid catalysts under batch and continuous processing conditions.[4-6]

**Experimental.** Acetone as well as higher alkyl ketones such as 2-butanone and 2-pentanone were used as model substrates, the consecutive aromatization via the dimer mesityl oxide to mesitylene and its derivatives was studied in liquid phase batch as well as flow conditions. Catalysts, reaction temperature and time were screened for maximum yield and selectivity to aromatics. Screening of solid acid catalysts (5 wt%) was performed in stirred batch autoclaves with acetone (10 g) at 130-190 °C (3-15 h). Time course of the reaction was studied in a batch reactor (2.5 wt% cat., 150 mL ketone) with a sampling line. Filtered product solutions were analyzed by GC and GC/MS with 1,4-dioxane (30 wt%) as internal standard and phase solubilizer. Catalyst stability was assessed in a fixed-bed reactor equipped with an online-GC at 130-230 °C at 40 bar and a WHSV of 8 $h^{-1}$ using 3 g of shaped catalyst particles.

**Results and discussion.** From a screening of 30 solid acid catalysts, ion exchange resin Purolite CT275DR, beta-zeolite H-BEA 35 and amorphous silica-alumina Siralox 70/170 were selected based on their mesitylene yield. The overall highest aromatics yield (15.8 % at 160 °C, 6 h) was found for Purolite, that turned out to be less selective at higher temperatures. Time-resolved experiments identified two consecutive phases with a high initial activity in the first 20-30 min and a subsequent activity drop. This is marked by a maximum in the dimer yield, whereas acetone conversion and consecutive product yields constantly increase over time. It was found that the aromatization activity generally increases with acid site density but is not dependent on acid strength. Reactions in continuous liquid flow revealed that Purolite was not thermally stable at elevated temperatures (150 °C) and that the majority of tested zeolites deactivated once aromatization activity was observed. In contrast, the amorphous silica-alumina Siralox 70/170 was highly stable for more than 35 h-on-stream at 230 °C and showed constant acetone conversion and mesitylene production. No significant catalyst deactivation was observed which is supported by TGA. In conclusion, amorphous silica-alumina was found to be stable and efficient for the one-step conversion of biomass-derived ketones. The high stability of the catalyst under liquid phase conditions is essential for the establishment of a new environmentally benign process for alkyl methyl ketone aromatization.

# Vapour phase upgrading of acetic acid over noble metal promoted metal oxides at hydropyrolysis conditions: reaction mechanisms and pathways

P.Tingelstad[1*], D. Chen[1]

[1]Norwegian University of Science and Technology, Trondheim, Norway.

**Keywords:** biomass pyrolysis, vapor phase upgrading, fundamental catalyst study, acetic acid.

**Introduction.**

Acetic acid is a main product from hydropyrolysis of biomass, account for up to 10 wt% of the formed products. Vapor phase upgrading directly after the pyrolysis reactor offers an attractive pathway for converting the low molecular weight and water soluble compounds to long chain hydrocarbons and aromatics. Acetic acid is explored here both as a model compound for other oxygenates, as well as a major naturally forming product of the pyrolysis process. Converting the acetic acid to longer chain hydrocarbons and aromatics offers an attractive route for increasing the carbon yield by 6 wt%-points [1]. Herein, the vapor phase conversion of acetic acid over noble metal promoted metal oxides is studied.

**Experimental/methodology.**

In this study, laboratory experiments were conducted in a PID Microactivity Reference unit with continuous flow of acetic acid (3 mol%), hydrogen (20 mol%), and nitrogen (77 mol%) over promoted TiO2 catalysts. The exit gas was analyzed by GC-FID/MS for quantitative and qualitative analysis. All mass balances were over 97 %.

The catalysts were characterized by XPS, XRD, TEM, Chemisorption and BET. The lewis acidity and bacicity was determined by CO2 and NH3 calorimetry.

**Results and discussion.**

All products were determined by GC-FID/MS. The pathway for all formed products were determined. Acetone was always the main product formed, with acetaldehyde being the second highest. These two molecules act as the main building blocks for the rest of the formed products, and their pathways can be seen in Figure 1. Mass balance closure was always above 97 %.

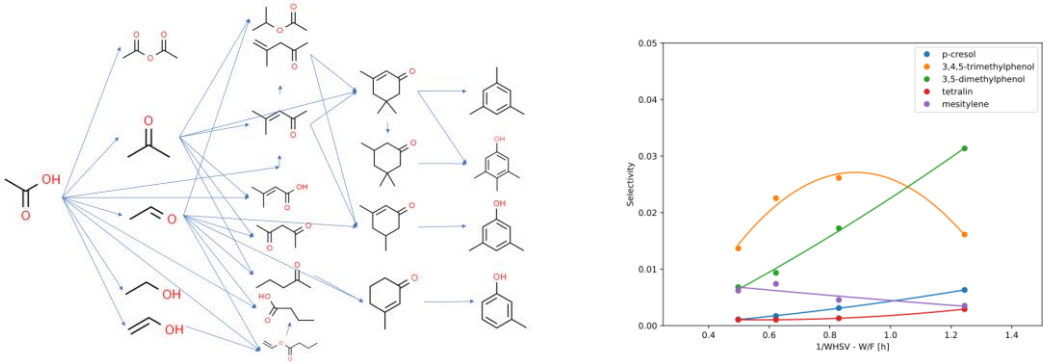

Figure 1: Reaction pathway for all formed compounds and selectivity of aromatics as function of spacetime. T = 350 °C, WHSV = 0.5-2.0 h, P = 1 atm. X/TiO2 = 0.600 g, 2.000 g SiC used as diluent. 3 mol% acetic acid, 20 mol% H2, 77 mol% N2.

A kinetic model has been developed that calculates the rate constant for each reaction as a function of catalyst only, the temperature has been set at 350 °C for all experiments. XPS has given the oxidation state of each element, and a statistical model is under construction that correlates the oxidation state and chemical bonds of each element (Ti, O, noble metal) to the reaction rate between each molecule. Selective doping of the catalyst by NH3 is also being investigated, to elucidate the active site.

# Stepwise approach for selective FFCA and FDCA production from HMF

J.J. Wiesfeld[1], R. Osuga[1], E.J.M. Hensen[2], K. Nakajima[1*]
[1]*Institute for Catalysis, Hokkaido University, Sapporo, Japan*
[2]*Laboratory of Inorganic Materials and Catalysis, Eindhoven University of Technology, the Netherlands*

**Keywords:** Biomass, Heterogeneous catalysis, HMF, Protection strategy

**Introduction** 2,5-Furandicarboxylic acid (FDCA) can potentially replace terephthalic acid, used for the production of PET polymer. Its starting material 5-hydroxymethylfurfural (HMF) is thermally unstable, leading to undesired condensation products in FDCA production using concentrated HMF solutions. The instability stems from its very reactive formyl group. Recently, our group reported the production of FDCA in high yield (>92%) from concentrated solutions (>10 wt%) of HMF protected as its acetal (HMF-A) with 1,3-propanediol (PDO).[1] PDO itself is slowly liberated during the reaction and partly oxidized, which lowers its recoverability (80%). We devised a stepwise approach (Fig. 1A) which separates the oxidation reaction from the deprotection step, while maintaining high FDCA yield.

**Experimental** Au/HAP catalyst was prepared via NaOH-assisted deposition precipitation.[1,2] HMF-A and FFCA-A were prepared as described in earlier works.[1] Oxidation reactions were performed in PTFE-lined batch reactors. Relevant reaction conditions are listed in the caption of Fig 1.

**Results and discussion** Kinetic data show that full conversion of aqueous 10 wt% HMF-A required 2 hours and produced FFCA-A in 94% yield through DFF-A as an intermediate (Fig. 1B). FDCA was formed only in minor quantities due to the high stability of PDO acetal in alkaline environment which prevented further oxidation. FFCA-A was then deprotected by acidifying the reaction mixture to pH 1, followed by a 4 hour heat treatment at 65 °C. Extraction of the aqueous solution with ethyl acetate yielded 99% of FFCA, while 94% of the PDO introduced as HMF-A remained in the water layer. FFCA in concentrations up to 20 wt% could be oxidized to FDCA (96% yield) without significant byproduct formation (Fig 1C).

**Conclusions** Concentrated HMF-A (10 wt%) was selectively oxidized to FFCA-A with only minor byproduct formation, owing to the acetal stability. FFCA-A was facily deprotected by lowering the pH and 94% PDO could be recovered after extraction and separation. Up to 20 wt% FFCA could be oxidized to FDCA. Overall yield was 90%.

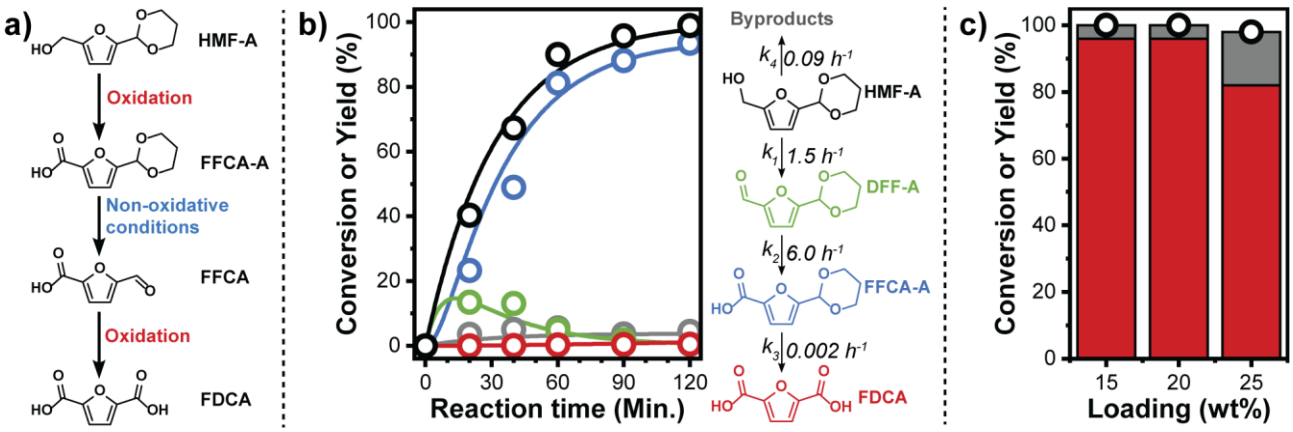

**Fig 1**. a) Stepwise approach scheme, b) HMF-A oxidation time course. Conditions: 100 mg HMF-A in 1 mL $H_2O$, 2 mol. eq. $Na_2CO_3$, 0.5 MPa $O_2$, 100 °C, c) Oxidation of FFCA to FDCA. Conditions: 150-250 mg FFCA in 850-750 µL $H_2O$, 1.5 mol. eq. $Na_2CO_3$, 0.5 MPa $O_2$, 140 °C, 5 h. Products are represented by molecules of the same color, black circles display conversion. Byproducts are shown in grey.

# Aqueous-phase reforming of ethylene glycol over platinum-based catalysts supported on functionalised carbon nanofibres

M. Pazos Urrea[1], F. Herold[1], S. Meilinger[1], E. Tusini[2], A. De, Giacinto[2], A. Zimina[2], D. Chen[1], M. Casapu[2], J.-D. Grunwaldt[2], M. Rønning[1]*

**Introduction.**
Aqueous phase reforming (APR) is a process for producing $H_2$ from low-value mixed oxygenated compounds [1]. It allows for utilization of biomass-derived waste streams to valuable products at relatively mild reaction conditions. The stability of the catalysts are affected during APR, with metal leaching, sintering and coke deposition as the main deactivation mechanisms [2]. Carbon materials possess good hydrothermal stability compared to metal oxides, are resistant to acidic and basic media and the physical properties can be tailored, such as surface functionalisation and heteroatom doping [3].

**Experimental/methodology.**
Pt and Mn-based monometallic and bimetallic catalysts were synthesized by incipient wetness impregnation supported on carbon nanofibres (CNF) produced by chemical vapour deposition and treated it in nitric acid to introduce surface oxygen groups (CNF-ox) and heat-treated at 700°C to remove the oxygen groups (CNF-H). N-doping of the CNF with ethylene diamine as the nitrogen source was performed at 875°C at 10°C/min in $N_2$ (CNF-N). The catalysts were characterized by BET, CO chemisorption, XPS, MP-AES and STEM-EDS. In situ XAS-XRD was performed at the Pt $L_{III}$ and Mn K edges at continuous flow APR conditions. APR of ethylene glycol was performed at 225°C and 20 bar initial pressure in batch, and 30 bar pressure in continuous reaction using as feed of 6 wt% ethylene glycol in water.

**Results and discussion.** The effect on the APR performance by functionalizing carbon supports with nitrogen and adding Mn to Pt-based catalysts was investigated. Bimetallic catalysts such as PtMn supported on N-doped carbon nanofibres are active and selective catalysts for aqueous phase reforming of ethylene glycol, with $H_2$ site time yield of 15.8 $min^{-1}$ at 225°C and 30 bar pressure. The enhancement in catalytic activity could be attributed to metal-support interactions between PtMn and N-doped carbon nanofibers, decreasing the electron density on Pt and promoting $H_2$ formation. The addition of Mn to the Pt-based catalysts further decreased the electron density of Pt by metal-metal interaction and increased the catalytic activity.

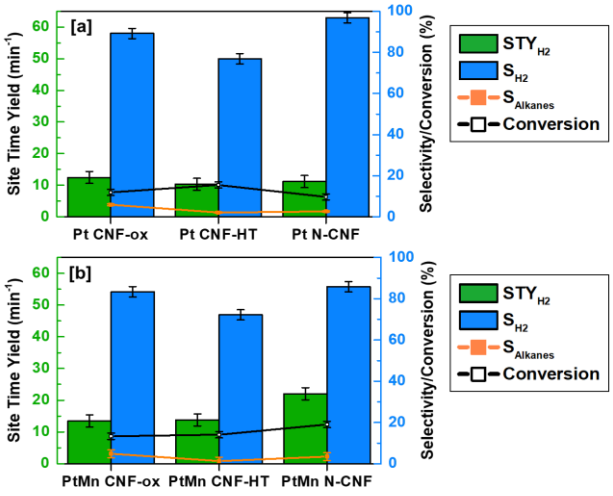

**Figure 1: APR of ethylene glycol at 225°C and 20 bar initial pressure in batch. Conversion of EG, $H_2$ STY$H_2$) $H_2$ and alkane selectivities for the [a] monometallic Pt and [b] bimetallic PtMn catalysts**

**Keywords:** renewable resources, biomass, γ-valerolactone, pentenoates, gas-phase reaction

**Introduction.** There is a growing demand for the production of nylon precursors from renewable resources, not only due to dwindling supply of fossil resources, but also because the current production processes of nylon are associated with a rather high carbon footprint. Lignocellulosic biomass is an ideal raw material for the production of building blocks, e.g. levulinic acid that can be hydrogenated to γ–valerolactone (GVL) [1]. Conversion of GVL into an isomeric mixture of methyl pentenoates (MP) via a ring-opening transesterification and dehydration reaction is one good option for the utilisation of bio-based feedstocks to produce nylon intermediates. The terminally unsaturated methyl 4-pentenoate (M4P) can be converted into a nylon-6 precursor, ε-Caprolactam, while the remaining M2P and M3P isomers can be converted to adipic acid, a nylon-6.6 precursor (Scheme 1). The aim of this study is to develop highly active and selective catalysts with a special emphasis devoted to understand the interconversion process of MP isomers due to C=C double bond isomerisation during the course of the reaction.

Scheme 1. Conversion of GVL into MPs

**Experimental/methodology.** Various $ZrO_2/SiO_2$ catalysts were prepred by impregnation[2]. The content of Zr was varied in the range from 2.5 to 30 wt%. The catalytic tests were carried out in a fixed bed tubular reactor in a gas phase continuous process in the temperature range of 255 to 335 °C. The products were collected in an ice-cooled trap and analysed by GC equipped with FID.

**Results and discussion.** Among all catalysts, 25 % $Zr/SiO_2$ exhibited the best performance. The influence of various key reaction parameters on the activity/selectivity was explored and suitable reaction conditions were optimised. The conversion of GVL and product distribution was found to be strongly dependent on the reaction temperature. The GVL conversion increased from 44 % to 85 % with rise in temperature from 255 to 315 °C and then levelled-off beyond this temperature. The sum selectivity of all the three MP isomers is varied in the range from 97 to 99 %. At low temperature (255 °C), M4P was the major product while M2P was minor product. However, with increase in temperature, the selectivity of M2P and M3P increased at the expense of M4P due to isomerisation of C=C double bond. In addition, the long-term stability of 25 % $Zr/SiO_2$ catalyst was examined and found that the catalyst displayed consistent performance with an excellent long-term stability for a period of >340 hours-on-stream. In order to gain deeper insights on the isomerisation of MPs, a set of control experiments were also performed by dosing individual MPs as educts under similar reaction conditions. These results indicate that M4P can be converted mainly to M3P and also partly to GVL due to ring closing. However, dosing of either M3P or M2P as a reactant did not result in the formation of either GVL or M4P. On the other hand, M3P can be easily converted to M2P isomer and vice versa. In summary, it can be stated that the key reaction parameters need to be selected carefully for better tuning of the product distribution in the desired way. Based on these results, we also proposed the most probable reaction pathway for the conversion of GVL into MPs.

**Keywords:** Aerobic methane oxidation, alloys, $C_1$ catalysis, selective oxidation

**Introduction.** Methane is an abundant carbon source (from natural gas and landfill sites) that can also be obtained sustainably through the anaerobic digestion of biomass. Methane is currently used for heating, power generation or synthesis of fuels and chemicals. The latter requires the reforming of methane to syngas (CO and $H_2$) under demanding conditions [1]. The direct conversion of methane, via oxidation to oxygenates under relatively mild conditions presents an opportunity for the efficient utilization of this abundant carbon source for the synthesis of chemicals [2]. The direct conversion of methane to $C_1$-oxygenates however remains a challenge due to either low catalyst productivity [1], or the use of expensive reagents [1,3]. Furthermore, the selective oxidation of methane to methanol or formaldehyde tends to suffer from the conversion/selectivity trade-off, wherein high selectivities are only obtained at low conversions [1]. A highly productive process that utilizes oxygen as an oxidant is thus highly sought after. Herein we report on the catalytic, aerobic oxidation of methane to formaldehyde over platinum-based catalysts in the presence of water.

**Experimental/methodology.** The Pt, $Pt_3Cu$, $Pt_3Ag$ and $Pt_3Au$ nanoparticles (d ~ 4 nm) were synthesized using a bottom-up wet chemical synthesis approach, and subsequently supported on titania (rutile) via impregnation using chloroform as the solvent yielding 10 wt.-% metal on the support. The oxidation of methane was carried out in a packed bed reactor fitted with a quartz liner at 220°C at elevated pressure.

**Results and discussion.** The rate of methane consumption over the platinum-based catalysts increases with increasing ratio of water to methane in the feed and reached 300 μmol/g/hr over the $Pt_3Cu$ catalyst, followed by Pt and $Pt_3Au$, with $Pt_3Ag$ being the least performing. The selectivity towards CO, $CO_2$ and $CH_2O$ were similar across all catalysts with the formaldehyde selectivity increasing with increasing conversion. The $Pt_3Cu/TiO_2$-rutile displaying the most promising performance for aerobic, selective oxidation of methane.

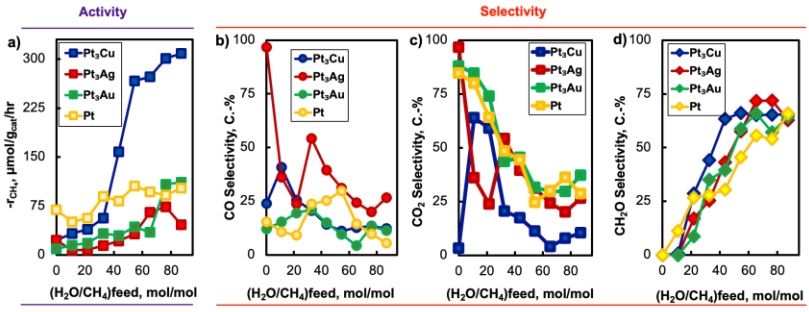

**Figure 1**: Rate of methane conversion (a) and product selectivity (b-d) over supported Pt-based catalysts as a function of the molar ratio of water to methane in the feed.

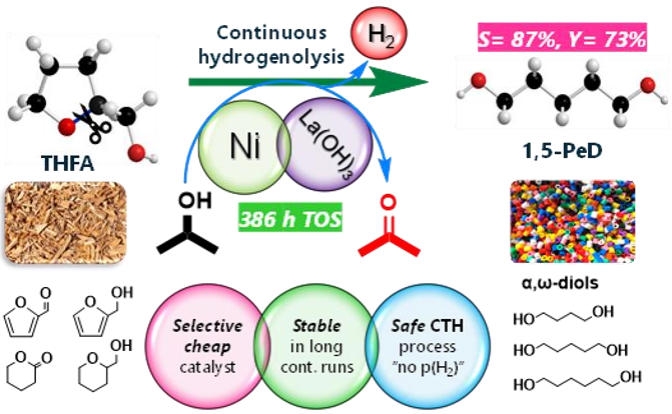
**Keywords:** α,ω-diols; 1,5-pentanediol; furfural; THFA; nickel; catalytic transfer hydrogenolysis, isopropanol



**Introduction.**

α,ω-Diols, such as 1,5-pentanediol (1,5-PeD), are value-added monomers produced from petrochemicals under harsh conditions and widely used for producing technical plastic, polyester and polyurethane resins [1]. Due to the increased demand for these plastic materials, it is essential to develop alternative reaction routes for their synthesis from bio-based lignocellulose feedstocks. For instance, direct hydrogenolysis of tetrahydrofurfuryl alcohol (THFA) to 1,5-PeD over modified Rh or Ir catalysts [2]. However, because of the high costs of these catalysts and their low stability in the continuous process [3], it is highly desired to replace them with stable and cheap nickel catalysts, which have more potential for industrial applications.

**Experimental/methodology.**

Nickel catalysts were prepared on lanthanum hydroxide (wt% Ni-La(OH)$_3$) by co-precipitation and sequential reduction at different temperatures [4]. The transfer hydrogenolysis (CTH) reaction conditions were optimized and compared in a batch reactor and a micro-reactor flow set-up. The catalyst stability and productivity were tested in long-term continuous runs. The structure-activity relationships were revealed using XRD, BET, TPX, XPS, XANES-EXAFS, STEM-EDX techniques. The reaction mechanism of C–O bond hydrogenolysis of THFA to 1,5-PeD was elucidated using $^{13}$C NMR isotope labeling and *in-situ* FTIR.

**Results and discussion.**

Continuous transfer hydrogenolysis (CTH) of THFA to 1,5-PeD was developed using stable Ni-La(OH)$_3$ catalysts in the hydrogen-donor isopropanol for the first time. Remarkably, 40Ni-La(OH)$_3$ was selective to 1,5-PeD (87%) and demonstrated high stability in long continuous runs (up to 386 h TOS). A maximum 1,5-PeD yield of 73% with a productivity of 1.4 mmol g(cat)$^{-1}$h$^{-1}$ was achieved. After evaluation of experimental and spectroscopic results, a direct hydride attack mechanism was proposed for the selective hydrogenolysis of the C–O bond of THFA on the interface between Ni and La(OH)$_3$ support. This joint interface was responsible for the high yield of 1,5-PeD over Ni-La(OH)$_3$ where the strong basic sites deprotonate the hydroxyl group of THFA, and metallic Ni species dehydrogenate isopropanol to acetone producing hydrogen. The elimination of the hazardous $H_2$ reduces the costs for a high-pressure apparatus and raises the level of safety in the workplace, which is as excellent advantages for large-scale industrial applications.

**Keywords:** Furfural, Levulinic Acid, 2-Methyltetrahydrofuran, Hydrogenation, Heterogeneous Catalysts

**Introduction.** The catalytic conversion of furfural (FUR) and levulinic acid (LA) expands the broad spectrum of chemicals that can be derived from lignocellulosic biomass. 2-methyltetrahydrofuran (MTHF), a widely used solvent in oil extraction and organic reactions and a gasoline additive, can be produced from both FUR and LA [1]. Several studies have reported the production of MTHF from separate FUR and LA feed [2,3], however, to the best of our knowledge, there are no reports on the use of combined FUR and LA feed to yield MTHF. Co-feeding FUR and LA to form MTHF is an attractive approach that will assist in the direct conversion of biomass to value-added chemicals since both FUR and LA can be co-produced from the cellulosic portion of the biomass.

**Experimental/methodology.** For the catalyst preparation, the alumina supports were synthesized using a sol-gel method and the metals were incorporated onto the support using the conventional impregnation method. For the hydrogenation reactions, both batch and continuous systems were utilized and the samples were analyzed using high performance liquid chromatography.

**Results and discussion.** The preliminary set of experiments investigated the types of feeds, feed ratios, and catalysts for the batch MTHF production. As depicted in Fig. 1a, complete conversion of the feed was attained for all the experimental runs but it can be observed that the main product varied from one type of feed to another. Interestingly, up to 55.0% yield of MTHF was achieved when FUR and LA was combined as feed. It can be assumed that the two reactions (FUR to 2-MTHF and LA to 2-MTHF) coexist in the reactor to produce 2-MTHF. Moreover, the feed ratio of 4:1 provided the highest MTHF yield (Fig. 1b), possibly due to the dominant presence of FUR in the feed that has prevented the formation of GVL, which is a highly stable intermediate in MTHF production. In addition, among the as-synthesized catalysts, the bimetallic Ni-Cu/$Al_2O_3$ catalyst showed the highest 2-MTHF selectivity which can be attributed to the synergistic effect of Ni and Cu as previously reported (Fig. 1c) [3].

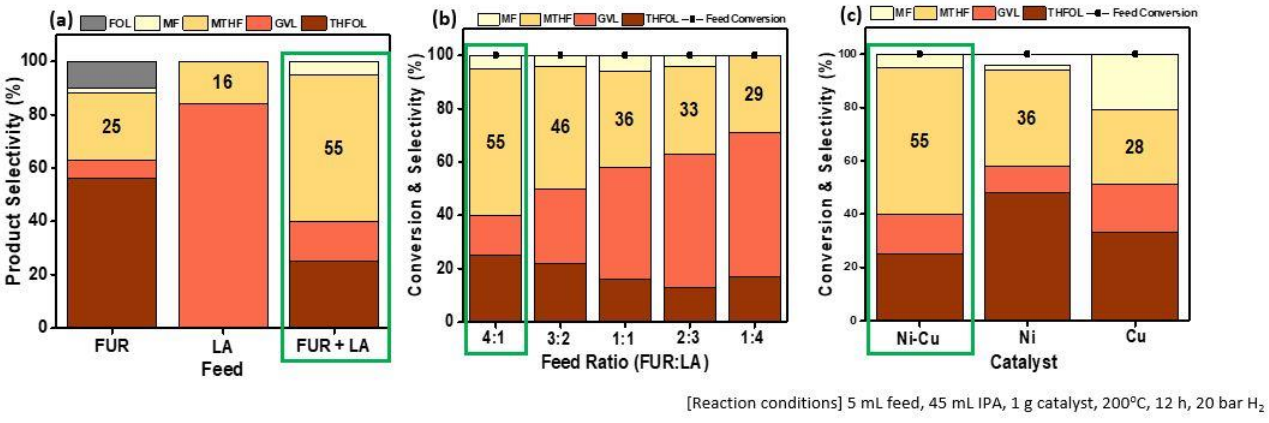

**Figure 1. Results of the screening of the (a) type of feed, (b) feed ratio, and (c) catalysts.**

**Keywords:** Adipic acid, Biomass conversion, Dehydroxylation, Deoxydehydration, Rhenium catalysts.

**Introduction.** Adipic acid and esters are crucial for polymer production, with millions of tons produced annually. The current method of production using petroleum-based feedstock leads to greenhouse gas emissions. Renewable methods using biomass, such as the catalytic dehydroxylation and hydrogenation of aldaric acids from lignocellulosic biomass, is a promising approach towards sustainable adipic acid production. This reaction has only recently evolved from a homogeneously to a heterogeneously catalyzed process making use of supported Re catalysts (Hočevar et al., 2021). Here we present how the properties of rhenium-based dehydroxylation catalysts and the process conditions influence the mucic acid conversion.

**Experimental/methodology.** Catalytic tests performed in stirred, heated autoclave reactors using mucic acid in methanol and solid catalysts (Re/C, Pd/C at 5 wt.-% metal loading, or bimetallic catalysts made via incipient wetness impregnation). All catalysts were pre-reduced under $H_2$ at 400°C. Tests were conducted at 120-175°C under N2 or H2, with 72 hour reactions and liquid samples analyzed by GC-MS.

**Results and discussion.** The selective dehydroxylation of mucic acid in yields > 90 % is possible at temperatures as low as 120 °C and without $H_2$ gas over monometallic Re/C (Figure 1-left). Methanol is both the reducing agent and protects the carboxyl functionality by esterification.

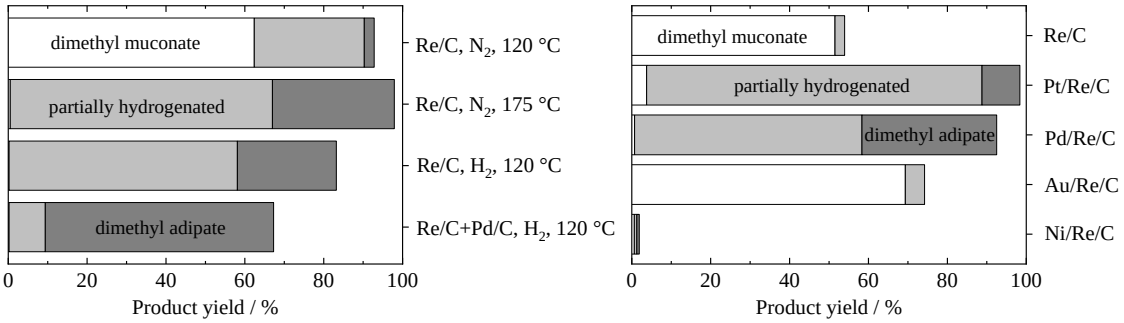

*Figure 1. Product yields after 72 h in the dehydroxylation of mucic acid in methanol over a Re/C catalyst at different reaction conditions (left) and after 24 h over bimetallic catalyst at 120 °C under $N_2$ (right).*

Deoxydehydration and hydrogenation of mucic acid derived from biomass can selectively produce adipates using rhenium-based catalysts. The reaction can be slow with the main product being dimethyl muconate. $H_2$ addition and increased temperature improve hydrogenation, while adding a hydrogenation catalyst like Pd/C can increase selectivity for dimethyl adipate up to 58%. Bimetallic catalysts of Re with noble metals (Pt and Pd) enhance activity and alter product distribution, with Pd/Re/C yielding 35% dimethyl adipate (Figure 1-right). Optimizing Pd loading and reaction time can achieve yields of up to 90%. Ni modification on the other hand is not suitable. To conclude, $H_2$-free production of dimethyl adipate with yields over 90% can be achieved through control of catalyst choice and reaction conditions.

**Keywords:** lignin pyrolysis oil, hydrodeoxygenation, non sulfided catalysts, aviation fuels

**Introduction**

Lignocellulosic biomass is an important source of renewable fuels and value-added chemicals. Lignin, which is a phenolic/aromatic macromolecule, can be converted to phenolic bio-oils via fast pyrolysis [1,2] and can be upgraded via hydrodeoxygenation (HDO) to aviation fuels ($C_7$-$C_{12}$). The aim of this study was the HDO of model phenolic compounds and mixtures, which simulate the light fraction of lignin pyrolysis bio-oils, with Ni-based bifunctional, non sulfided catalysts. Furthermore, the hydrotreatment/HDO of real thermal pyrolysis lignin bio-oils was also investigated.

**Experimental/methodology**

HDO experiments were performed in a high pressure batch autoclave reactor with hexadecane as a solvent and nickel (Ni) based catalysts supported on zeolites (ZSM-5, BETA, USY, etc.) and on mixed oxides/spinels, with different micro/mesoporous and acidic properties. Process optimization study included the effect of temperature, time, $H_2$ pressure, type of phenolic compound. Lignin bio-oils (obtained from fast pyrolysis of alkali lignin from Miscanthus on a twin-screw pilot-scale reactor) and hydrotreated samples were analyzed with GC-MS, GC-FID, 2D HSQC NMR, GPC and other tecnhiques. Catalysts were charcacterized by XRD, $N_2$ sorption, FTIR, TEM, XPS, acidity measurements, etc. before and after reaction.

**Results and discussion**

The model phenolic compounds were hydrodeoxygenated mainly towards cyclohexane and its isomer, methylcyclopentane. The fundamental reaction steps were identified by studying phenol HDO with 10%Ni/ZSM-5 (Si/Al=40), at a broad temperature range, ca. 140-250$^o$C, and comprised of the cascade formation of cyclohexanone/cyclohexanol, cyclohexene, and finally cyclohexane and methylcyclopentane. At optimized mild conditions, such as 220$^o$C, 1 hr, and 50 bar $H_2$ pressure, complete conversion of phenol was observed with up to 75% cyclo-alkanes. The effect of phenolic/aromatic ring substituent groups was then investigated, with the additional -OH (catechol) and methoxy (-$OCH_3$) groups (guaiacol) not affecting conversion/selectivity, reaching up to 85% yield of HDO products (cyclohexane, methylcyclopentane and 1,1-bicyclohexyl), over both small-micropore ZSM-5 zeolite and micro/mesoporous Beta zeolite. More complex/substituted rings, i.e., syringol, vanillin and 1,2,3-trimethoxybenzene, resulted in lower conversion and selectivity, with HDO product yields being lower than 30% over Ni/ZSM-5 catalysts, indicating space-restrictions considering the kinetic diameter of the feed compounds. The effect of intra-crystal mesoporosity of ZSM-5 and of the Brönsted to Lewis acid sites ratio of Beta zeolite was also investigated. Under the above optimized mild conditions, HDO of model mixtures consisting of alkoxy and alkyl phenols led to almost complete hydrodeoxygenation with products in the range of $C_6$-$C_9$, indicating also the ocurence of hydroalkylation reactions, in addition to the standard phenol HDO paths. When real lignin bio-oil feeds were tested, more intense temperature, time and pressure conditions were required, e.g. 280-350$^o$C, 1-5 hrs and 50-90 bars $H_2$ in order to induce substantial deoxygenation of the contained mainly alkoxy/alkyl-phenols and heavier oligomers. Catalyst stability was also studied via characterization and reuse of spent materials, exhbiting high HDO efficiency (>95%), for at least three successive catalytic cycles. The metallic phase of Ni, as well as porous and acidic properties, were retained after use, as confirmed by XRD, XPS, BET and acidity tests, while coke formation was very low (<5 wt.%).

**Keywords:** Furfural, Hydrogen peroxide, Heterogenous catalysis, Niobia

**Introduction.** Selective oxidation of furfural with hydrogen peroxide offers a promising pathway (Fig. 1) to C4 chemical intermediates. Liquid-phase oxidation of furfural with hydrogen peroxide produces mainly 2-(5H)-furanone, succinic acid , malic acid, furoic acid and maleic acid. Formic acid is cleaved as a stoichiometric co-product in the oxidation. Both succinic and maleic acids can be dehydrated to their corresponding anhydrides at elevated temperatures. Numerous novel applications have been deduced for these molecules such as plant growth regulators, bactericides, and biodegradable plastics, e.g. polybutylene succinate, polyurethanes, plasticizers. Moreover, stoichiometrically efficient hydrogenation routes exist to upgrade them further to chemical intermediates, thus providing bio-based substitutes for these multimillion ton per year products, currently made almost entirely from fossil-based feedstock [1].

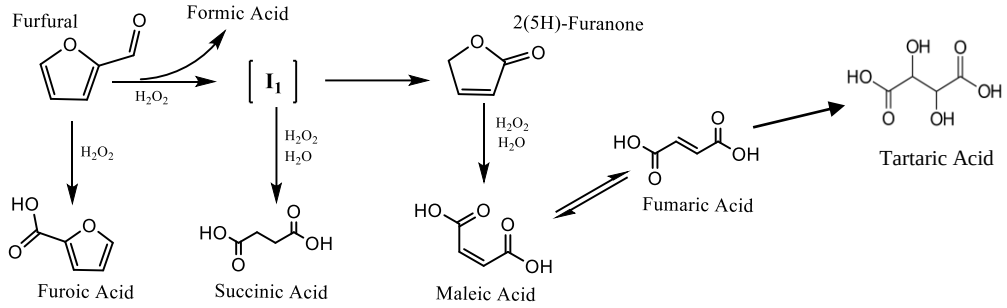

Figure 1. Simplified reaction scheme of furfural oxidation on niobium catalyst.

**Experimental/methodology.** The oxidation of furfural with hydrogen peroxide was studied in a 100ml jacked glass reactor under vigorous mechanical stirring at 50-90°C. Various niobium oxide catalysts were synthesized and screened. Multiple analytical techniques such as $^1$H NMR, GC-MS, HPLC were applied for the identification and quantification of the final products. As for the characterization of the synthesized catalytic materials, relevant techniques such as HR-TEM, acidity, nitrogen physisorption, EDS and XPS were utilized in order to explain the catalytic reaction mechanism and the obtained results.

**Results and discussion.** Various niobium catalysts such as $Nb_2O_5$ (commercial), $N_2O_5$(meso), Nb-SBA-15 and Nb-$SiO_2$ were screened for the liquid-phase oxidation of furfural. It was evidenced that when a mesoporous niobium catalyst is used, the product selectivity of the system leans towards tartaric acid, instead of the typical products, e.g succinic and maleic acids. The formation of tartaric acid was observed to be independent of the amount of niobium deposited on the catalyst and rather influenced by the pore size and the acidity of the material as indicated by the results from the experiments using $N_2O_5$(meso) and Nb-SBA-15. The reaction mechanism was elucidated by performing independent experiments using maleic acid and fumaric acids as starting materials, and it was observed that the formation of tartaric acid mainly takes place through the oxidation of fumaric acid. The stability of the catalyst was tested by reusing the spent catalysts. Calcination at 450˚C was found to be necessary in order to regenarate the catalyst keep the level of conversion and yield constant in succesisve reaction cycles. The XPS analysis of the fresh, spent and regenarated catalyst revealed the oxidation state of niobium species during the stability test.

**Keywords:** Hydrodeoxygenation (HDO), Palm Oil, Zeolite Beta, Alkaline Earth Promoters, Periodic trends

**Introduction.** The global threats of environmental pollution and climate in the world have triggered the ongoing "low-carbon revolution," which reshapes the global energy market by lowering the significance of fossil fuels and boosting the reliance on renewable energy including biomass. Green biofuels are carbon-neutral renewable fuels derived from biomass that are converted to bio-oil through pyrolysis [1]. However, bio-oil is regarded as unsuitable for direct use in diesel engines and turbines due to its high oxygen and carboxylic acid contents. In this work, an experimental and theoretical investigations are carried out to elucidate the role of alkaline earth-metal promoters on biofuel production through palm oil HDO.

**Experimental/methodology.** The support used in this study, i.e., zeolite beta (Z-β) was supplied by ZEOLYST INTERNATIONAL ($NH_4$-form, $SiO_2/Al_2O_3$=25). Wet impregnation was followed for the support which was modified by different alkaline earth metalsas well as for the Ni introduction into the catalyst.

**Results and discussion.** Structural studies (XRD) display peaks of Z-β structure (JCPDS 48-0074) and Ni metal (JCPDS 01-070-1849), whereas as the cation's radii ($Mg^{2+}$< $Ca^{2+}$< $Sr^{2+}$< $Ba^{2+}$) increase, a decrease in zeolite peak intensity is observed and a concomitant broadening of Ni peaks due to the competitive growth of both metal/promoters' crystallites. The RGB mapping (HAADF-STEM analysis) of Mg-promoted catalyst suggests an even distribution of the metal ($Ni^0$) and the cation ($Mg^{2+}$) over Z-β matrix. Whereas for Ba-promoted catalyst, Ni particles are homogeneously anchored onto Z-βmatrix forming bigger agglomerates (23 nm) compared to Mg-promoted catalyst (17 nm), which can be justified by the segregation of $Ba^{2+}$ species from the surface. Unveiling of the Ni localized environment was attempted using XANES. The normalized XANES results at the Ni K-edge (8333 eV) show a reduction in the absorption edge feature and an increase in the post-edge peak (EXAFS) with respect to Ni foil (reference), suggesting that Ni atoms were significantly oxidized, particularly in Mg-promoted catalyst. Based on the magnitude of the Fourier Transforms (FTs) of the EXAFS signals in R-space, the peak at ~2 Å represents the first Ni-Ni coordination shell, followed by two specific Ni-Ni interactions (3-5 Å). The peak centered at ~1.8 is attributed to Ni-O interaction. For all catalysts, the long-distance ordering and the features of crystalline structure are evidenced. The prepared catalysts were assessed for palm oil conversion; the highest conversion was obtained over 10Ni/5Sr-Beta catalyst (44 %) at 400 °C due to its moderate acid sites ($NH_3$-TPD) and higher Ni dispersion which promoted the electrophilicity of the catalyst and subsequently accelerated the adsorption of oxygenated molecules and activation of C-O bonds. Bader charge analysis indicate a periodic trend in the electronic transfer from Ni atoms to the promoters (i.e. $Mg^{2+}$ > $Ca^{2+}$ > $Sr^{2+}$ > $Ba^{2+}$) indicating the close proximity of the constituents. The DFT studies were conducted over Ni(111) surface using palmitic acid as model compound due to the abundance of the latter in the palm oil. Different adsorption geometries were examined and the parallel dual-site adsorption of OH*hollow-hcp site of palmitic acid on Ni(111) surface was found to be the thermodynamically more favorable.

# Biofuels production via hydrocracking of hydrothermal liquefaction biocrude oil and lignocellulosic pyrolysis oil

A. Dimitriadis[1], N. Tourlakidis[1], G. Meletidis[1], S. Bezergianni[1]

[1]*Centre for Research & Technology Hellas (CERTH),*
*Chemical Process and Energy Resources Institute (CPERI) Thessaloniki, 57001, Greece*
[*]*adimitr@certh.gr*

**Keywords:** Biofuels, hydrocracking, biocrude oil, pyrolysis oil, hydrothermal liquefaction

**Introduction.**
Biomass pyrolysis and hydrothermal liquefaction (HTL) are two comparable technologies, as they both render bio-based intermediate products (often referred to as pyrolysis oil and biocrude oil respectively) [1]. However, both products from pyrolysis and hydrothermal liquefaction required further upgrading to enable its end-use as fuel as well as its compatibility with the corresponding combustion systems [2]. Catalytic hydrotreatment (HDT) of pyrolysis oil as well as biocrude oil allowing stabilization and deoxygenation is considered the state-of-the-art technology [3]. To that aim the current work targets to investigate the HDT upgrading of both pyrolysis oil as well as HTL biocrude oil.

**Experimental/methodology.**
The upgrading of both feeds was tested on the same operating window, utilising the same commercial hydrotreating catalyst (NiMo) in order to find out which feed will render the highest quality liquid fuels and how will affect the catalyst performance. Three operating conditions were investigated with both feeds. The aim was to investigate the effect of hydrotreating temperature as well as the effect of $H_2$/oil ratio on product quality and yields of the process. The HDT experiments were performed in the small-scale continuous flow pilot plant TRL 3 of CERTH.

**Results and discussion.**
The results have shown that hydrotreating of both pyrolysis oil and biocrude oil leads in a two-phase liquid product that consists from the organic phase and the aqueous phase. The aqueous phase is formed via the decarboxylation and dehydration reactions, which is a typical side product of biomass catalytic hydrodeoxygenation. For both feeds, it was found that the optimum operating condition is at 330°C, 1000 psi, LHSV 1$hr^{-1}$ and 5000 scfb $H_2$/oil ratio. From the comparison of the two products, it was found that the product from biocrude oil has lower density (0.841 g/ml) fulfill diesel specifications (0.80-0.85 g/ml), lower viscosity (5.3 cSts), higher cetane number (56, fulfill diesel specifications >51) and higher organic phase yields (organic yields: 65.5%wt), compared to the HDT product of pyrolysis oil (density: 0.92 g/ml, viscosity: 9.0 cSts, cetane index: 35, organic yields: 59.5 wt%).

# The key to obtain a high yield of renewable jet fuel from hydroprocessing of fatty acids and esters

Asbjørn S. Andersson[1*], Uffe V. Mentzel[1], Rasmus G. Egeberg[1]

[1]*Topsoe, Lyngby, Denmark*
[*]*assa@topsoe.com*

**Keywords:** Sustainable Aviation Fuel, Renewable Jet Fuel, HEFA-SPK, dewaxing, isomerization
**Introduction.** Sustainable Aviation Fuel (SAF) is a prerequisite for low-carbon travel. Industry players, passengers, and the planet will all benefit. SAF can be produced by different processes and from various feed stock types and Topsoe offers technology solutions for multiple pathways. In this study the focus will be on converting triglycerides or fatty acids into renewable jet fuel.
**Experimental/methodology.** Results from hydroprocessing pilot plant studies reacting both real feed and model feed over a fixed catalyst bed will be discussed.
**Results and discussion.** In order to convert fatty acids and esters into renewable jet fuel the feed stock needs to undergo various types of chemical reactions, like hydrodeoxygenation (HDO), hydroisomerization (HI), and hydrocracking (HDC). Detailed knowledge and control of these reaction mechanisms is key to design a process, that will produce a high yield of renewable jet fuel meeting the ASTM D 7566 specification.

The catalytic reaction with hydrogen to remove oxygen from fatty acids or esters results in mixture of normal alkanes with a melting point point above room temperature. To be used as jet fuel the freezing point needs to be lowered to -40°C or below, which can be achieved by using a hydroisomerization catalyst. Other property requirements like density and distillation curve are also playing a key role in how to balance the different reaction types and to meet these requirement it is also necessary to do some conversion by hydrocracking.

While the boiling point decreases with increasing degree of isomerization, the effect on density is not as unequivocal. Thus, it would be quite attractive to find a catalyst that can do isomerization and density reduction without a high yield loss due to cracking. Data from pilot plant testing of several catalyst formulations will be presented and the results discussed. The effect of the two different HDO pathways[1] leading to either even-numbered alkanes or uneven-numbered alkanes will also be discussed with respect to the consequence on jet yield and density.

**Introduction.** The hydrodeoxygenation (HDO) reaction of m-cresol, a model molecule representative of the lignin-derived bio-oil, is strongly affected by the type of catalyst. Hydrogenation of m-cresol yielding oxygenated compounds such as ketone and alcohol is promoted by supported metals while deoxygenation toward toluene can be promoted by a metal-oxophilic site interface [1]. C-C hydrogenolysis can also takes place by using metals such as Ni [2]. In this work we studied the effect of the interfacial sites between Ni particles and $NbO_x$ species to promote deoxygenation and minimize hydrogenolysis, by preparing a series of Ni-$NbO_x$ dispersed on SBA-15 catalysts and testing in the HDO reaction of m-cresol at gas phase.

**Experimental/methodology.** SBA-15 was prepared by conventional templating method. The Ni-Nb/SBA-15 samples, varying the content of Ni and Nb between 2.5-5 wt.% were prepared by melting infiltration method, followed by thermal treatment at 500 °C for 6 h. The samples were characterized by $N_2$ physisorption, XRD, $H_2$-TPR, STEM and IV-pyridine. The HDO of m-cresol was performed in a fixed-bed reactor operating at 300 °C and atmospheric pressure. The catayst were reduced *in situ* at 500 °C, 1 h, under pure $H_2$ flow before reaction. Reactant and reaction products were analyzed by gas chromatography.

**Results and discussion.** By comparing the product distribution obtained at low level of conversion for all catalysts, important differences were observed depending on the catalyst composition. Oxygenated produts such as 3-methylcyclohexanone and 3-methylcyclohexanol (50 and 19 % of selectivity, respectively) were the major products obtained over Ni/SBA-15, with minor production of toluene (22 %) and phenol (6 %). By introducing niobium to the catalyst, the selectivity to these oxygenated products continuouly decreased while increasing the selectivity to deoxygenated products such as toluene, methylcyclohexenes and methylcyclohexane, with a maximum being observed for a catalyst containing a Nb/Ni molar ratio of 1 (72 % of toluene, 12 % of methylcylohexenes and 6 % of methylcyclohexane). Besides that, phenol is not further detected. The formation of such products can be explained by three main reaction routes: (i) the direct deoxygenation (DDO) to yield toluene, (ii) hydrogenation (HYD) of the aromation ring yielding the ketone and alcohol followed by dehydration to the alkanes which may be further hydrogenated to the respective alkane, and (iii) hydrogenolysis (HYG) of the methyl group yielding phenol. The addition of Nb close to the Ni particles, as evidenced by the characterization results, significantly increased the DDO rate up to 7-fold while eliminating the hydrogenolysis pathway (Figure 1). Thus, the results clearly evidenced that deoxyenation of m-cresol over Ni-based catalysts can be optimized by creating interfacial sites with oxophilic species such as $NbO_x$.

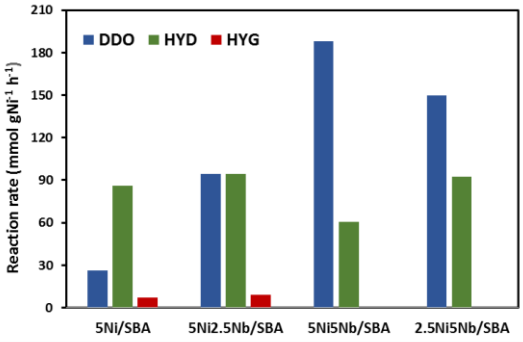

**Figure 1.** Reaction rates for the different reaction routes as a function of catalyst composition.

**Keywords:** Biomass, Waste Valorization, Sugar alcohols, Hydrodeoxygenation, Ionic Liquids

**Introduction.** Due to the high oxygen functionality of biomass, the valorization of renewable substrates to valuable chemicals typically requires deoxygenation reactions, such as deoxydehydration (DODH) or simple dehydration. We hypothesized that if a fast dehydration (by the $Bu_4PBr$ IL) is combined with exclusive hydrogenation of C=O bonds, even in the presence of C=C bonds, the overall sequence may result in the stepwise deoxygenation of a sugar polyol to a bio-olefin, as a kinetically stable end product. By using $H_2$ as a reductant, this is essentially a hydrodeoxygenation (HDO), which would be formally similar to, but a more atom efficient, greener complement to the classical DODH (using $PPh_3$). [1] In this work we successfully converted **crude biowaste glycerol** directly into **biopropylene in high yield (82%) and olefin selectivity (94%)** carefully avoiding overhydrogenation.[2] Next, a series of more complex, economically relevant sugar alcohols (erythritol, xylitol and sorbitol) were converted to their respective mono-olefins.[3] CO was discovered to be crucial to maintain high catalyst stability over multiple cycles, this was confirmed using advanced X-ray Absorption Spectroscopy (XAS) at the European Synchrotron Radiation Facility (ESRF).[4]

**Experimental/methodology.** All reactions were performed in a 10 mL custom-build pressure reactor. A simple pretreatment step with a CO source was performed prior to the catalytic reactions. After each reaction, the mixture is cooled and spontaneous product separation occurs: the catalyst and ionic liquid solidifies and the olefin products are easily extracted in an apolar dodecane layer, quantified *via* GC/GC-MS. Catalyst characterization was based on *in-situ* XANES and EXAFS measurements performed at ESRF in Grenoble (BM23) and Soleil in Paris (SAMBA).

**Results and discussion.** Intensive screening of different hydrogenation catalysts has led to the discovery of homogeneous Ru catalysts resulting in high olefins selectivities, rather than overhydrogenation to the alkane. It was hypothesized that this was a result of the formation of a stable Ru-Carbonyl-Halide complex, in multiple ways, e.g. through pretreatment with CO gas [2], *in-situ* decarbonylating of aldehyde intermediates or *via* controlled thermal decomposition of formaldehyde [3]: All resulting in small partial pressures of CO which are essential to form the desired Ru-hydrogenation complex. The different steps in the formation of the active catalyst were characterized at ESRF to get *in-depth* insights in the Ru environment, confirming changes for both Ru-Halide and Ru-CO interactions.[4] In order to tolerate common waste stream impurities (Water, MeOH, NaCl) found in crude glycerol from *ex-biodiesel* saponification, again CO pretreatment proved to be crucial in maintaining catalyst stability and selectivity over 8 cycles.[2] In addition, the catalyst applicability was extended to other **biobased sugar alcohols**: erythritol, xylitol and sorbitol. All were converted selectively to their respective **mono-alkenes (>95% olefin selectivity)**.[3] To the best of our knowledge, this is the first report of the successful conversion of these higher polyols to mono-alkenes.

**Introduction.** The production of bio-based monomers is a constantly growing field in industry and academia.[1] The synthesis of 2,5-furandicarboxylic acid (FDCA) from 5-(hydroxymethyl)furfural (HMF) is particularly interesting due to the high quantity of possible bio-based feedstocks for HMF production, like cellulose or inulin.[2] The state-of-the-art heterogeneous catalysts for this oxidation process are based on noble metals. However, the use of biomass for the production of FDCA is still a challenge due to its complex nature. To decrease costs and increase the sustainability of FDCA production, all stages of its production have to be optimized with minimal intermediate purification steps and biomass waste, e.g. chicory roots, should be used. To accomplish this, we have studied the influence of by-products in bio-based solutions on the catalysts and optimized the catalytic system accordingly.[3,4] We aim to develop an efficient process for FDCA production by improving the reaction conditions and process design (Fig. 1).

**Experimental/methodology.** Noble metal (Au, Pt, Pd, Ru) based catalysts supported on carbon black were prepared by supporting priorly prepared colloids or by impregnation method. The catalysts were characterized in detail by X-ray diffraction, X-ray absorption spectroscopy, electron microscopy and optical emission spectrometry. The oxidation of pure and bio-based HMF solution was performed in aqueous phase using $Na_2CO_3$ as base and air as oxidant in batch autoclaves as well as in a continuous flow reactor.

**Results and discussion.** The oxidation of HMF solution derived from saccharides was optimized in terms of catalyst composition and process conditions. We found an influence of amino acids deriving from the chicory roots on the oxidation process leading to poisoning of the catalysts. The influence of key amino acids on Au-, Pt-, Pd- and Ru-based catalysts was systematically investigated. Particularly, cysteine and cystine poisoned the catalysts at concentrations in the range of µg $mL^{-1}$. Based on these results, we combined the more stable Pd with the highly active Au in order to obtain an active and robust catalyst. The AuPd alloy outperformed all monometallic catalysts and led to an improved tolerance against sulfur containing compounds. Moreover, we optimized the reaction conditions (T, p, base equivalents) with bio-based HMF solution to minimize the catalyst mass and at the same time achieve an FDCA yield >90%. In addition, we tested higher HMF concentrations in the bio-based feedstock, since high dilution of HMF is often seen as a drawback. Optimization of the base dosage was the key to increasing the FDCA yield leading us to the implementation of a two-step process to enable higher concentrations. Finally, we tested the AuPd-based catalyst in continuous flow oxidation of pure and bio-based HMF solution to investigate on a further improvement of the process design. Continuous operation renders the process more sustainable and economical by avoiding catalyst separation and process interruption between each batch. The identification of critical compounds in bio-derived solution, improvement of the catalyst system and optimization of reaction conditions, allow the development of an efficient process for the production of FDCA monomer from chicory root. This study emphasizes the importance of systematically investigating and rationally optimizing each step to make the overall process feasible for the use of bio-based feedstock.

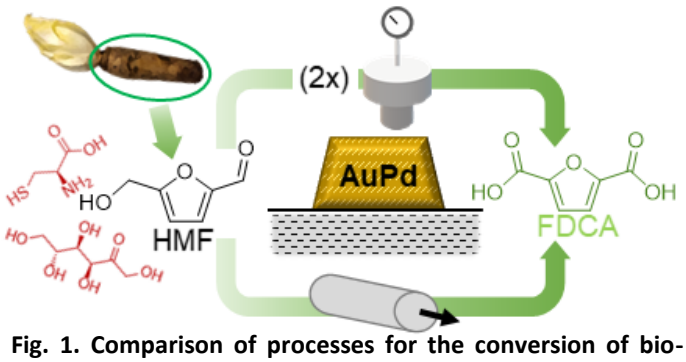

**Fig. 1. Comparison of processes for the conversion of bio-based HMF to FDCA.**

**Keywords:** Polyoxometalates, thermomorphic catalyst, glycolic acid

**Introduction.** Polyoxometalates (POMs) have been identified as promising catalysts for both acid catalysed hydrolysis and retro-aldol reactions as well as metal catalysed oxidation.[1] Their Brønsted acidity and redox activity can be tuned depending on the composition of the POM. Due to the good solubility of POMs in water and organic solvents, recycling strategies are needed to design industrially applicable processes. In our work, we have investigated the oxidative hydrolysis of cellulose to the value-added product glycolic acid (GA), which finds application in the pharma and food industry. Complexation of the most promising POM with a suitable ionic liquid allows the complete recycling of the catalyst.

**Results and discussion.** The POM $H_3PMo_{12}O_{40}$ ($H_3PMo$) was tested among others in the homogeneously catalysed oxidative hydrolysis of cellulose where it outperformed the other POMs yielding 52 % GA at 80 % conversion. Formic acid (FA), 5-hydroxymethylfurfural (5 HMF) and $C_6$-sugars were obtained as side products. To be able to recycle the catalyst we prepared assemblies of $H_3PMo$ with the ionic liquid MIMPS which show a thermo-responsive behaviour (i.e. the catalyst is immiscible with water at RT, but dissolves completely in water at reaction temperature (> 60°C)). Different amounts of MIMPS were used to replace either one, two or all three acidic protons of the $H_3PMo$ resulting in $[MIMPS]_xH_{3-x}PMo$ materials. Compared to the completely homogeneous $H_3PMo$, a similar activity and selectivity was found for $[MIMPS]H_2PMo$ (Figure 1). The main product GA was formed with a yield of 51% and a conversion of 82% was reached. With increasing substitution of protons by MIMPS yield and activity decrease. MIMPS itself is moderately active in the conversion, which can be explained by its minor Brønsted acidity. A successful recycling of the catalyst with minor loss of activity over 5 runs could be shown.

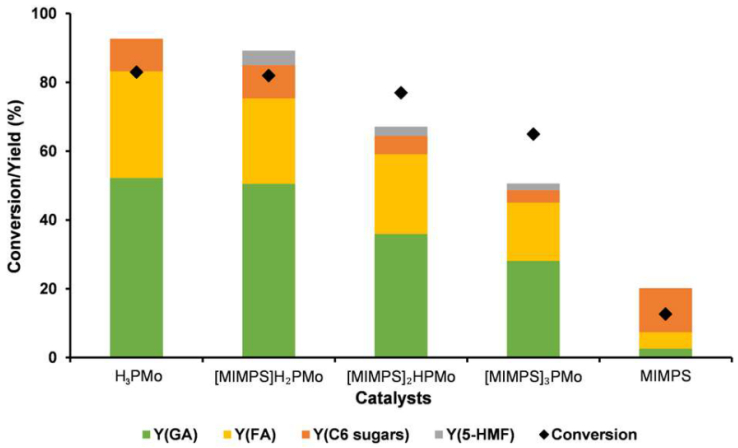

**Figure 1: Effect of $H_3PMo$, $[MIMPS]_xH_{3-x}PMo$ and MIMPS on the oxidative hydrolysis of cellulose. Reaction conditions: 0.1 g cellulose, 150 °C, 0.06 mmol catalyst, 1.0 MPa $O_2$, 8 h.**

**Conclusion.** $H_3PMo$ was identified as promising catalyst for the oxidative hydrolysis of cellulose, which can be solidified by complexation with the ionic liquid MIMPS resulting in a thermo-responsive catalyst showing molecular activity and selectivity. The recyclability of $[MIMPS]H_2PMo$ was shown over 5 consecutive runs confirming its high potential as multifunctional catalyst in different sustainable conversions.

# Oxidation of cyclohexane to KA oil using noble metal-free Ce and Zr-based mixed oxides

Alessandro Vomeri[1*], Marta Stucchi[1], Ana B. Hungria[2], Jose J. Calvino[2], Laura Prati[1]

[1]*Università degli Studi di Milano, Milan, Italy*
[2]*Universidad de Cádiz, Puerto Real, Spain*

**Keywords:** KA oil, cycloehaxane oxidation, mixed oxides, inverse microemulsion, heterogeneous catalysis.

**Introduction.** Cyclohexane oxidation is a key reaction of industrial chemistry as KA oil (a mixture of cyclohexanol and cyclohexanone) is the starting point for the industrial production of nylon-6 and nylon-6,6. However, the reaction presents kinetic and thermodynamic difficulties and proceeds through a complex free radical mechanism. The current industrial process is performed in the presence of homogeneous Co-based catalyst and limits conversion of cyclohexane in order to maintain a relatively high selectivity to K-A oil (around 80% at 4-5% conversion)[1]. In the past years, many heterogeneous catalysts have been studied, such as metal (Au, Ag, Co, V, Fe, Cr, Ti, etc.) supported on oxides, carbons, mesoporous materials and metallorganic structures[2,3]. In this work, a series of non-noble metal (Cu, Fe) Ce and Zr-based mixed oxides, prepared by inverse microemulsion, have been shown to be active in cyclohexane oxidation and open the way to a new class of active catalysts for this reaction.

**Experimental/methodology.** The preparation of the mixed oxides was carried out by inverse microemulsion[4] in order to obtain Ce or Zr mixed oxides containing either Cu or Fe in a lower amount (1:9 molar to the amount of Ce or Zr). A bare Ce-Zr mixed oxide with 1:1 molar ratio was also prepared. These mixed oxides were reduced in the presence of $NaBH_4$ at 300°C in order to introduce defects in the structure of the oxides. The bare oxides and the reduced ones were tested in the catalytic oxidation of cyclohexane at 120°C and 4 bars of $O_2$, using benzaldehyde (10 uL) as radical initiator, as in our previous work[5]. The catalysts were charcaterized by different solid-state analytical techniques, such as STEM/EDX, XRD, BET and XPS.

**Results and discussion.** The prepared materials show better productivity per hour than many of the best state-of-the art catalysts mentioned in a recent 2022 review[6]. Among those, no catalyst outperforms ours at comparably mild reaction conditions (120°C, 4 bar $O_2$) or avoiding the use of expensive radical initiators (TBHP, $H_2O_2$) or the use of noble metals. We found that Ce-based oxides in general behaved better than Zr-based ones. Selectivity control was noticed in Cu-containing bare oxides, which resulted in favouring the more industrially valuable cyclohexanone[7] giving a K/A>1.5, while the other oxides gave a K/A<1. Reducing the mixed oxides, thus introducing some defects and reducing the metals, the Zr-based ones boosted up their activity. The behaviour before and after reduction differs greatly for Cu or Fe containing oxides and this has been correlated with some structural modification. Indeed, studying the variation in the mixed oxides composition (STEM/EDX), lattice parameter (XRD) and oxidation states (XPS) due to the reduction step, we found correlation between the changes in composition and lattice parameter and the resulting productivity. Therefore, Cu and Fe modified Ce and Zr- mixed oxides represent an attractive discovery in terms of ease of preparation, effectiveness and stability.

# The dehydration of fructose to 5-HMF over hierarchical USY zeolites: mechanistic aspects and catalyst optimization

Y. Han, K. Larmier, G. Pirngruber*
*IFP Energies nouvelles, Solaize, France*
**gerhard.pirngruber@ifpen.fr*

**Introduction.** 5-HMF is a very important intermediate for the production of biomass-based products. It is obtained by Bronsted acid catalyzed dehydration of fructose. Selectivity is a big issue: the formation of by-products (humins) resulting from oligomerization reactions must be avoided [1]. Large pore zeolites are promising candidates as heterogeneous catalysts, but even 12MR pore systems might encounter diffusion problems in the conversion of bulky sugar molecules. In our study we first evaluated a series of commercial USY zeolites with varying acidity and mesoporosity. We then modified the acidity and porosity of the USY zeolites by acid and base treatments, in order to optimize their activity and selectivity.

**Experimental.** The conversion of fructose by zeolite catalysts was carried out in DMSO solvent (in order to inhibit Lewis acid catalyzed reactions) at 95°C. The products were analyzed by HPLC and NMR. For introducing hierarchical porosity in USY zeolites a base treatment with tetralkylammonium hydroxide was employed (0.2 M, 65°C, 2h), if necessary preceded by a dealumination step with oxalic acid.

**Results and discussion.** Some of the commercial USY zeolites were active and selective catalysts for the production of 5-HMF from fructose. 5-HMF was not a primary product; it only appeared after a short induction period. By dedicated experiments with labelled fructose we could identify the intermediates on the pathway to 5-HMF [2]. Quite surprisingly, the 5-HMF production rate was anti-correlated with the concentration of Bronsted acid, but increased with increasing mesopore volume of the zeolite (Figure 1). We, therefore, decided to explore USY catalysts with increased mesopore volume, obtained by desilication with a base. USY zeolites are quite sensible to base treatment and easily loose crystallinity, unless organic protecting agents are added during the treatment. They impede amorphisation by adsorbing on the pore surface. We tested tetralkylammonium cations of different chain lengths, from C1 to C4, as protecting agents. Methyl had a weak protecting effect. It generated high mesopore volumes, but also led to significant amorphisation of the zeolite structure. On the other extreme, butyl had a strong protecting effect and, thus, limited the mesopore formation. The best compromise was found with tretrapropylammonium hydroxide. The Si/Al ratio of the zeolite also played an important role. Zeolites with low Si/Al ratio were quite inert during the base treatment, while high Si/Al ratios easily amorphised. The optimal range of Si/Al for applying the base treatment was between 16 and 27 (Figure 1c).

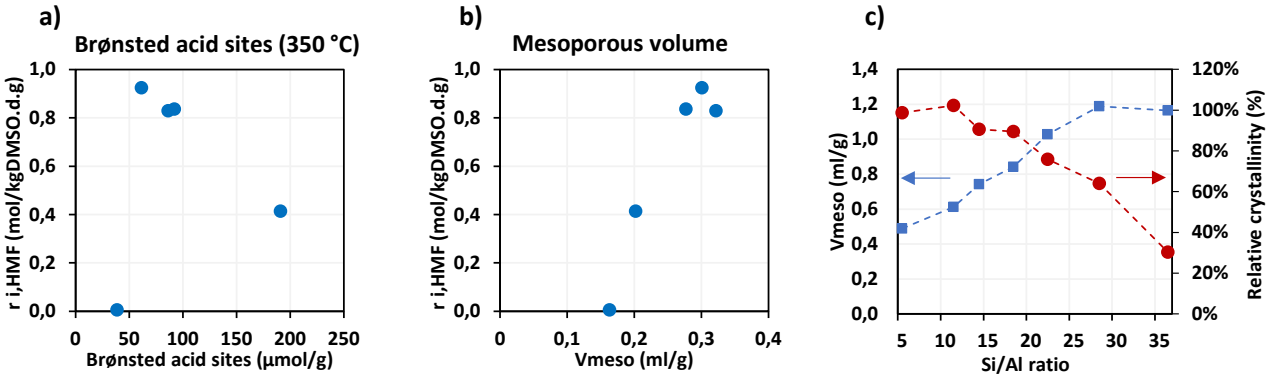

Figure 1 Rate of 5-HMF production as function of a) Bronsted acid site concentration and b) mesopore volume of commercial USY zeolites. c) Compromise of mesopore volume vs crystallinity.

The hierarchical USY zeolites were tested in the conversion of fructose and showed surprising results. If a gain in mesoporosity was obtained by sacrifying crystallinity, the activity was low. At constant mesopore volume, increasing the Bronsted acid site concentration had a detrimental effect on activity. We are currently investigating whether this is related to an increase in hydrophilicity, leading to inhibition by $H_2O$ generated during the reaction. Still, a minimum concentration of Bronsted acid sites remains indispensable; increasing mesoporosity is beneficial if it increases the accessibilty of Bronsted acid sites.

**Keywords:** hydrodeoxygenation, nickel catalyst, solid acidic support, phase change material

**Introduction.** Linear even number hydrocarbons (*n*-$C_{16}$ and *n*-$C_{18}$) as phase change material (PCM) can be produced via selective hydrodeoxygenation (HDO) of vegetable oil and suppression of other side reactions. It was reported that the conventional hydrotreating sulfided Mo/$Al_2O_3$ catalysts with a little addition of Co showed high selectivity toward the hydrodeoxygenation (HDO) pathway [1]. Additionally, the selectivity could be controlled by using the acidic zeolite supports, e.g. SAPO-11, HBeta and ZSM-22 [2-4]. Also, the addition of P to the Ni catalyst [5] or the use of a bimetallic Mo- Ni catalyst [6] can promote significantly the HDO pathway. How to selectively obtain even hydrocarbons have not been clarified. Hence, in this study, the influence of several acidic support on the formation of the active phase on Ni-based catalyst, the reaction pathway and the yield of *n*-paraffin was investigated. In addition, the addition effect of the promotor on Ni catalysts and reduction condition were also investigated.

**Experimental.** Ni based catalysts were prepared by impregnation method using $Al_2O_3$, SAPO-11 and H-Beta etc. These samples were characterized by using BET, pyridine FT-IR, CO chemisorption, XPS and $H_2$-TPR. Their catalytic performance in hydrotreating of methyl laurate and Palm Fatty Acid Distillate (PFAD) were tested by using a fixed-bed flow reactor system. The reactions were conducted at different temperatures (275–375 °C) and under 3 MPa. The liquid products were analyzed using GC-FID and GC-MASS.

**Results and discussion.** Ni/HBeta and Ni/SAPO-11 demonstrated higher activity and isomerization selectivity than Ni/$Al_2O_3$ due to the presence of the Brønsted acid on the supports. In addition, Ni/HBeta and Ni/SAPO-11 showed higher selectivity of *n*-$C_{12}$ at 275 °C and 300 °C, respectively. Ni/$Al_2O_3$ showed lower *n*-$C_{12}$ selectivity than the zeolite catalyst due to its lower activity compared to other catalysts, and increased cracking selectivity due to its large pore size. Consequently, it was concluded that Brønsted acid affect the formation of $Ni^0$ species which is related with activity of the catalyst; however, it also promoted the isomerization and cracking reactions. Further, Comparing with Ni/ALPO-11, Ni/SAPO-11 showed higher deoxidation activity and selectivity to *n*-$C_{12}$.

The addition effect of various promoters such as Fe, Ru, W, Mo and Re etc. on Ni/SAPO-11 was investigated. The addition of the promoter inhibited cracking and isomerization. Comparing with other promoter, the addition of Mo onto Ni/SAPO-11 significantly resulted in increasing selectivity to *n*-$C_{12}$ because of modification to adsorption mode of methyl laurate onto HDO active site. Further, the addition amount of Mo to Ni/SAPO-11 catalyst was optimized. It was found that NiMo/SAPO-11 catalyst with Ni/Mo=8 showed the highest selectivity to *n*-$C_{12}$. It is suggested that the addition of Mo enhanced the reduction of Ni; and the presence of a little amount of $MoO_x$ (x<3) inhibited the decarbonylation reaction (formation of $C_{11}$) via changing adsorption mode of methyl laurate on to HDO active sites. Also, it was found that the conversion of methyl laurate and selectivity to *n*-$C_{12}$ on NiMo/SAPO-11 catalyst increased with increasing reduction temperature from 400°C to 550°C due to the formation of $Mo^{4+}$ and $Mo^{5+}$.

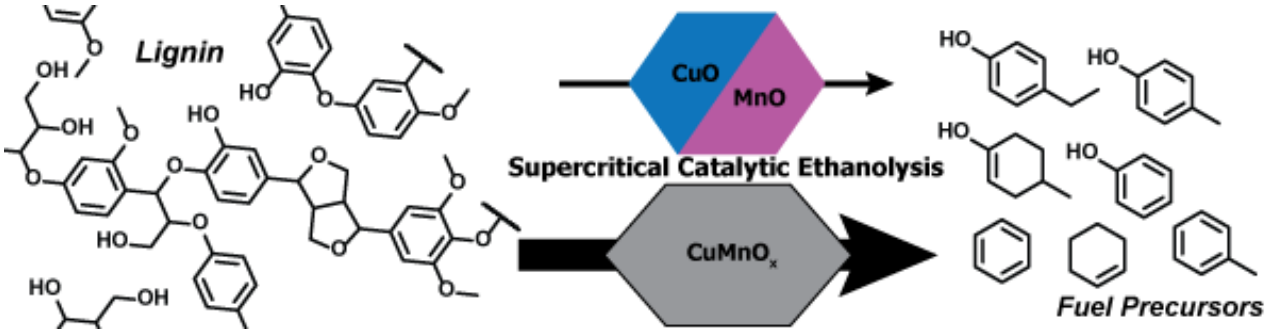
**Introduction.** Northern Europe and Canada are the countries of intensive utilization of forest biomass. The main use of biomass is the production of pulp and paper via the Kraft process, which implies that lignin and most part of hemicelluloses are dissolved in alkali under elevated temperatures, whereas cellulose fibers remain in solid form. A very valuable side product of Kraft pulping is tall oil, which consists of fatty acids, e.g. oleic, linoleic, linolenic and abietic acids. In developing the most modern biorefineries, a further refinement of the tall oil fatty acids (TOFA) is an acute issue. Epoxidation of unsaturated fatty acids with hydrogen peroxide is an attractive alternative, since epoxidized fatty acids and fatty acid esters can be used as intermediates for biolubricants, plasticizers, biobased rigid foams and non-isocyanate polyurethanes. The classical technology for fatty acid epoxidation is an indirect process requiring a reaction carrier, such as formic or acetic acid, which reacts with hydrogen peroxide giving a percarboxylic acid as the real epoxidizing agent. This complicated multiphase process has a safety risk because of the appearance of percarboxylic acids. Therefore, the direct epoxidation of fatty acids in the presence of an immobilized enzyme is an attractive green and safe pathway to epoxidized fatty acids. The main challenge is to find a catalyst for direct epoxidation. Enzymatic epoxidation was investigated in this work, including kinetic experiments, process intensification with the aid of acoustic irradiation and very detailed kinetic modelling.

**Experimental/Metholology**. Immobilized lipase *Candida Antarctica* lipase B on an acrylic resin support (Novozym® 435, Novo A/S) was used as as the catalyst and aqueous hydrogen peroxide as the epoxidation agent. Extensive kinetic and catalyst stability studies were conducted in a jacketed laboratory-scale glass reactor, which was operated both in batch and semibatch modes: hydrogen peroxide was added to the reaction mixture either instantaneously or gradually. Intensive stirring was applied to maintain the oil-in-water system. The reactor was equipped with an ultrasound stick to investigate the effect of acoustic irradiation on the reactant conversion and product selectivity. The reactant molar ratio, temperature, stirring rate and hydrogen peroxide addition policy were the experimental parameters. The concentrations of epoxide groups and double bonds were determined by titrimetric analysis and the ring-opening products were identified by proton NMR. The catalyst morphology was investigated by SEM.

**Results and discussion.** The experimental results showed that almost complete conversions of the double bonds in oleic acid are achievable in isothermal batch and semibatch operation conditions, with low concentrations of ring-opening by-products formed. Ultrasound irradiation enhanced the rate and retarded the catalyst deactivation, and higher oleic acid conversions were reached compared to silent conditions. Kinetic modelling of the experimental data was based on the following stoichiometry: A + H = B + W, A+ B = R + A where A= oleic acid, H= hydrogen peroxide (HP), B=peroleic acid, W= water, R= epoxide. The adsorption and desorption steps in the reaction mechanism were assumed to be rapid, whereas the surface reaction steps were taken as rate determining. Rate equations for the formation of peroleic acid and epoxide were derived and the numerical values of the kinetic and adsorption parameters were estimated with non-linear regression analysis. The model equations (ODEs) were solved numerically. The model gave a very good fit to the experimental data as illustrated below (left: batch, right: semibatch operation; blue: oleic acid (OA), yellow: hydrogen peroxide (HP), magenta: epoxidized oleic acid (EOA).



# Copper Manganese Spinel Oxide for Enhanced Solvolysis of Technical Lignin

Davey F. de Waard[1], Panos D. Kouris[1], Michael D. Boot[1], and Emiel J.M. Hensen[1]
[1]*1Eindhoven University of Technology, 5600 MB Eindhoven, The Netherlands*

**Keywords:** Lignin, Catalytic solvolysis, Ethanolysis, Copper-Manganese, Spinel Oxides

The aromatic nature of lignin makes it a prime feedstock for the production of renewable aromatic compounds. Due to its recalcitrant and heterogenous nature, extraction of aromatic monomers has been proven challenging thus far.[1] The use of a Cu-Mg-Al mixed metal oxide can effectively depolymerise technical lignin in supercritical ethanol.[2] In an effort to improve the activity of such mixed oxides, various first row transition metals were screened as dopants for the Cu-Mg-Al mixed metal oxide. Among these, Mn showed promising performance in terms of monomer extraction and solvolysis performance. XRD and XPS indicated the formation of a Cu-Mn spinel oxide. Cu increased the reducibility of Mn, indicating its potential role in the observed synergy. In order to investigate the role of the Cu-Mn spinel oxide in the catalytic solvolysis in more detail, various spinel oxides were synthesized through impregnation and co-precipitation methods. Their catalytic performance was determined in the solvolysis of technical soda lignin (P1000) in supercritical ethanol. Proximity effects of the Cu and Mn species were evaluated using single metal oxide catalysts as reference. The Cu-Mn spinel oxide was found to produce the highest aromatic monomer yield of 35 wt% with full solvolysis of lignin oligomers.

# The supported Cu-Ni bimetallic catalysts for vapor phase conversion of furfuryl aldehyde

J. Kaim, M. Śliwa, K. Samson, M. Zimowska, M. Ruggiero-Mikołajczyk, J. Podobiński, M. Witko, D. Rutkowska-Zbik*

*Jerzy Haber Institute of Catalysis and Surface Chemistry PAS, Krakow, Poland*
**dorota.rutkowska-zbik@ikifp.edu.pl*

**Keywords:** furfuryl aldehyde, hydrogenation, decarbonylation, bimetallic catalysts

**Introduction.** Furfuryl aldehyde (furfural, FAL) is an aromatic compound, which is commonly known as an important platform molecule. It can be produced in huge quantity via acid hydrolysis of pentoses, five-carbon sugars, such as xylose and arabinose [1]. The catalytic conversion of FAL leads to the broad range of products, which are valuable intermediates from the point of view of the bio-fuels technology and chemical industry. The distribution of products strongly depends on the catalyst nature (metal type, support properties) and the reaction conditions. Among detected products, furfuryl alcohol (FOL) and 2-methylfuran (2-MF), are of great importance. The hydrogenation of FAL can be performed over catalysts containing transition metals: Cu, Ni, Co, Fe, Pt, Pd [2]. The goal of this work was to study the FAL conversion pathways over bimetallic Cu-Ni supported catalysts and influence of the support type on the catalyst final activity.

**Experimental/methodology.** The bimetallic Cu-Ni catalysts were supported on $SiO_2$, $CeO_2$ and $ZrO_2$ via wet impregnation method. The obtained catalysts, referred as $Cu_{1.0}Ni_{1.0}/ZrO_2$, $Cu_{1.0}Ni_{1.0}/CeO_2$, $Cu_{1.0}Ni_{1.0}/SiO_2$ and $Cu_{2.5}Ni_{2.5}/ZrO_2$, $Cu_{2.5}Ni_{2.5}/CeO_2$, $Cu_{2.5}Ni_{2.5}/SiO_2$, were characterized by the following several techniques: XRD, $H_2$-TPR, $N_2$-physisorption, XRF and SEM/EDS. The catalytic reaction was performed in the fixed-bed flow reactor. The products and substrates were analyzed using gas chromatograph equipped with FID detector. For typical measurement, the 150 mg of catalyst was mixed with quartz and placed in the reactor. Next, the sample was reduced in the mixture of 20%$H_2$/Ar and temperature was lowered to 120 $^oC$. The thermostated bubbler at 54.5 $^oC$ was used to generate vapors of FAL. The volume ratio of FAL to hydrogen in the reaction stream was 1:10. The catalytic reaction was carried out at 120$^o$C, 160$^o$C and 200$^o$C.

**Results and discussion.** The XRD analysis revealed the presence of CuO and NiO phase only in the case of catalysts supported on $SiO_2$. On the other hand, no XRD reflexes assigned to active phases are present in the diffraction patterns of catalysts supported on $CeO_2$ and $ZrO_2$. This can result from the very small crystallites of CuO and NiO which are formed on the surface of $CeO_2$, below the detection limits of XRD. Nevertheless, the presence of copper and nickel on the support was confirmed by XRF analysis, which showed that determined concertation values of both active phases closely corresponds with nominal values. In the $H_2$-TPR profiles of bimetallic catalysts overlapping signals of CuO and NiO reduction are present. The position of these signal depends on the used supports and for all catalysts is below the reduction temperature of standard CuO and NiO. In the case of all catalysts, the conversion of FAL increases with the temperature of the reaction, reaching 73% for $Cu_{1.0}Ni_{1.0}/CeO_2$ at 160 $^oC$. The selectivity to FOL is the highest when reaction is performed at 120 $^oC$ (33% for $Cu_{2.5}Ni_{2.5}/SiO_2$). The increase of temperature causes that selectivity to FOL drops and furan starts to dominate among detected products. This proves that decarbonylation pathway is favored over hydrogenation of FAL. Additionally, 2-MF and propane was also detected which suggests that hydrogenolysis and ring opening reactions occur over synthesized catalyst too.

# "Catalytic valorization of sugarcane molasses to 5- hydroxymethylfurfural (HMF) in water"

K. Morawa Eblagon[1,2]*, J. L. Figueiredo[1,2], M. Fernando R. Pereira[1,2]

[1]*LSRE-LCM - Laboratory of Separation and Reaction Engineering – Laboratory of Catalysis and Materials, Faculty of Engineering, University of Porto, Rua Dr. Roberto Frias, 4200-465 Porto, Portugal*

**Keywords:** biomass conversion, 5-hydroxymethylfurfural, dehydration, sugarcane molasses

**Introduction.** Technologies transforming renewable carbon sources such as agroindustrial residues into chemicals or liquid fuels are urgently needed to address the energy crisis and environmental issues linked with the extensive reliance on fossil fuels. Within this context, sugarcane molasses (SCM), a waste product from the sugar industry, can be transformed into a versatile biorefinery intermediate called 5-hydroxymethylfurfural (HMF) using a solid acid catalyst in water. The dehydration of SCM involves multiple steps, which can be catalysed by Lewis acids in combination with organic acids [1], or amorphous carbon with strong Brønsted acid sites [2].

**Experimental/methodology.** Environmentally friendly carbon catalysts derived from rice starch were obtained via a hydrothermal carbonization method. The catalysts included: i) amorphous carbon with only Brønsted acid (BA) sites in the form of -$SO_3H$ groups (abbr. C-$SO_3H$) and ii) a bifunctional catalyst (abbr. C-P-$SnO_2$) having a combination of BA sites (i.e. P-OH groups) and Lewis acid (LA) sites (i.e. $SnO_2$). The conversion of sugarcane molasses to HMF was studied in water using a microwave reactor. In order to discard the influence of impurities present in industrial SCM, the reaction parameters were first optimized using synthetic SCM (i.e., a neat mixture of sucrose, glucose, and fructose) and then validated in industrial-grade SCM.

**Results and discussion.** HMF production from synthetic SCM was enhanced when high temperatures (190 °C) and moderate catalyst/substrate ratios (0.1) were employed in short reaction times (20-30 min). A higher HMF yield of 30.6% was obtained using C-$SO_3H$, containing only BA sites, compared to 25.9% recorded for bifunctional C-P-$SnO_2$. Insufficient isomerization of glucose to fructose was a major barrier to achieving higher yields of HMF from synthetic SCM using C-$SO_3H$. In contrast, LA sites on C-P-$SnO_2$ successfully catalysed glucose isomerization to fructose. However, the slower sugar to HMF conversion rate rendered a lower overall HMF yield on this catalyst.

When industrial-grade SCM was applied as a feedstock, a steep decrease in HMF yield from 30.6% to 12.5% was recorded using C-$SO_3H$. It was noted that the conversion of sugars (i.e., sucrose, glucose, and fructose) was higher in the case of crude feedstock. Still, the selectivity to HMF was significantly lower. The analysis of the reaction side-products showed that HMF was likely further converted to insoluble humin. The non-sugar impurities facilitated the side reactions in industrial SCM. Last but not least, different methods of industrial SCM pretreatment were considered to increase the yield of HMF.

# Designed seafood waste-biochar catalysts for sustainable biorefinery

Andreia F. Peixoto*, Inês S. Marques, Renata Matos, Marta Monteiro, Diana M. Fernandes

[1]*LAQV-REQUIMTE, Dep. de Química e Bioquímica, Faculdade de Ciências, Universidade do Porto, Rua do Campo Alegre s/n, 4169-007 Porto*

**Keywords:** biorefinery, biochar based catalysts, biomass conversion

**Introduction.** Despite the abundance of carbon in nature, a significant portion of the existing biomass carbon materials in livestock, agriculture, and marine fishery industry are currently being wasted. Most of seafood waste (SW) is disposed into landfills or back into the ocean being associated with several environmental issues. Because of the reactive amino-group, chitin-derivatives can serve as novel platform molecules for the synthesis of a plethora of industrially valuable chemicals and materials.[1,2] Following the concept of biorefinery and circular bioeconomy, the Shell4BioA project arise to meet these challenges targeting the production of biobased products including bioamines and designed biochar materials from SW aligned with green chemical principals and with the goals for the sustainable development. Several designed SW-biochar catalysts (sulfonic-acid functionalized and metal-supported) were prepared and used to produce biobased chemicals, biofuels and energy in a biorefinery concept.

**Experimental/methodology.** Shrimp shells obtained from portuguese marine fishery industry were frozen, dried, grounded (particle size < 0.5 mm) and stored in sealed bags at room temperature until use. Biochar-based catalysts were prepared according to modified procedures from literature[3,4]. Metals/metal oxides (Metal: Co, Fe, Co-Mo, Ni, etc.) were supported on the N-doped SW-biochar using co-precipitation, wet impregnation and ball milling mechanic impregnation.[3] The biochar-based catalysts functionalized with sulfonic acid groups were prepared by mechanical synthesis by mixing the biochar with the organic sulfonic acids precursors. All catalysts have been used in catalytic reactions for the production of biobased products: ethyl levulinate, furfuryl alcohol, methylfuran and bio-based amines.

**Results and discussion.** Herein, we present the preparation of several designed SW-biochars. The activation under chemical/physical experimental conditions allowed to obtain high surface areas (BET > 200 $m^2$/g).The sucessfully preparation of the funcionalized catalysts was verified by XPS, XRD, Raman, FTIR and SEM/EDS; the formation of highly porous structures was displayed in SEM and, XPS results showed the presence of N-functionalizations. Ethyl levulinate (EL) was obtained from 5-HMF with (EL yield = 90%) at 130 °C over the sulfonic acid funcionalized biochar (after 6 h reaction). The catalyst is recyclable without significant loss of catalytic activity. γ-Valerolactone (GVL) was also obtained (yield > 95 %) from furfural, as an additional valuable chemical and an intermediate in the production of fine chemicals using only water and formic acid at 280 ºC, 4h reaction using Co-Mo supported SW-biochar catalyst. All the catalytic results and the catalysts perfomance will be discussed according to the characterization results.

# Comparison of oxygen and hydrogen peroxide as oxidants for obtaining furoic acid from furfural over supported gold catalysts

P. Rapado, L. Faba, S. Ordóñez*

[1]*Department of Chemical and Environmental Engineering, University of Oviedo, Oviedo, Spain*
**sordonez@uniovi.es*

**Keywords:** furfural upgrading; sustainable polymers; aqueous-phase partial oxidation; biorefinery

**Introduction.**

Furfural is one of the most versatile bioplatform molecules since the technologies for its production from biomass are well-established and even commercially available. This fact is especially important in comparison to HMF, whose manufacturing procedures are less developed. Among the chemicals that can be synthesized from furfural, furoic acid (FCA) is of key relevance because of its chemical applications and, mainly, since its carboxylation produces the furfuryl dicarboxylic acid (a renewable monomer).[1] Two different oxidants are considered for FCA production from furfural, $H_2O_2$ (allowing working at mild temperatures and pressures) and air (cheaper and more sustainable, but requiring harsher reaction conditions). In both cases, gold catalysts are considered the most active ones.[2] The scope of this work is to compare both oxidations, identifying their key steps and proposing a comprehensive kinetic model.

**Experimental/methodology.**

The reactions were performed in a stainless-steel autoclave reactor of 0.5 L total volume of a 0.5 M solution of furfural. Experiments were carried out at 0.5 MPa of $N_2$ ($H_2O_2$) or in a pressure range of 0.5-2 MPa (pure $O_2$) comparing two catalysts: Au/$TiO_2$ and Au/Mg-Al (mixed oxides). Reaction products were analyzed by HPLC.

**Results and discussion.**

The high reactivity of $H_2O_2$ allows working at lower temperatures (50$^o$C) than when using $O_2$ (no reaction observed below 80$^o$C), but the selectivities to FA reached with $H_2O_2$ were markedly lower than those obtained with $O_2$. The optimum conditions with $H_2O_2$ lead to a FCA selectivity of 20 %, with a furfural conversion of 40 % (50$^o$C, similar results for both catalysts). The selectivities to other by-products as maleic acid (MA) and 2-hydroxyfuran (HF) are in the same order of magnitude. The kinetic analysis of these data and those obtained with separate experiments with intermediate products suggest that both FCA and HF are primary products that undergo secondary reactions yielding MA, among other organic acids. The oligomerization of furfural to humins is not relevant at these conditions, likely because of the lower reaction temperature.

When using $O_2$ as the oxidant, the product distribution changes markedly, being possible to work at high conversions (>60%) with FCA as the only organic acid detected (Au/$TiO_2$, 100ºC, 0.2 MPa). At higher temperatures, the formation of MA starts to be relevant, but always at one order of magnitude lower than the FCA selectivity. By contrast, the formation of insoluble humins is more important working with $O_2$ (leading to carbon balance unclosures of about 20 %; <5 % with $H_2O_2$). Higher $O_2$ pressures have a positive effect on the FCA selectivity because of two concomitant causes, the increase in the FCA formation rate (more marked in the case of using Au/MgAl), and the unexpected inhibition of the humins formation. Obtained results were fit to a mechanistic kinetic model useful for both understanding the reaction mechanisms and designing the optimum chemical reactors for this purpose.

**Keywords:** Furfural, γ-valerolactone, continuous flow, Ti/Zr/O catalysts

**Introduction.** The molecule γ-valerolactone (GVL) has recently gained great attention as a green solvent and additive as well as versatile building block for chemical synthesis [1]. Biomass-derived GVL is currently produced by a multistep process using acidic and metal-based catalysts and this strategy suffers from several limitation. GVL can also be produced by acid-catalysed cascade reactions from furfural (FU) using catalytic transfer hydrogenation (CTH) reaction as alternative to molecular $H_2$ reductions. This process can be industrially relevant due to the high availability of FU on industrial scale and his good solubility in most solvent, moreover the use of CTH approach, with alcohols acting as solvent and H-donor can maximize the product yields without the use of precious metals, high $H_2$ pressure and an excessive number of operations. The direct conversion of FU to GVL in a single reaction step requires the development of appropriate catalysts with both Lewis and Brønsted acidity. Zr-Al materials and zeolite were demonstrated to be active in the reaction in batch reaction,[2] nevertheless, considering the growing interest in FU conversion to GVL, the developing of more efficient and scalable process using CTH approach in continuous mode is still necessary.

In this study, we demonstrated the application of Ti/Zr/O as effective catalysts for the one-pot reaction of FU into GVL in a continuous flow liquid phase reactor using 2-propanol as solvent and H donor.

**Experimental.** Ti/Zr/O catalysts ad different Ti/Zr ratio were synthesized via coprecipitation in 5 M $NH_4OH$, then digested for 48h at pH 9 before calcination at 500°C. The materials were characterised through XRF, XRD, NH3-TPD and porosimetry. Catalytic tests were carried out feeding the solution of FU in 2-propanol (2-propanol/FU molar ratio 200) onto 1 mL of catalyst kept at 180°C, with residence time of 10 min.

**Results and discussion.** While XRD highlighted no noticeable segregation of either titania or zirconia in the synthesized materials, $NH_3$-TPD revealed a nonlinear effect of the increase of Ti content on the acidity of the catalysts: a maximum of acid sites density is registered with an equimolar amount of Ti and Zr. This was correlated with the catalytic performances, showing a maximum in GVL selectivity. The mechanism of the reaction has been studied by investigating the reactivity of the intermediates and varying reaction parameters, such as contact time and temperature. The long-time performance of the catalysts has been studied showing promising catalytic stability and the catalytic data have been correlated with the characterisation of the fresh and used catalysts.

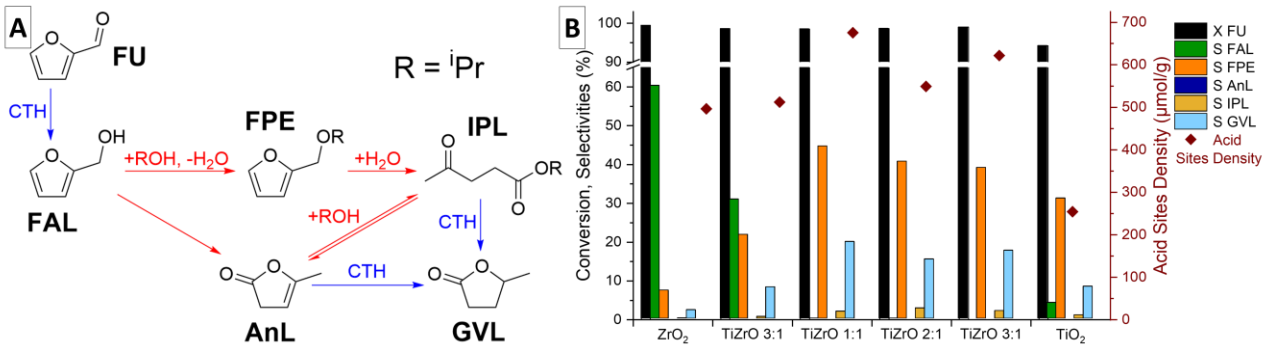

**Figure 1. Scheme of the studied reaction (A). Catalytic performances of the tested materials (B).**

**Keywords:** biomass-derived polyols, secondary alcohol, hydrodeoxygenation, regioselectivity

**Introduction.** Selective recognition and activation of target C–O bonds of substrates are critical but quite challenging for the transformation of renewable biomass-derived polyols to platform chemicals in the chemical industry. The C–O hydrogenolysis for the secondary OH groups to produce primary alcohols from 1,2-diols has been achieved so far by using Ir–$ReO_x$ and Pt–$WO_x$ catalysts.[1-2] In stark contrast, effective catalysts have not yet been developed for selectively removing the primary OH groups of biomass-derived polyols. In order to extend the scope of products from biomass, various types of catalysts with different regioselectivity in hydrogenolysis of polyols are necessary. The catalysts with good selectivity to secondary alcohols from 1,2-diols will offer a new route for biomass conversion, such as 2,3-butanediol (a platform chemical for pharmaceutical, cosmetic, and polymer industries) from erythritol. Here, Ir-$MO_x$/rutile $TiO_2$ (M: Fe, Mn, Co, Ni, Cu, Zn Ga, In, Sn) was explored for 1,2-butanediol (1,2-BuD) hydrogenolysis as a model reaction to develop catalyst with such regioselectivity, considering available biomass-based 1,2-BuD from erythritol[3] and wide applications of 2-BuOH (such as fuel additive and solvent). Ir-$FeO_x$/rutile was found to be effective for the removal of primary OH group of 1,2-diols and related alcohols by hydrogenolysis.[4]

**Experimental.** Ir-$MO_x$/rutile catalysts were prepared by a sequential impregnation method. The activity test was carried out in a stainless-steel autoclave (190 mL) equipped with an inner glass vessel. The organic substances in both liquid and gas phases were analyzed by FID-GC and HPLC.

**Results and discussion.** As shown in Figure 1, the selectivity to 2-butanol (2-BuOH) over Ir/rutile $TiO_2$ (Ir = 5 wt%) was moderate (53%) initially but rapidly decreased (39%) at longer reaction time (72 h). Addition of Fe to Ir/rutile enhanced both activity and selectivity, while other screening modifiers were not effective. Fe/Ir ratio was further optimized as 0.25. Other oxide supports including anatase $TiO_2$ gave lower selectivity to 2-BuOH. Severe deactivation phenomenon was observed during reuse experiment over the Ir-$FeO_x$/rutile (Ir = 5 wt%, Fe/Ir = 0.25) catalyst. Interestingly, the reusability of catalyst was reinforced by optimizing the preparation method (involving the calcination followed by reduction and subsequent loading of Fe; $Ir_{c-r}$-$FeO_x$/rutile). $Ir_{c-r}$-$FeO_x$/rutile (Ir = 5 wt%, Fe/Ir = 0.25) was reusable at least 4 times and gave high 2-BuOH yield (64%) from 1,2-BuD. Such regioselectivity given by $Ir_{c-r}$-$FeO_x$/rutile was also demonstrated in the hydrogenolysis of related alcohols (Figure 2): 1,2-propanediol to 2-propanol (yield: 53%), glycerol to 2-propanol (yield: 30%), 1,3-butanediol to 2-BuOH (yield: 83%), and erythritol to 2,3-butanediol (yield: 30%). The characterization with XRD, $H_2$-TPR, TEM-EDX, XANES, EXAFS, CO adsorption and DRIFT of adsorbed CO suggested that Ir particles with Ir-Fe alloy on the surface (3 nm) modified with $FeO_x$ species were constructed on the active catalyst. The active sites should be the interface between Ir-Fe surface alloy and $FeO_x$ species.

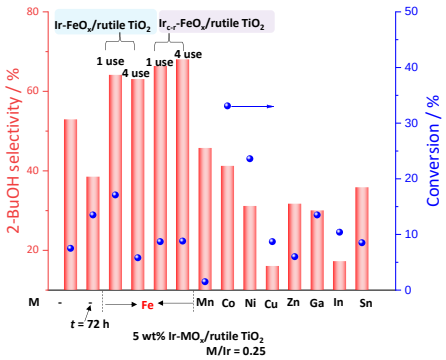

Figure 1. 1,2-BuD hydrogenolysis over Ir-$MO_x$/rutile catalysts.

Reaction conditions: 1,2-BuD = 0.5 g, $H_2O$ = 4 g, $m_{cat}$ = 0.2 g, $P(H_2)$ = 8 MPa, $T$ = 453 K, $t$ = 24 h.

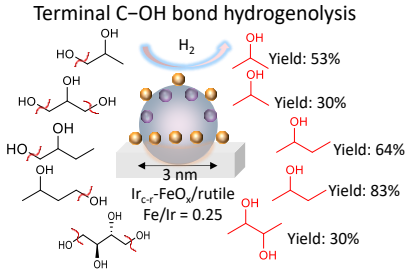

Figure 2. Related alcohols hydrogenolysis.

**Keywords:** Deoxygenation; Anisole; Nickel catalyst; Reaction pathway; Reaction equilibrium.

**Introduction.** Lignin is a major natural polymer that constitutes about 30 % of biomass and it is a potential source of sustainable chemicals. Depolymerization of lignin results in phenolics like guaiacol, syringol, and catechol. Deoxygenation (DO) of these compounds may produce aromatics (eg., benzene) from sustainable feedstock (waste lignocellulosic biomass). DO of lignin-derived phenolics also produces hydrocarbons with boiling points in the range of transportation fuels. In this study, anisole (methoxybenzene) was chosen as a model compound for the investigation of the DO pathway over nickel-based catalysts.

**Experimental/methodology.** 5-16 wt% $Ni/Al_2O_3$ catalysts were prepared by wet impregnation using nickel nitrate as the precursor and alumina granules as the support. The catalysts were characterized using ICP-OES, XRD, BET, TPR, and $H_2$-chemisorption. Testing of the catalysts for DO of anisole was carried out in a continuous flow reactor at 80-300 °C, 5-40 bar $H_2$, and weight-hourly space velocity (WHSV) 12-180 $h^{-1}$. The use of a wide range of reaction conditions allowed the depiction of the reaction progression and equilibrium conditions. The most abundant reaction intermediates like methoxycyclohexane and cyclohexanol were also deoxygenated to study the side reactions and trace intermediates.

**Results and discussion.** The DO of anisole initiates through hydrogenation of the aromatic ring, resulting in the formation of methoxycylohexane, at temperatures lower than 160 °C. At temperatures above 160 °C, methoxycyclohexane undergoes demethoxylation to cyclohexane. Traces of cyclohexanol (maximum selectivity of 6%) were detected, suggesting the demethylation of anisole throughout the observed temperature range. Phenol which is a precursory intermediate for cyclohexanol formation was seen only at very low anisole conversion at WHSV 120 and 180 $h^{-1}$, 270 °C, and 5 bar. At moderate pressures (5-12 bar), dehydrogenation of cyclohexane to benzene was observed above 220 °C. Deoxygenation experiments with methoxycylohexane and cyclohexanol (the most abundant reaction intermediates) showed the significance of hydrogenation-dehydrogenation reaction equilibrium in determining the anisole DO product distribution. Additionally, in the pressure range of 5-12 bar transmethylation reactions were observed above 260 °C. This work shows that the DO of anisole over nickel catalysts may result in a myriad of compounds depending on the process conditions.

## Introduction

Hydrodeoxygenation (HDO) is a hydrotreating catalytic process that is being widely investigated nowadays. Among its several applications, HDO can be used to transform O-rich liquids derived from biomass to high value aromatic hydrocarbons that are currently produced from depleting petroleum-derived chemical processes. Catalyst choice is essential in directing HDO reaction pathway and product selectivity. Molybdenum oxide catalysts showed high yields of aromatics production from phenolic compounds issued from biomass, which was attributed to the oxophilic character of Mo that favors the direct cleavage of the $C_{aromatic}$– O bond (DDO pathway) [1]. Nevertheless, $MoO_3$ catalysts were reported to be less active than sulfide ones in HDO [2]. It then seemed interesting to investigate how to obtain both activity and selectivity into aromatics enhancements. Adding W was considered due to an observed synergy with Mo in sulfide catalysts for HDS [3]. The better sulfidation of both elements suggested their easier reducibility that could be beneficial in HDO where $Mo^{5+}$ species are suggested as active sites [1].

## Methodology

Mixed MoW oxides catalysts having 10 wt.% total metal content supported on $ZrO_2$ were prepared from synthesized $H_4SiMo_xW_{12-x}O_{40}$ heteropolyacids with x = 0, 3, 6, 9 and 12 through dry impregnation. The catalysts were then characterized by several techniques (ICP, $N_2$-physisorption, XRD, Raman, $H_2$-TPR and XPS) and they were evaluated in the HDO of m-cresol at 340°C under 30 bar.

## Results and discussion

Unlike Mo, W alone exhibited poor activity in these conditions. Nevertheless, a beneficial synergy was observed between W and Mo. In terms of activity, the rate constants of mixed MoW catalysts were found to be higher than the estimated values calculated from the experimental rate constants of $SiMo_{12}/ZrO_2$ and $SiW_{12}/ZrO_2$ (Figure 1), especially in the case of the most active catalyst $SiMo_9W_3/ZrO_2$. Furthermore, the selectivity to aromatic toluene improved in the presence of W, reaching almost 100%. It was concluded from XPS analysis that the presence of W improved Mo reducibility. A correlation was found between the quantity of $Mo^{5+}$ atoms on the reduced catalysts and the catalytic activity, confirming that $Mo^{5+}$ species can be considered as active sites for HDO. The increase in the amount of $Mo^{5+}$ was obtained using mixed MoW precursors, mainly for $SiMo_9W_3/ZrO_2$.

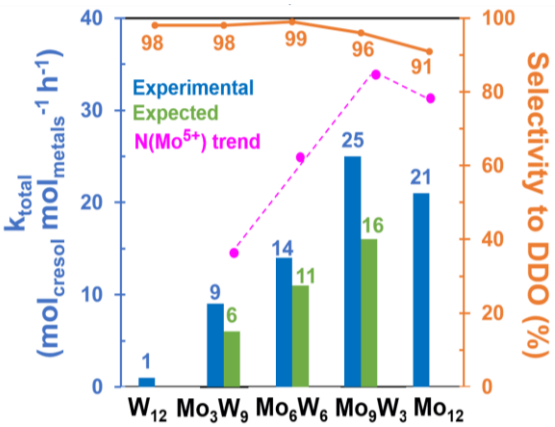

**Figure 1 : Effect of W incorporation into Mo catalysts on activity, selectivity and reducibility**

**Keywords:** Propylene, Molybdena catalysts, Hydrodeoxygenation, glycerol

**Introduction.**

The market demand for propylene as an important petrochemical intermediate continues to grow with a stable annual rate of 4%. With the majority of propylene being produced from fossil-based processes, the need for new sustainable routes is imperative [1]. An alternative way is by utilizing biomass and its derivatives, such as glycerol (a by-product from biodiesel process). Complete glycerol deoxygenation along with a formation of a C=C bond is a challenging path that could lead to propylene. This work refers to one-step glycerol hydrodeoxygenation (HDO) to propylene over molybdenum based catalysts, as it was found that they are attractive candidates for such reactions [2]. The effect of reaction parameters is exploited and optimized via response surface methodology.

**Experimental/methodology.**

Molybdenum based catalyst (8.7wt% Mo loading) supported on a commercially availabe black carbon (BC) Vulcan XC72 (Cabot) was prepared by wet impregnation method [2] and evaluated in a high-pressure fixed bed reactor (FlowCat, HEL), in vapor phase, using 10wt% aqueous glycerol solution. Prior to reaction, the catalyst was reduced ex-situ at 500$^{o}$C for 30min. The X-ray diffractometry (XRD) technique, $H_2$ temperature program reduction (TPR) and X-ray Photoelectron Spectroscopy (XPS) were performed to determine the main physicochemical properties of the catalyst, while $CH_3OH$ temperature programmed surface reaction ($CH_3OH$-TPRS) was applied to indentify the nature of the catalyst active sites.

**Results and discussion.**

The effect of reaction parameters (T:240-280$^{o}$C, $P^{o}_{H2}$=8.7-61.5bar, $P^{o}_{H2}/P^{o}_{glyc}$=22-250, LHSV=0.4-1.2$h^{-1}$, W/F=211-422$g_{cat}/mol_{glyc}h$) was studied at constant TOS=4h. The parametric study indicated that increased temperature, hydrogen availability ($P^{o}_{H2}$ and/or $P^{o}_{H2}/P^{o}_{glyc}$) and W/F are key parameters for propylene production. The main product detected in liquid phase is 1-propanol, in addition with the partially deoxygenated products, such as 2-propenol and propanal. The reaction was optimized using three response surface prediciton models expressing the effect of process parameters ($P^{o}_{H2}$,$P^{o}_{H2}/P^{o}_{glyc}$,LHSV,W/F) on responses (propylene yield and rate, sum yield of propanal and 1-propnol). Under optimum reaction conditions glycerol is completely converted to propylene achieving 71% yield at 60bar system pressure and 280$^{o}$C. Furthermore, catalyst stability was investigated and the results showed that the catalyst remained stable for the first 10h, while lost only ~35% of its initial activity after TOS=30h. XPS confirmed the presence of the reduced $Mo^{4+}$,$Mo^{5+}$ species which are most likely the active sites of the reaction while $CH_3OH$-TPRS indicated that $Mo^{4+}$,$Mo^{5+}$ host redox/acid sites. The reaction pathway of glycerol to propylene was also examined by performing experiments with the main intermediate products formed. The results suggested that 2-propenol is selectively converted to propylene with the highest rate indicating that it is the primary intermediate of glycerol HDO over Mo/BC. 2-propenol isomerization to propanal is a secondrary route with the latter being converted to 1-propanol due to $H_2$ presence.

**Keywords:** Ruthenium-based catalyst, Deoxygenation, Black liquor, Sulfur, Supercritical water

**Introduction.** The Black Liquor to Fuel (BL2F) project, a EU Horizon 2020 project, aims to produce high quality marine and aviation fuels from pulp mill by-product, i.e. black liquor.[1] The first step of the process is the conversion of the black liquor *via* hydrothermal liquefaction (HTL) to intermediate HTL-oil.[2] A second key step is the development of integrated hydrothermal hydrodeoxygenation (iHDO) process in supercritical water (SCW) conditions. This step aims to remove part of the sulfur and oxygen from the HTL-oil and upgrade it to a more stable and easily transportable fuel intermediate. The operational conditions impose special demands on the catalyst of choice, i.e. the catalyst should be stable under continuous SCW flow and be sulfur tolerant. In this work, we will report the catalytic HDO of isoeugenol, as a model compound for HTL-oil, over metallic and sulfided Ru/AC (Ru nanoparticles supported on activated carbon) catalyst.

**Experimental/methodology.** A Ru/AC catalyst was provided by Ranido (Prague, Czech Republic). Ru-S/AC, a sulfided catalyst, was prepared in a batch reactor under $H_2$ atmosphere in a mixture of hexane and dimethyl disulfide (DMDS) at 350 °C for 4 h. The HDO experiments were performed with isoeugenol as a model compound. Isopropanol was used both as a solvent and as an *in situ* $H_2$ source during the reaction. The catalytic activity was assessed in a continuous flow fixed-bed reactor operated at 400-410 °C and 30 MPa using 35 % isopropanol and 5 % isoeugenol/ 35 % isopropanol in water (vol.%) solutions with a controlled space velocity (WHSV = 425 − 8500 $g_{Org}\ g_{Ru}^{-1}\ h^{-1}$). The gaseous products were analyzed online with a micro-GC. The liquid products were analyzed with GC-FID and GC-MS.

**Results and discussion.** The catalyst performance was assessed under SCW conditions in a continuous flow. Though Ru/AC was found to be highly active for supercritical water gasification (SCWG) of isopropanol, the gasification rate was found to be strongly inhibited when isoeugenol was added to the feed. Micro-GC analysis showed a gas composition typical for SCWG, i.e. a mixture of $CH_4$ and $CO_2$ with ca. 10 % of $H_2$, indicating a sustainable *in situ* $H_2$ production in the reactor. The GC-FID analysis of the liquid products revealed a complete conversion of isoeugenol with WHSV strongly influencing the product composition. Specifically, while dihydroeugenol was the main product at a high space velocity, the reduction of WHSV shifted the reaction towards phenolic compounds with 4-propylphenol being the main product.

Next, the HDO activity of preliminary sulfided Ru/AC catalysts was assessed. Ru-S/AC was found to be rather inactive for SCWG. That may be explained by the sulfur poisoning of Ru being one of the main deactivation mechanisms in SCWG.[3] However, a significant amount of $H_2$ was produced *via* dehydrogenation of isopropanol to acetone. The GC-FID analysis of the liquid products revealed a complete conversion of isoeugenol to a variety of compounds. A moderate amount of propylbenzene and propylcyclohexane was detected among them indicating a complete deoxygenation of isoeugenol over sulfided Ru-S/AC catalyst. Overall, those results demonstrate that sulfided Ru/AC can be a promising catalyst for the HDO of S-rich HTL-oil under SCW conditions.

Amino acids are important components of proteins, which are produced mainly by fermentation. There is growing interest in developing altervative and sustainable methods for producing amino acids, particularly alternative the approaches that use biobased feedstock [1] [2] [3]. For instance, the use of glycerol derived from biomass to produce alanine repsents one of the environmentally friendly process to obtain amino acids[2]. Theoretically, the process involves two steps: (*I*) catalytic dehydrogenative oxidation of glycerol to lactic acid; (*II*) convertion of lactic acid to alanine via amination (as shown in Figure 1). The reaction is typically performed in a hydrogen atmosphere using costly noble metal catalysts[1] [2] [3].

In this work, we prove that it is possible to synthesize alanine by the reaction of glycerol and $NH_3$ without additional $H_2$ and employing a non-noble Ni-based catalyst. The results show that the catalytic performance of Ni/$TiO_2$ for step *II*, which is the rate-determing step, is largely controlled by the structure of $TiO_2$ ($TiO_2$-rutile v.s $TiO_2$-anatase). Ni/$TiO_2$-Anatase is unable to catalyse the conversion of lactate to alanine, while Ni/$TiO_2$-Rutile works effectively, resulting in a 53% alanine yield and a 72% lactate conversion (shown in Figure 1). Remarkably, the use of P25, a type of $TiO_2$ containing 20% $TiO_2$-rutile and 80% $TiO_2$-anatase, as the catalyst support for Ni/$TiO_2$ allowed to obtain nearly the same alanine yield (45%) as with Ni/$TiO_2$-rutile. While, a physical mixture of Ni/$TiO_2$-rutile (20 wt % ) and Ni/$TiO_2$-anatase (80 wt %) catalysts led to a significanly lower lactate conversion and alanine yield. We propose that Ni nanoparticles on the rutile phase or at the interface between rutile and anatase are the active species in catalysing lactate amination as well as the whole process from glycerol to alanine.

**Introduction.** The development of biorefinery is of crucial importance for academic and industrial perspectives. For example, bioethanol is one of the promising renewable resources, which can be converted to several chemical compounds, such as ethylene, diethyl ether, and acetic acid. In this context, various hierarchical zeolites have been successfully synthesized including ZSM-5, and FER[1-4], which can be applied as catalysts for greatly improved catalytic performances in bioethanol to ethylene. To gain insights into the mechanistic perspectives of bioethanol conversion, we also studied the effect of different zeolite frameworks on the catalytic transformation of bioethanol via *in-situ* diffuse reflectance infrared Fourier transform spectroscopy (DRIFTS)[2]. To further develop a catalyst for industrial use, the rational design of binder-free hierarchical zeolite monoliths derived from zeolite@layered double hydroxides (LDH) composites via extrusion and 3D printing technologies has been illustrated and they exhibit exceptional catalytic performances in bioethanol dehydration, eventually boosting ethylene yield up to 96%[1]. To tackle the industrial challenges, we also illustrated the application of the designer catalysts in the bioethanol dehydration to ethylene on a pilot-plant scale. This example provides a new perspective idea of using hierarchical zeolites and their composites in industrial bioethanol upgrading.

**Experimental/methodology.** Various hierarchical zeolite frameworks including ZSM-5 and FER were synthesized via a hydrothermal process. Subsequently, the binder-free extruded hierarchical zeolites were prepared by the transformation of zeolites@LDHs composites without using a commercial binder. The catalytic performance in bioethanol dehydration was studied using both lab-scale and pilot-scale fixed-bed reactors.

**Results and discussion.** Herein, we reported that the synthesized hierarchical zeolites with different frameworks enable bioethanol conversion in different mechanistic pathways. For example, the FER is highly selective to ethylene and inhibits the formation of by-products, showing a high ethylene yield (~95%). To further illustrate their applications in practical applications, the rational design of extruded hierarchical ZSM-5 monolith derived from zeolite@LDH composites has been illustrated via extrusion and 3D printing technologies. The designer catalyst applied in bioethanol dehydration boosts ethylene yield by over 93.4±2.2% (Figure 1).

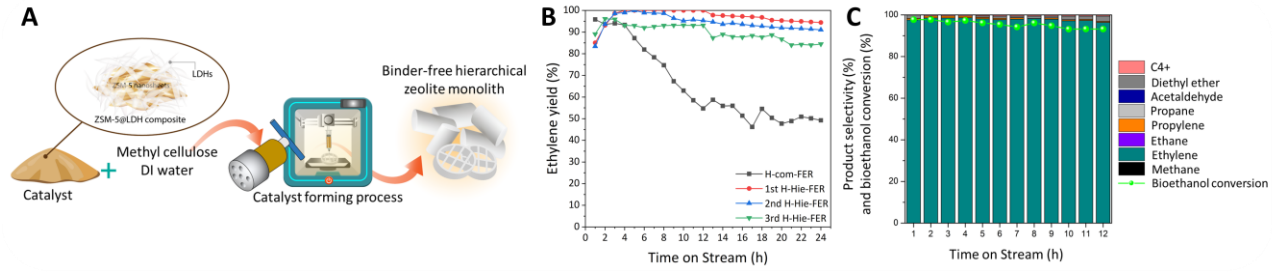

**Figure 1.** (A) Illustration of the fabrication of binder-free hierarchical zeolite monoliths[1] and (B-C) Catalytic performances in ethanol dehydration over different catalysts; (B) Hierarchical FER vs. Commercial FER[2]; (C) Binder-free extruded hierarchical ZSM-5[1].

**Introduction**

Lignin remains the highest source of aromatic-based platform chemicals with a high potential to substitute fossil-based sources. However, the development of environmentally friendly and energy-saving approaches for its selective depolymerization remains a daunting task. Photocatalysis looks promising to harvest aromatic building blocks from lignin [1]. A critical challenge with photocatalysis is the development of highly selective photocatalysts for the transformation of aromatic-rich lignin under environmentally benign conditions [2,3]. Therefore, this study aimed to enhance the photo-responsiveness and intrinsic properties of the commercially available $TiO_2$ photocatalyst by co-incorporating CdS and g-$C_3N_4$ for lignin valorization.

**Experimental/methodology**

Herein, a ternary $TiO_2$/g-$C_3N_4$/CdS catalyst was synthesized via a sequential ball milling (Fritsch, Pulverisette P7 with 80 mL jar and milling balls of 10 mm diameter) and ultrasonication strategy. The photoactivity of the as-prepared photocatalyst was compared with other pure photocatalysts (g-$C_3N_4$, $TiO_2$, CdS) and binary catalysts ($TiO_2$/g-$C_3N_4$ and g-$C_3N_4$/CdS) by monitoring the conversion, selectivity, and yield of phenolic monomers from biomass-derived lignin model compounds (benzyl alcohol and 2-phenoxy-1-phenylethanol). For the photocatalysis experiments, the effect of catalyst loading (0.625, 1.25, and 1.875 g/L), reactions time (0,1, 3, 6, 9, 12 and 18 hours), and reaction media (water only, acetonitrile only and $H_2O$: acetonitrile) were investigated in a SUNTEST CPS+ solar simulator. The liquid fraction was analyzed by GC/MS to identify the products and quantification was done using an HPLC with a reverse phase C18 column. Mechanistic investigations were accomplished using radical quenching experiments using t-BuOH, $K_2S_2O_8$, p-benzoquinone, and $(NH_4)_2C_2O_4$ as •OH, electrons, $O_2$•− and photogenerated holes scavengers, respectively. The as-prepared catalysts were characterized using XRD, XPS, FTIR, TEM, and morphological analysis, while the optical properties were studied by UV–vis diffuse reflectance spectra analysis.

Results and Discussion

The ternary composite $TiO_2$/g-$C_3N_4$/CdS photocatalyst was highly selective towards the activation and cleavage of bonds in benzyl alcohol and 2-phenoxy-1-phenyl ethanol as compared to control photocatalysts. Meanwhile, the mechanistic investigation revealed that multiple radical species triggered the activation and cleavage of bonds in the model dimer, with holes being the most active species. This study will throw more strategies to enhance the photo-responsiveness of $TiO_2$ photocatalyst, and provide an understanding of the interaction between catalyst surface and complex lignin structures while providing novel routes for valorizing lignin to value-added platform chemicals via photocatalysis.

# Supported bimetallic (Ni/Cu) nanoparticles catalysts for the thermal hydrogenolysis of lignin model compounds

R. Abolivier[1*], J. A. Sullivan[1]

[1]*School of Chemistry, University College Dublin, Dublin, Ireland*
[*]*raphael.abolivier@ucdconnect.ie*

**Keywords:** Lignin, biomass valorization, heterogeneous catalysis, transition metals

**Introduction.**
Because of $CO_2$ release at end-of-life, the use of renewable resources for the generation of platform compounds (through biorefining processes) has recently attracted increased attention. Lignin is expected to become an important source of aromatic compounds. However, a viable lignin valorization technology remains to be developed. This project focuses on the development of sustainable (*e.g.,* using abundant transition metals) catalysts for ether bond hydrogenolysis of lignin model compounds.

**Experimental/methodology.**
Catalytic hydrogenolysis of a range of model compounds, each containing representative intramolecular lignin linkages, was investigated over different sets of ZSM-5 supported bimetallic (Ni/Cu) catalysts. A hydrothermal method was used to deposit metal-oxide nanoparticles on ZSM-5 and these nanoparticles were then reduced in a 3 % $H_2$/Ar atmosphere (at 500 °C) to prepare the catalysts.

Catalysts with different Ni/Cu ratios (1:1; 1:5 and 5:1) and different reduction temperatures (300 °C; 400 °C and 500 °C) were prepared. The catalysts were characterized using XRD, SEM/TEM, TGA-DSC and $N_2$ adsorption and the reactivity at elevated temperatures (up to 350 °C) in a $H_2$ pressurized (up to 80 bar) Parr reactor analyzed.

**Results and discussion.**

The deposition of dispersed nanoparticles on the ZSM-5 support was confirmed by electron microscopy and XRD. The catalysts were stable in the temperature range of interest (up to 500 °C) and maintained the high specific surface area of the zeolitic support (290-390 $m^2/g$)

The Ni/Cu ratio was identified as a key parameter for efficiency in the reaction. High conversions of benzyl phenyl ether (> 99.0 %) were obtained over a 1:1 ratio catalyst (with 5 wt% of each metal) after a 1 h reaction at 300 °C. However, under the same reaction conditions, over a catalyst with a lower metal loading (1 wt% each of Ni/Cu), a significantly lower conversion of the subtrate was obtained (~ 23 %). Investigation of catalysts with other Ni/Cu ratios suggested that the nickel surface was the active site for hydrogenolysis. A 5:1 Ni/Cu ratio led to a ~ 62 % conversion of benzyl phenyl ether whilst a 1:5 ratio did not lead to similar conversion to the 1:1 (1 wt%) material (~22 %).

Metal particle size effects on reactivity were investigated using catalysts prepared following different reduction temperatures (higher reduction temperature promoting particle sintering). Over a catalyst reduced at 300 °C, a low substrate conversion ( ~37 %) was obtained. A reduction of the nanoparticles at 500 °C led to a lower conversion of the model compound (~69 %) than a 400 °C temperature (> 99 %).

An investigation of the hydrogenolysis reaction using other model substrates (2-phenoxyacetophenone; 2-phenoxyacetophenol and diphenyl ether) was also undertaken. The reaction steps involved in 2-phenoxyacetophenone conversion to ethylbenzene, and phenol were elucidated. The role the $C_\alpha$ substituent (-OH; =O or -H) in β-O-4 model compounds was found be a key parameter for the catalyst's reactivity in the hydrogenolysis reaction.

**Introduction.** Biomass has emerged as a leading candidate feedstock for the chemical industry due to its renewable nature and the vast number of compounds it can be used to generate, many of which have similar or improved properties compared to their petroleum-based counterparts. The efficient production of biomass-derived chemicals is of technological importance for the transition to a more sustainable future. In this regard, 5-hydroxymethylfurfural (5-HMF) has been identified as a key platform chemical for the production of high value chemicals. Importantly, given the multi-functionalities of 5-HMF, the major difficulty to produce promising monomers is how to selectively hydro-convert a particular functional group(s) under mild-conditions. HMF could be hydrogenated to useful chemicals with applications as solvents, monomers, or precursors for the production of other high-value chemicals. In this project, two important monomers were primarily targeted, including 2.5-Bis (hydroxymethyl)furan (BHMF) and 2,5-Bis-(hydroxylmethyl) tetrahydrofuran (THFDM).

**Keywords:** Biomass, hydrogenation, HMF, Ni-based catalysts, heterogeneous catalyst.

**Experimental.** The experiments were carried out in a 300 mL stainless-steel Büchiglas reactor. In a typical experiment, a suitable amount of reactant, catalyst, and solvent were loaded into the reactor. The reactor was sealed and purged with hydrogen to remove the air at room temperature. The stirrer was started while heating with a stirring speed of 700 rpm. After the reaction, the reactor was cooled to room temperature and the liquid reaction mixture was thereafter collected. The catalysts and liquid products were separated for further analysis. Note that liquid samplings were taken for each experiment, first after 30 min and then every 1 h.

**Results and discussion.**
Initially, hydroconversion of 5-HMF to BHMF was studied over mono- and bimetallic supported catalysts in a batch reactor (Figure 1). We found that monometallic Ni/$SiO_2$ catalysts exhibited superior performance with a total yield of BHMF of up to 99 wt.% at 180 ºC, 75 bar $H_2$ for 2 h . This excellent performance might be attributed to the high Ni dispersion and low acidity of the support. The influence of Dimethyl sulfoxide (DMSO) contamination of HMF was also investigated due to the route used for its production (not shown for brevity). It was found that the conversion of HMF decreased by nearly 57% when an additional 8.5 wt% of DMSO was added to the reaction mixture [1]. Unlike BHMF, the production of THFDM requires hydrogenation of the furan ring. A good performance with complete conversion of BHMF, along with the highest selectivity of over 95% to THFDM, was attributed to the well-balanced properties of the support $ZrO_2$–$SiO_2$ (Figure 2)[2].

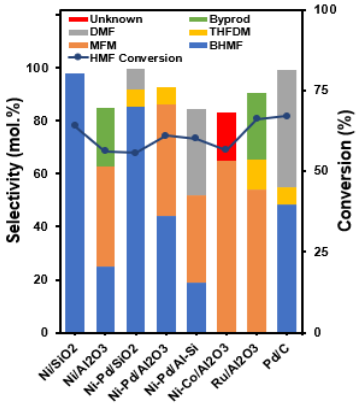

**Figure 1.** HMF conversion and products selectivity over various catalysts at 130 C, 40 bar, 6 h.

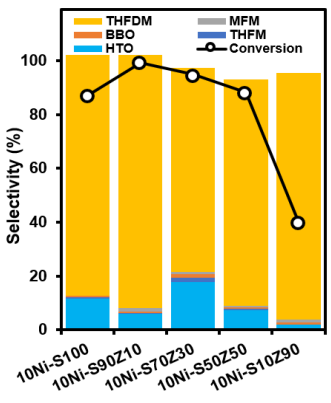

**Figure 2.** Effect of support on BHMF conversion and selectivity over 120 min

**Keywords:** Biomass and Plastics valorisation, Value-added chemicals, Py-GC/MS, MOF-Derived Materials.

**Introduction.** Catalytic co-hydropyrolysis might be a potential thermochemical process for producing value-added compounds, valorising plastics, and biomass residues. Catalysts derived from metal-organic frameworks could enhance selectivity toward aromatics compounds due to highly dispersed metal nodes on the surface, favouring hydrogenation reactions. This study evaluated the effect of nickel supported on carbo-alumina (Ni/C-$Al_2O_3$) on the selectivity of aromatics compounds (Benzene, Toluene, and Xylene) produced by biomass/plastic co-hydropyrolysis.

**Experimental/methodology.** MIL-53(Al) was heated up to 800°C to produce carbo-alumina (C-$Al_2O_3$) support and then impregnated with 15%Ni by incipient humidity. XRD, TPD-$NH_3$, and $N_2$-physisorption were used to characterise the catalysts. The co-hydropyrolysis assays were performed at 550°C/150 PSI $H_2$ on a Py-GC/MS (CDS5200 -Clarus689/SQ-8T) system, combining Oak wood, HDPE, and LDPE.

**Results and Discussion.** Amorphous C-$Al_2O_3$ formation and supported Ni nanoparticles (8.6 nm) were confirmed by XRD patterns. Due to the structural breakdown, the C-$Al_2O_3$ poses a lower surface area and larger pore size than its precursor (Table 1). However, Ni impregnation on C-$Al_2O_3$ had no significant effect on textural properties. Thus, Ni/C-$Al_2O_3$ was effective in hydrodeoxygenation reactions, reducing oxygenated compounds (OCs). Figure 1A shows a minimal production of OCs (1%) at higher heating rates and lower contact time for gases, minimising by-product reactions. At a lower heating rate (Figure 1B), the selectivity to hydrocarbons increased (72%), as well as OCs, due to further reactions [1]. Aromatic hydrocarbons resulted from Diels-Alders reactions between furans and olefins [2] and phenols hydrodeoxygenation [3]. Hydrogen was activated by supported Ni, while larger molecules were cracked on C-$Al_2O_3$ acidic sites [2,3].

**Table 1.** Textural properties of catalysts.

| Catalyst | $S_{BET}$ ($m^2g^{-1}$) | $V_{ADS}$ ($cm^3g^{-1}$) | $V_{DES}$ ($cm^3g^{-1}$) | Pore size (nm) |
|---|---|---|---|---|
| MIL-53 | 698 | 0.15 | 0.13 | 4.9 |
| C-$Al_2O_3$ | 272 | 0.26 | 0.22 | 13.3 |
| Ni/C-$Al_2O_3$ | 216 | 0.29 | 0.26 | 7.0 |

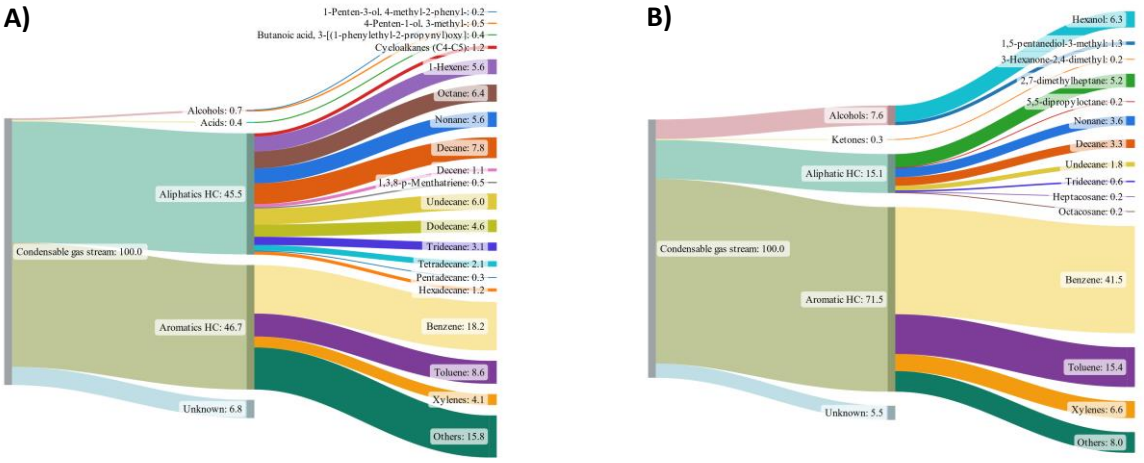

**Figure 1.** Product distribution using 87% Ni/C-$Al_2O_3$. A) LDPE, 10000°C/s. and B) LDPE, 12.5°C/s.

**Key words:** 5-Hydroxymethyl furfural, Ru-$TiO_2$, SBA-15, hydrogenation

**Introduction:** Biomass is a plentiful renewable feedstock that has a huge potential to meet the challenges of sustainable and green chemistry. Lignocellulose is the main component of biomass, which can be converted into platform chemicals. Among them, 5-hydroxymethylfurfural (HMF) is called the sleeping giant, because of having 3 different functional groups (-OH, C=O and furan ring) whose potential remains underused. HMF can be reduced to various chemicals like 2,5-dimethylfuran, levulinic acid, and γ-valerolactone. However, it is challenging to reduce HMF into non-deoxygenated alcohols like bis-hydroxymethylfuran (BHMF) and bis-hydroxymethyltetrahydrofuran (BHMTHF) because of the selectivity issues. This research is conducted to design catalysts which can selectively reduce the aldehyde group of HMF only. For that reason, we designed a series of Ru-based catalysts.

**Methodology:** In this research, we impregnated 1 wt.% of Ru on different $TiO_2$-based supports ($TiO_2$/SBA-15, anatase, rutile, P25). $TiO_2$/SBA-15 was obtained by deposition of $TiO_2$ monolayer on SBA-15. All synthesized catalysts were in-situ reduced and tested in HMF hydrogenation. Catalytic tests were carried out in an autoclave at 220 °C and 70 bar $H_2$ pressure, using 1,4-dioxane as a solvent. After HMF reduction, liquid reaction product mixtures were analyzed by GC-FID to identify and quantify the individual reaction products. Structural, textural and composition properties of supports and Ru-containing catalysts were determined by XRD, TPR, BET and XRF.

**Results:** The reduction patterns obtained during TPR preliminary suggest different interactions of Ru with the different types of $TiO_2$ supports. When tested for HMF hydrogenation in a batch reactor for 3 h, the performance of the catalysts in terms of HMF conversion and desired products selectivity may be ranked in the following order Ru/Rutile>Ru/Anatase>Ru/$TiO_2$-SBA-15>Ru/high surface $TiO_2$. The selectivity of the desired product, BHMF, was 55 % and 30 % with Ru/Rutile and Ru/P25 catalyst, respectively. This work allows a better understanding of different metal-support interactions in selective hydrogenation of HMF.

**Keywords:** hydrogenation, sugar alcohols, sweeteners, structured catalyst, biorefinery

**Introduction.** The use of structured catalysts, such as solid foams, represents a promising technology for the continuous production of high-value compounds derived from biomass such as sugar alcohols (e.g., sorbitol, xylitol, arabitol, galactitol). Solid foams combine the benefits of slurry and shaped body catalysts, i.e., thin catalyst layers that ensure high effectiveness factors, as well as open structures that minimize the pressure drop [1,2]. Sugar alcohols are generally produced by the catalytic hydrogenation of monomeric and dimeric sugars using a finely dispersed nickel-based catalyst in semi-batch reactors[3]. Even though this is a well-established industrial practice, process intensification is necessary to achieve production levels that allow biomass-derived resources to be utilized more efficiently. Therefore, the goal of this work was to develop a Ru/C foam catalyst and to study its catalytic activity and the hydrogenation kinetics of sugars and sugar mixtures at different temperatures, hydrogen pressures, and initial concentrations.

**Experimental/methodology.** Cylindrical pieces were cut from a commercially available aluminium foam sheet (96% porosity) and the pieces were coated via controlled polymerization of furfuryl alcohol mixed with poly(ethylene glycol) (M=8kDa) as pore-former. The coated foams were pyrolyzed, activated with air at 380°C, and acid-treated. Ruthenium incorporation was carried out through incipient wetness impregnation using ruthenium nitrosyl nitrate as the precursor, followed by *ex-situ* reduction at 300°C with hydrogen. The prepared Ru/C catalyst was used in experiments with xylose, arabinose, galactose, as well as binary sugar mixtures at 60-120°C and 20-60 bar hydrogen pressure. Finally, mathematical models based on plausible surface reaction mechanisms, i.e., non-competitive and semi-competitive adsorption between the carbohydrates molecules and hydrogen were developed to describe the experimental data.

**Results and discussion.** The carbon coating based on the formation and pyrolysis of poly(furfuryl alcohol) was identified as a critical step for the catalyst performance. In that sense, poly(ethylene glycol) (PEG) was added in the coating process to tune the porosity of the resulting carbon. The addition of 5 wt. % PEG resulted in a carbon with a ratio of meso-to-micropores volume of 1. The induced mesoporosity yielded a superior dispersion of the Ru nanoparticles (i.e., higher hydrogenation activity) and higher stability due to the spatial restriction induced by the mesopores. The obtained Ru loading on the catalyst was of 1 wt.% with an average nanoparticle size of 3 nm, which maintained a stable activity for more than 200 hours. Selectivities towards sugar alcohols exceeding 98% and sugar conversions reaching 50-99%, depending on the temperature, were obtained. The kinetic models based on non-competitive and semi-competitive adsorption of the sugars and hydrogen gave an excellent description of the concentration profiles and the impact of the process parameters along with insights on the complex mode of adsorption of sugars on the active sites of the catalyst.

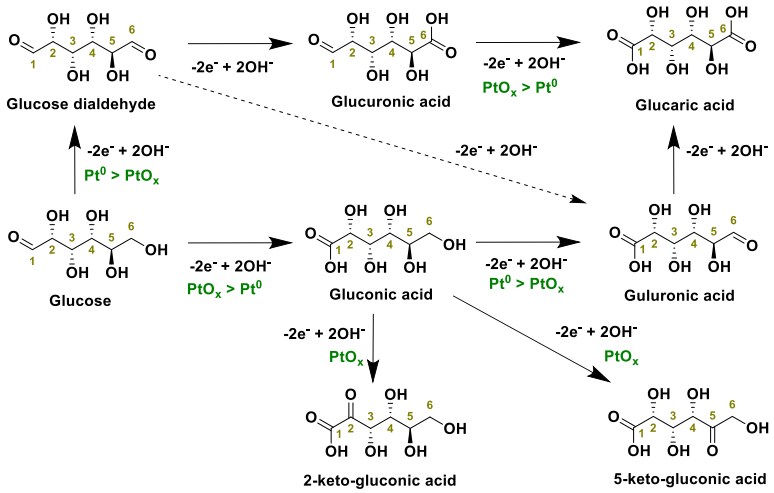
# On the role of Pt oxidation state in the electrocatalytic dehydrogenation and oxidation of glucose

Matthijs van der Ham [1,2], Ellis van Keulen [1], Marc Koper [2], Akbar Asadi Tashvigh [1], Harry Bitter [1]*



[1] *Biobased Chemistry and Technology, Wageningen University & Research, Wageningen, The Netherlands*
[2] *Catalysis and Surface Chemistry, Leiden University, Leiden, The Natherlands*
*harry.bitter@wur.nl*

**Keywords:** Electrocatalytic oxidation, dehydrogenation, glucose, Pt oxidation state, chromatography

Glucose is a highly abundant and sustainable feedstock that can be dehydrogenated and oxidized with Pt electrocatalysts into a large variety of platform and specialty molecules, such as gluconic acid, glucaric acid and 2-keto gluconic acid. The selective production of a single product is one of the key challenges in catalysis and can be improved when the reaction pathway is elucidated.[1] Yet, the glucose oxidation pathway is poorly understood, consequently it remains unclear how the Pt oxidation state affects the electrocatalyst selectivity.

For this study, we 1) combined two analytic methods to quantify all glucose oxidation products, which 2) allowed us to elucidate how the Pt oxidation state affects the dehydrogenation and oxidation of glucose. Glucose (oixdation products) were electrocataytically dehydrogenated/oxidized with a Pt mesh in a divided electrochemical cell at pH = 7 (0.2 M phosphate buffer) at 0.64 V vs. RHE and 1.16 V vs. RHE, corresponfing to metallic platinum ($Pt^0$) and platinum oxide ($PtO_x$). The products were quantified by combining high-performance liquid chromatography and high-performance anion exchange chromatography.

Product analysis shows a ~100% carbon balance closure and ~100% faradaic efficiency, indicative that all products were quantified and electrons were retreived. Here we reveal that the glucose oxidation pathway consists of two parallel pathways (Scheme 1). On the one hand, $Pt^0$ promotes the dehydrogenation of primary alcohol groups, thereby favouring the formation of glucose dialdehyde from glucose and guluronic acid (85%) from gluconic acid. On the other hand, $PtO_x$ promotes the oxidation of aldehyde groups, thereby favouring the formation of gluconic acid (91%) from glucose and glucaric acid (100%) from glucuronic acid. Moreover, $PtO_x$ also promotes the dehydrogenation of the secondary alcohol group of gluconic acid, thereby promoting the formation of 2-keto gluconic acid and 5-keto gluconic acid. These results show that the the Pt oxidation state influences the type of reaction that it catalyzes and thereby be used to steer the reaction pathway for glucose oxidation.

**Scheme 1. The electrocatalytic oxidation of glucose at pH = 7 (0.2 M phosphate buffered systems) and the preference of metallic platinum (MPt, E = 0.64 V *vs.* RHE) and platinum oxidation ($PtO_x$, E = 1.16 V *vs.* RHE).**

**Introduction**

The transformation of biomass-based levulinic acid (LA) to γ-valerolactone (GVL) is considered as an attractive biomass conversion route providing GVL as a versatile building block, green solvent, and fuel [1,2]. Finding a cheap and stable catalyst, using water as a solvent, no extra $H_2$ and reaction temperatures below 200 °C are the main challenges for this reaction. A 2.5%Ru/$ZrO_2$ catalyst showed a GVL yield of 73% at 150 °C in water (6 h), however, selectivity was too low [3]. On the other hand, 20%Cu/$ZrO_2$ gave 100% GVL yield at 200 °C within 6 h in a batch reactor in presence of water [3]. In the present work, we tested NiP/$SiO_2$ in the continous aqueous phase hydrogenation of industrial waste LA in the presence of formic acid (FA) as H-donor.

**Experimental/methodology**

Home-made NiP/$SiO_2$ was prepared by reduction of $NiCl_2$ with sodium hypophosphite ($NaPO_2H_2 \cdot xH_2O$) in the presence of colloidal silica. Fresh and spent catalysts were characterized using XRD, ICP, BET SEM and TEM. The reaction was performed in a tube reactor (82 ml) using both model mixtures and an industrial waste stream containing carbohydrates (hydrothermally treated before hydrogenation) in presence of FA. The product was analysed offline with GC and GC/MS, while the gas phase was analysed with online-GC.

**Results and discussion**

When raising the temperature with a model feed LA/FA = 1:1.2 from 180 to 200 °C, the yield of GVL jumped from 50 to 95% and remained stable for 4 h (WHSV = 6 $g_{feed}/(g_{cat} \cdot h)$). In the further course of the test, the yield slowly decreased to 73% after 72 h on stream (Figure 1a). With the waste mixture (LA/FA = 1:0.4), GVL yield reached 90% at a WHSV = 3 $g_{feed}/(g_{cat} \cdot h)$ and exceeded 50% for more than 20 h (Figure 1b). Deactivation occurred due to structural changes (loss in surface area, Ni leaching) and/or deposition of polymers.

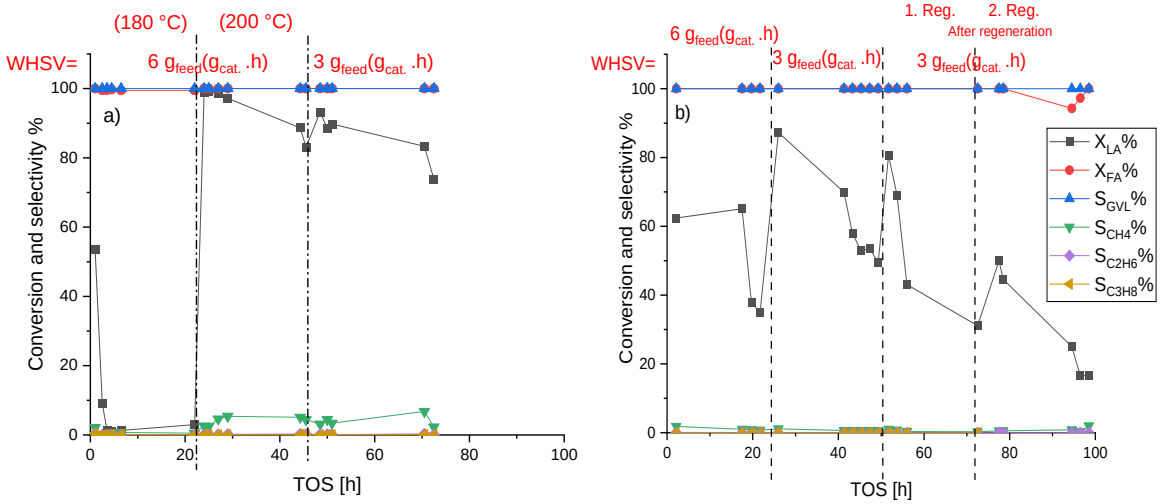

Figure 1: Effect of WHSV on the conversion of LA with 70%NiP/$SiO_2$ (5 g, 1:2 diluted with quartz) at 200 °C and 30 bar with time on stream using a) model mixture of LA/FA = 1:1.2 and b) waste mixture with LA/FA = 1:0.4.

# Modified SBA-15 materials for the valorization of biomass-derived compounds

J. Aubrecht[1], B. Amin[1], O. Kikhtyanin[2] and D. Kubička[1,2]

*[1] University of Chemistry and Technology Prague, Department of Petroleum Technology and Alternative Fuels Technická 5, Prague 6, 166 28, Czech Republic*
*[2]Technopark Kralupy, Náměstí Georga Karse 7/2, 278 01 Kralupy nad Vltavou, Czech Republic*

**Key words:** SBA-15, modification, synthesis, HMF

**Introduction:** Ordered mesoporous material SBA-15 (Santa Barbara Amorphous No 15) is an ordered silica having a large surface area reaching up to 1000 $m^2.g^{-1}$. This is due to a channel-type system with a pore diameter of about 5-15 nm. Together with the negligible acid-base character, the large surface area makes SBA-15 a very promising catalytic support. The SBA-15 support can be modified in many different ways, such as by coating the surface with a layer of an oxide having acid-base sites such as $TiO_2$, $ZrO_2$ or $Al_2O_3$. The connection between the high surface area and typical properties of low surface area oxides opens a new chapter of a catalyst support design. Therefore, we investigated the use of SBA-15 as a large surface area template to be coated with different oxides. More importantly, we focused on the formation of an oxide monolayer rather than bulky deposition by standard impregnation.

**Methodology:** SBA-15 material was synthesized by Zhao procedure (Science 279, 1998). In the synthesis, Pluronic P-123 was used as a structural template and tetraethyl orthosilicate as a source of $SiO_2$. After that oxides such as $TiO_2$, $ZrO_2$ and $Al_2O_3$ were introduced from organic precursors such as Ti-terc-butoxide, Zr-propoxide or Al-tri-sec-butoxide, respectively, using a different precursor quantity to prepare an oxide monolayer on the SBA-15 surface. After the successful synthesis Ru as the active metal was loaded on these supports. The prepared catalysts were tested in HMF hydrogenation to yield furandiols. All catalysts were characterized using XRF, XRD, TPR, BET, TPD-$CO_2$ and TPD-pyridine to determine their properties.

**Results:** The unique set of catalysts was prepared using the oxide-monolayer approach. We proved the successful loading of 10, 30 and 50% of oxides. Despite the high metal oxide loading the material had still a high surface area of over 300 $m^2.g^{-1}$ and accessible pores and channels. The loaded ruthenium made the catalyst active in HMF hydrogenation. We compared all catalysts in terms of activity and compared them with a typical low-surface area $SiO_2$. The introduction of various oxides changed the acid-base character (probed by TPD techniques) and affected the catalyst selectivity.

# Taking Off with Furfural: Transforming Biomass into Biojet Fuel

R.Baldenhofer [a], J. Lange [a], S.Kersten [a], M.P. Ruiz [a]

[a] *University of Twente, Enschede, Netherlands*

Due to the increasing scarcity and environmental impact of fossil-based fuels, it is becoming very important to search for renewable alternatives. One of the platform chemicals identified to play a key role in the energy transition is furfural.[1] Furfural is an important candidate for the production of jet fuels, among others, and it can be produced from lignocellulosic biomass.[2]

Many different routes for the upgrading of furfural to fuels are known. The most important steps consist of C-C coupling followed by a deep hydrogenation. Different approaches have already been discussed in literature, but most of them lack a cyclic component needed to provide adequate combustion and freeze point properties. A more promising route is to upgrade furfural via the aldol condensation between furfural and cyclopentanone.[3] Using a cyclic component will result in the desired properties which could be used as blend-in fuel.

The challenge of this upgrading route is to obtain cyclopentanone. Besides already existing industrial practices, cyclopentanone can be synthesized from biomass via the reductive rearrangement reaction of furfural, figure 1.[4] Here, furfural is hydrogenated towards furfuryl alcohol, then undergoes an acid catalyzed rearrangement and is subsequently hydrogenated further to form cyclopentanone and cyclopentanol. Understanding and controlling parameters in this reaction could lead to a renewable feedstock for fuels and other applications.

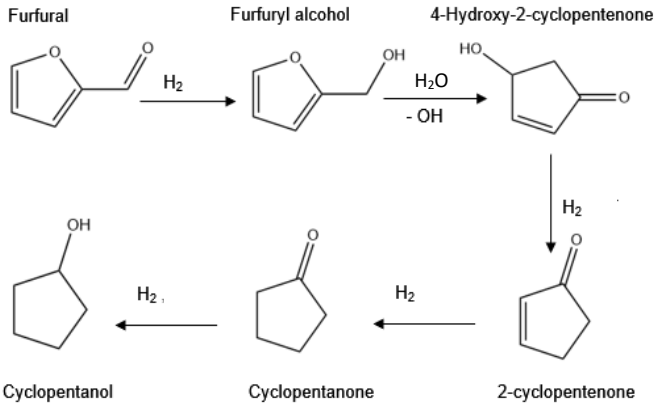

**Figure 1: Proposed reaction intermediates for the catalytic reductive rearrangement of furfural to cyclopentanone.**

# Catalytic Transfer Hydrogenation of Biomass-based Furfural over Copper Catalyst

Debarun Banerjee[1,2], Aloka Kumar Sahu[1], Jack K. Clegg[2], Sreedevi Upadhyayula[1*]

[1]*Indian Institute of Technology Delhi, Hauz Khas, New Delhi 110016, India*
[2]*The University of Queensland, St. Lucia, QLD 4072, Australia*

**Keywords:** furfural, catalytic transfer hydrogenation, catalyst activation

**Introduction.** Catalytic transfer hydrogenation of furfural has emerged as one of the most important reactions to yield valuable bio-based chemicals and fuels such as furfuryl alcohol (FAL) and 2-methylfuran (MF) [1]. The conventional catalyst activation process for furfural transfer hydrogenation is limited using extraneous $H_2$ gas which incurs high infrastructure cost, safety and handling issues [2]. Herein, we report a low-cost and green catalyst activation method which can be highly beneficial for the selective production of MF and FAL from furfural via catalytic transfer hydrogenation with isopropanol as hydrogen donor.

**Experimental/methodology.** Amorphous silica supported Cu-based catalysts were prepared via the traditional wet impregnation method followed by calcination under static air. The activation of the calcined catalysts was performed under a light source for 2h. In a typical catalytic activity run, the high-pressure batch reactor was filled with a pre-determined quantity of H-donor, furfural, catalyst, and pressurized up to 3MPa with nitrogen after several cycles of purging. Afterward, the reactor was heated to 210°C and kept at that temperature for 4h with continuous stirring. After cooling the reactor, the products were analyzed using nitrogen as carrier gas in a gas chromatograph with capillary column and flame ionized detector.

**Results and discussion.** The PXRD patterns (Figure-1a) show the prevalence of CuO phases in the calcined catalyst, which underwent reduction to metallic $Cu^0$ phases during the activation process. The catalytic activity studies (Figure-1b) reveal a steep increase of combined selectivity up to 95% toward FAL and MF by using the activated catalyst compared to the combined selectivity achieved using calcined (21%) and admixed (49%) catalysts. This was due to the formation of $Cu^0$ sites by activation which promoted hydrogenation and hydrogenolysis of furfural, thereby causing greater selectivity toward FAL and MF. However, the furfural conversion dropped from 75% to 64% while using activated catalyst compared to the admixed catalyst which is attributed to the decrease in synergistic effects of Lewis acidic CuO and metallic $Cu^0$ sites due to conversion of CuO phases to $Cu^0$ by activation.

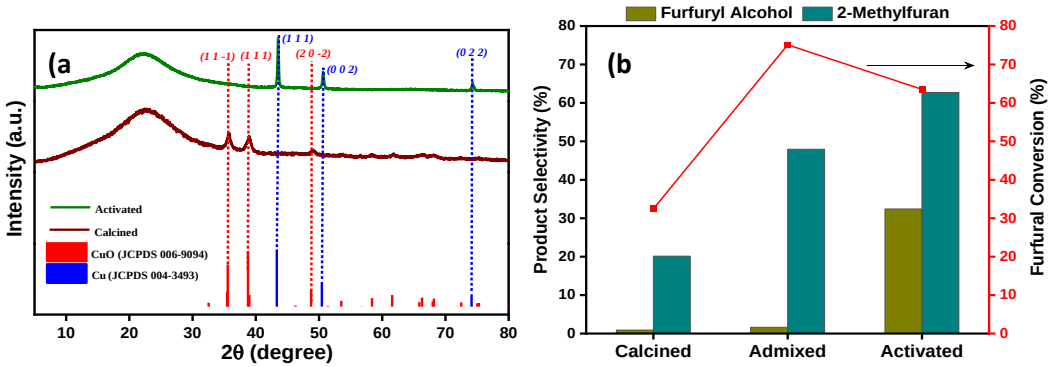

**Figure 1. (a) PXRD patterns of the calcined and activated catalysts; (b) Results of catalytic activity studies.**

# Oxidative Conversion of Lignosulphonates into Vanillin with a Copper–Cobalt Catalyst

S. Bekirovska[1], O. Abdelaziz[1*], C. Hulteberg[1]

[1]*Department of Chemical Engineering, Lund University, SE-221 00 Lund, Sweden*

**Keywords:** Catalytic depolymerization, Lignin valorization, Biorefinery, Aromatic chemicals

**Introduction.**
Lignin, an aromatic polymer constituent of lignocellulosic material, is a vastly underutilized side-stream in the pulp and paper industry as it is commonly incinerated for energy recovery [1,2]. Vanillin is predominantly produced from petroleum-derived guaiacol, as the demand for the chemical exceeds the supply of the vanilla bean [1]. The sustainable production of vanillin and the valorization of lignin could be attained through oxidative lignin depolymerization. This particularly applies to lignosulfonates derived from softwood, where the main product is vanillin since the monomer selectivity is dependent on the botanical origin [3]. The technology dates back to 1937; however, the current process development of oxidative depolymerization is focused on increasing monomer yields and optimizing reaction conditions with, for instance, the addition of catalysts [1,2]. In this work, different metal combinations were tested homogenously using a 50 g/L lignosulfonates solution, which is to be used as a basis for future immobilization.

**Experimental/methodology.**
A lignosulfonate solution of 20 mL was depolymerized in a 50 mL autoclave at 200 °C and 3 bar $O_2$ for 10 min (after reaching the operating temperature). The lignin mixture was prepared in a 2 M NaOH aqueous solution with a concentration of 50 g/L. A catalyst loading of 1.4 mmol/g lignin was applied, and eight different homogenous catalyst combinations were tested: Fe-Cu, Fe-Mn, Fe-Co, Cu-Co, Mn-Co, Cu-Mn, Fe-Cu-Mn, and Fe-Cu-Co, with equimolar ratios. A reaction without co-catalyst, i.e. metal catalysts, was also performed and used as the control. A chromatographic system was used for the identification and quantification of the aromatic monomers in the product samples.

**Results and discussion.**
All the catalyzed reactions resulted in higher yields of total monomers than the control. The highest yields of monomers and vanillin were obtained with the Cu-Co catalyst, having an increased total monomer and vanillin yield of 26% and 24%, respectively, when compared to the control. The immobilized Cu-Co catalyst has been used previously to depolymerize organosolv lignin and has shown considerable breakage of both β-O-4 and carbon–carbon bonds in lignin [5]. To further develop the process into becoming industrially viable, the Cu-Co catalyst needs to be immobilized, and optimization of the operating conditions and catalyst loading needs to be performed. Based on the potentially negative health and environmental effects of both Co and Cu, leaching of the immobilized metals will be a much-studied future topic.

**Keywords:** *Zingiber montanum*, Carbon dots, Forensic Science, Antibacterial activity

**Introduction** : *Zingiber montanum* is a type of natural herbal plant that has high potential medicinal plant as an anticancer, anti-inflammatory, antifungal, antioxidant, anti-allergic and antibacterial, due to the natural ingredients it contains such as Zerembone, Curcumin, etc. Fingerprint is one of the most important types of an evidence in the crime cases because human has different fingerprint mark. Carbon dots (CDs) are a new class of carbon nanomaterials with zero-dimensional carbon based, has the character with sizes below 10 nm and have a three-dimensional structure in the nano regime. The general structure of CDs is $sp^3/sp^2$, which means CDs can use a fluorescence property that can be applied in various fields such as bioimaging, biosensors, pH sensing, and biomolecule or drug delivery.

**Experimental / methodology :** Carbon dots (CDs) from *Zingiber Montanum* as a natural source were prepared by hydrotherrmal synthesis methods and applied with starch powder to detect latent fingerprint on non-porous surface materials. In the same way, such nitrogen doped CDs (N-CDs) were also synthesized using one-pot hydrothermal method between *Zingiber montanum* powder and L-histidine. Additionally, the crude extract of *Zingiber Montanum* was used to prepared ZnO photocatalyst as well.

**Result and Discussion** : Since the N-CDs give rising their fluorescence intensity followed with more brightness under commercial UV lamp compared with bare CDs. The N-CDs were then mixed homogeneously with starch powder and applied on various non-porous material surfaces for latent fingerprint detection, resulted clearer minutiae image compared with black commercial powder under UV lamp. For antibacterial activity, the N-CDs were also applied via agarose disk diffusion assay against various gram-negative and gram-positive bacteria. It was shown that the obtained N-CDs can be high potential use as antibacterial activity as well. In addition, the ZnO photocatalyst preapared from the crude extract of *Zingiber Montanum* was used to degarde the reactive red azo dye. The efficeincy of about 90% was obtained after 90 min of photo irridation.

**Keywords:** pyrolysis oil upgrading, Hydrodeoxygenation, alternative marine fuels

**Introduction.** The marine industry contributes a substantial share to the worldwide $CO_2$ emissions and is expected to grow over the next decades due to an increasing demand for logistics and transportation [1]. Significant reductions in greenhouse gas emissions within this sector along with other hard-to-abate sectors like land and air-based transportation, require innovative and sustainable technologies and fuels in order to meet the necessary targets. Electrification with battery-based technologies faces many challenges for these applications especially regarding the low energy density compared to many liquid fuels [1].

Biomass and plastic waste utilization using catalytic fast pyrolysis to produce oils has experienced increasing interest over the last decades both in fundamental research and industrial application. The crude pyrolysis oil produced typically has a high water and oxygen content leading to a high acidity, low storage stability and low energy density [2]. Removing oxygen-containing groups through catalytic deoxygenation improves the properties and leads to a high value biofuel. It can be mixed with conventional fossil fuels as a drop-in fuel, or it can prospectively replace fossil fuels all together [3].

This contribution focuses on the application of low-cost calcium-based catalysts in the conversion of furfural as a biomass model compound. Different materials including cement raw meal (mixture of $CaCO_3$, $SiO_2$ and clays), calcined cement raw meal, $CaCO_3$, CaO and $Ca(OH)_2$ were screened as potential catalysts in the catalytic upgrading of pyrolysis oil vapours.

**Experimental/methodology.** Furfural has been converted with calcium-based catalysts in a mass ratio of 5:1 in a stirred batch reactor at different temperatures from 200 to 300°C in inert atmosphere and at a residence time of 1 h. The liquid product and the spent catalyst were separated, and the oil was analysed using gas chromatography with mass spectroscopy (GC-MS), thermogravimetric analysis (TGA) and elemental analysis.

**Results and discussion.** $CaCO_3$ and cement raw meal showed little effect on furfural in the whole temperature range, whereas activated basic forms like CaO, $Ca(OH)_2$ and calcined cement raw meal show catalytic activity. Autopolymerisation products of furfural were found at 250°C with increased viscosity and reduced oxygen content. At 300°C, using CaO and $Ca(OH)_2$ total conversion towards gas and char under strong temperature and pressure increase took place. This shows the high activity of calcium-based materials as low-cost catalysts in deoxygenation of biomass-derived compounds, whilst further research on the application of these catalysts in pyrolysis oil upgrading is ongoing.

**Keywords:** Lignin, Pyrolysis, Oil upgrade, Catalytic Hydrotreatment

**Introduction.**

Kraft lignin is one of the most produced lignin available on the market, and it is produced as a side-product of the paper industry[1], [2]. Moreover, Kraft lignin presents a relevant amount of S whose content represents an obstacle to its valorization. Pyrolysis of lignin is one of the most powerful methods used for its depolymerization, aimed at the production of aromatics[3]. The oil produced from pyrolysis is rich in phenol-like compounds, but further upgrading is needed to make the pyrolysis oil (Pyoil) suitable for future applications[4], [5]. In this project, a first step of pyrolysis has been conducted, and after the characterization of the oil, $Cu/TiO_2$ catalysts have been used to address the production of phenolic-like monomers[6].

**Experimental/methodology.**

The pyrolysis setup consisted of a steel reactor where 30g of lignin have been loaded and heated up to 550°C for 20 minutes. Vapors produced during the process have been cooled down in three different steps in series with water, ice, and liquid nitrogen, respectively. Part of the sulfur presents in the raw biomass still remained in the oil in the form of disulfides and thiophenes. For this reason, a catalytic test has been performed on a model compound, 4-methyl-guaiacol, adding thiophene as an external sulfur source in order to see the influence of sulfur on the activity of the catalyst. $Cu/TiO_2$-P25 catalytic activity in the presence of different amounts (wt.%) of sulfur has been studied. The catalyst $Cu/TiO_2$-P25 (0.100 g) and SiC support (0.200 g) were loaded into the reactor and reduced *in situ* at 360°C at 6 bar of $H_2$ pressure for 2 hours. The tests have been performed using a down-flow reactor for a Time of Stream (TOS) of 4h in the same conditions. Hydrodeoxygenation (HDO) tests have been conducted at 300-350°C, and 100 bar of $H_2$ pressure using the Pyoil as reagent in presence of 0.5g of $Cu/TiO_2$.

**Results and discussion.**

The yield of pyrolysis oil obtained is around 30 wt.%, the char around 35 % as well as non-condensable gas calculated by difference. GC-MS analysis showed a wide range of alkyl-phenol compounds, where 4-methyl guaiacol was one of the most abundant ones. These results have been confirmed from $^{13}C$ NMR, while Gel Permeation Chromatography showed good depolymerization of the raw biomass and good data reproducibility. $Cu/TiO_2$-P25 was active for the demethoxylation of 4-methyl guaiacol with either 0.1 wt.% and 1 wt.% sulfur. The reaction products mainly consist of methyl, dimethyl, trimethyl, and tetramethyl phenols. An increase in the amount of sulfur slightly affects the conversion. HDO tests of the Pyoil showed a decrease in the content of methoxy phenols of 10%, , and an increase of alkylated (methyl, dimethyl and trimethyl) phenols from 1.2 to 6.5%. Dealkylation does not occur during HDO and phenols lacking alkyl substituents are unreactive.

# Development of Ni-Mo catalysts supported on silica for the transformation of residual fatty raw materials into green diesel

J. Zafeiropoulos[1], G. Petropoulos[1], E. Kordouli[1,2], C. Kordulis[1,2], A. Lycourghiotis[1,2], K. Bourikas[1,*]

**Keywords:** Selective Deoxygenation, Green diesel, Ni-Mo Catalysts, Silica, Residual fatty raw materials

**Introduction**

A great source of renewable energy is biomass comprised from natural triglycerides, which contain smaller amounts of oxygens compared to other kinds of biomass. The selective deoxygenation (SDO) is an attractive upgrading process for this kind of biomass [1,2]. It is realized by hydrotreatment through decarboxylation ($deCO_2$), decarbonylation (deCO) and hydrodeoxygenation (HDO). In this context, two types of catalysts are proved to be very effective: supported noble metals and conventional sulphided NiMo, CoMo and NiW supported catalysts. However, both kinds of catalysts present several weaknesses. The noble metals have high cost and limited availability. On the other hand, the conventional sulphided NiMo, CoMo and NiW catalysts need to be maintained in the sulphided form by introducing sulphur compound in the feed, which presumably results to S-contaminated end products. The aforementioned weakness motivated, in the last years, intensive research on the less expensive transition metal catalysts in their metallic, phosphide, and carbide forms [2]. In this context, we developed Ni-Mo catalysts supported on silica with different atomic ratios of Ni/(Ni+Mo), in order to find the optimum ratio for the best peroformance of the catalysts in the the catalytic deoxygenation of sunflower oil towards green diesel. In the next step, we evaluated the best catalyst in the transformation of residual fatty raw materials (RFRMs) such as Waste Cooking Oil (WCO), Free Acid Distillates (FAD), Chicken Oil (CHO) and Spent Coffee Ground Oil (SCGO), into green diesel.

**Experimental/methodology**

A series of 4 catalysts ($NiMo/SiO_2$) was prepared using the wet impregnation technique, with various atomic ratios of Ni/(Ni+Mo) (0.84, 0.91, 0.95, 0.98). For comparison, the corresponding monometallic catalysts were also prepared. All catalysts had total metal loading equal to 50 wt %, since this has been found the optimum one in $Ni/SiO_2$ catalysts concerning SDO [3]. $[Ni(en)_3]^{2+}$ was used as the precursor Ni complex (where en stands for ethylenediamine) and ammonium heptamolybdate was used as the Mo precursor. In all cases, the deposition of the active phases was followed by drying, calcination and reduction. The physicochemical characteristics of the catalysts were studied using various techniques, such as $N_2$ adsorption-desorption, XRD, TPR, $NH_3$-TPD and TGA. The evaluation of the catalysts was performed in a semi-batch reactor at the following conditions: ratio of feed to catalyst mass 100 ml / 1 g, pressure 40 bar, $H_2$ flow rate 100 ml / min, speed of stirring 2000 rpm, temperature 310°C. A liquid sample was withdrawn from the reactor every hour and analyzed on a GC-MS system. The reaction was monitored for a period of 9h.

**Results and discussion**

All catalysts proved very active and selective in the SDO of sunflower oil to green diesel. The optimum ratio of Ni/(Ni+Mo) was found equal to 0.95. The promoting effect of Mo is due to its interaction with Ni, which significantly improves its dispersion, to the increase of the moderately acidic sites of the catalyst and to the creation of oxygen vacancies that appear in the molybdenum oxide and accelerate the SDO mechanism. The best catalyst, with the optimum Ni/(Ni+Mo) ratio, proved very effective also in the SDO of the residual fatty raw materials. The end products were mainly normal alkanes in the diesel range (n-C15, n-C16, n-C17, n-C18). The composition of the reaction liquid mixture in total green diesel follows the order: 92% (CHO), 90% (WCO), 68% (FAD) and 16% (SCGO). The comparison made between fresh and used NiMo catalyst showed that the coke deposit on the surface of the latter is significantly smaller compared to that of the Ni catalyst and the reduction in its active surface was relatively small. The above indicate that this catalyst maintains its physicochemical characteristics to a satisfactory degree and is quite stable even after a long time of reaction.

**Keywords:** biodiesel upgrading, green diesel, biofuels, Ni catalysts, natural mordenite treatment

**Introduction.**

In nowadays there is a rapid increase in the energy requirements of modern societies due to the growing population as well as the modern way of life. On the contrary, we are ever closer to the exhaustion of fossil fuels, the use of which is inextricably linked to climate change phenomena. This has alarmed the global scientific community, which is in constant search for renewable fuels. Biodiesel is such a fuel existing already in the market. The production of biodiesel via transesterification in microalgae and subsequent extraction appears to be a promising process in the future for biodiesel production. However, the biodiesel produced cannot be used as a direct substitute for conventional diesel and it needs to be upgraded. The development of cheap catalysts for this process is a key research task [1]. The present work focuses on the nickel catalysts development exploiting a Greek natural zeolite, mordenite, as a catalytic support. Two activation modes (acid and acid/alkali treatment) were tested for improvement of supporting properties of natural mordenite. The Ni catalysts prepared were evaluated for biodiesel transformation to green diesel at various reaction temperatures.

**Experimental/methodology.**

Natural mordenite from a Greek island [2] was treated with HCl aqueous solution (2M, 70 °C, 4h, mass / volume: 1/20) and then the solid was dried (110 °C overnight) and calcined (500 °C, 2 h), $MO_A$. An aliquot of $MO_A$ sample was treated with NaOH aqueous solution (2M, 65 °C, mass / volume: 1/15) and then exchanged with $NH_4NO_3$ aqueous solution (1M, 80 °C, 24h). Finally, it was dried and calcined as mentioned before, $MO_{AB}$. Two Ni catalysts (30 wt % Ni) were prepared using the activated supports by deposition-precipitation method ($NiMO_A$, $NiMO_{AB}$). XRF, $N_2$-physisorption, XRD, TEM, SEM, $H_2$-TPR, $NH_3$-TPD were used for catalysts characterization. A semi-batch high pressure (4MPa) reactor was used for catalysts evaluation.

**Results and discussion.**

Figure 1 shows that $NiMO_{AB}$ catalyst proved the most efficient one resulting in 94 % hydrocarbons (green diesel) yield after 9 h at 350 °C. Its high efficiency is attributed to the higher surface area, higher $Ni^0$ surface, moderate acidity related with lower coke formation, and its resistance to thermal sintering in comparison with the $NiMO_A$ catalyst. The hydrocarbons produced had one carbon atom less than the corresponding fatty acids being in biodiesel feed. Free fatty acids (Acids in Fig. 1) and high molecular weight esters (Esters in Fig. 1) are intermediate products upon biodiesel hydrotreatment.

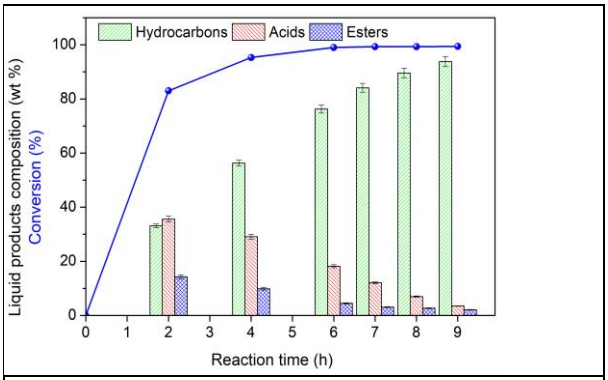

**Figure 1. Catalytic performance of $NiMO_{AB}$ catalyst**

# Promoted nickel catalysts supported on palygorskite for green diesel production

Fani K.[1], Lycourghiotis S.[1], Kordouli E.[1,2], Kordulis C.[1,2], Bourikas K[1,*].
[1]*School of Science and Technology, Hellenic Open University, Patras, Greece*
[2]*Department of Chemistry, University of Patras, Patras, Greece*
[*]*bourikas@eap.gr*

**Keywords**: Palygorskite, Promoted nickel catalysts, Green diesel, Waste cooking oil, Selective deoxygenation.

**Introduction.**

Beyond doubt our society is dealing with the depletion of fossil fuels in which there is a worldwide dependence as a main energy source. It is clear that a very promising approach is the use of biofuels. Green diesel can become a great potential to be a sustainable replacement for fossil fuel through selective deoxygenation of waste cooking oils (WCO) [1]. Additionally large amounts of catalysts will be essential in order to enhance the production of biofuels. Efforts of using cheap and abundant minerals as carriers for heterogenous catalysts have aggregated the interest of scientists [2]. In this work, nickel catalysts, promoted by different metals (Mo, W) supported on the natural cheap mineral palygorskite, were evaluated for green diesel production.

**Experimental/methodology.**

The raw material palygorskite was cleaned by a clay fraction method in order to be discharched of contaminants. Three nickel catalysts were synthesized via deposition-precipitation method with urea as precipitation agent: one monometallic catalyst with 30 wt. % nickel loading (30NiPal), a molybdenum promoted catalyst with Ni/(Ni+Mo)=0.95 (30NiMoPal) and a tungsten promoted catalyst with composition similar to the aforementioned one (30NiWPal). Both promoted catalysts had also30 wt. % total active phases loading. The final catalysts were obtained by reduction of the catalysts precursors with $H_2$ stream (30 mL/min) at 500$^O$C for 2.5 hours. The reduced catalysts were characterized using nitrogen adsorption-desorption isotherms, XRD and $NH_3$-TPD. Precursor samples (before reduction) were characterized by $H_2$-TPR. 30NiPal and 30NiMoPal were evaluated in the SDO of WCO at 310 $^o$C, hydrogen pressure 40 bar and reactant volume to catalyst mass equal to 100 mL / 1 g. Then, 30NiMoPal was evaluated to four different temperatures 330, 350, 370 and 390 $^o$C. At optimal temperature, 370 $^o$C, the amount of catalyst was duplicated in order to maximize green diesel production. Likewise at aforementioned conditions (T=370$^o$C, reactant volume to catalyst mass 100 mL/2g), the 30NiWPal catalyst was evaluated for comparison reasons.

**Results and discussion.**

Comparing monometallic Ni catalyst with the Mo-promoted Ni one, we found that the addition of molybdenum as a promoter enhanced significantly the production of hydrocarbons in the range of diesel ($C_{15}$-$C_{18}$) in the liquid product (from 23 to 45 wt %). This is attributed to the well known promoted action of Mo [3] as well as to the increase of the active surface of Ni in the promoted catalyst. Concerning the ideal temperature of the SDO reaction with the 30NiMoPal catalyst, it proved to be 370 $^o$C, where a value of 80% in hydrocarbons in the liquid product was achieved. In the same temperature, double mass of catalyst was examinated and green diesel in the liquid product reached 90%. Concerning the W-promoted Ni catalyst, at the same conditions, the evaluated 30NiWPal catalyst produced the same amount of hydrocarbons as the 30NiWPal catalyst. These results demonstrate similar promoting action of tungsten with molybdenum, which has been also observed in other catalytic systems [4]. Taking into account these results, Mo(W)-promoted nickel catalysts supported on palygorskite could be successfully used as low cost and very efficient natural catalysts for green diesel production from waste cooking oils.

# Synthesis of ion-exchange-resins-based bifunctional catalysts for MIBK one-pot production

E. Canadell, J.H. Badia, R. Soto, R. Bringué, E. Ramírez, J. Tejero

*Chemical Engineering and Analytical Chemistry Department, Universitat de Barcelona, Barcelona, Spain*

**Introduction.** Due to environmental concerns, the research for renewable alternatives to petrol-based derivatives has increased significantly. Among many potential candidates, methyl isobutyl ketone (MIBK) has drawn certain attention since it is a value-added chemical that can be obtained from acetone through a three-step catalytic pathway, including aldol condensation, dehydration and hydrogenation reactions [1,2]. Bifunctional acidic ion exchange resins, such as Amberlyst$^{TM}$CH28 (ACH28), have exhibited promising results, in terms of yield and selectivity, allowing to carry out the MIBK synthesis under mild conditions throughout a one-pot synthesis approach [1,3]. To enhance our knowledge on such synthesis, in the present work, the commercial ion exchange resins (Amberlyst$^{TM}$15 and Dowex 50Wx2), have been doped by wet impregnation with noble (Pd and Ru) and non-noble (Cu) metals and are tested in the MIBK reaction.

**Experimental/methodology.** The bifunctional catalysts were prepared by simple wet impregnation. In a typical experiment, 40.0 g of acetone and 2.0 g of the dried bifunctional catalyst, in the unreduced form, were loaded to a 100 mL stainless-steel batch reactor (316 SS Autoclave Engineers, Inc). Then, the air was removed with three $N_2$ flushing cycles. Afterwards, the $N_2$ was replaced with $H_2$. Temperature was set at 120 °C and stirring speed at 300 rpm. The reactor pressure was kept constant at 30 bar with $H_2$. The reaction mixture was analyzed by gas chromatography, after the reaction time.

**Results and discussion.** Pd-doped catalysts were the most active ones. Among them, Dow2-1%Pd showed the highest yield (36.8 %) to MIBK, a similar value as the obtained with the commercial ACH28 (see Table 1).

**Table 1**. Experimental results (120 °C, 20 bar, 300 rpm, 5 wt.% catalyst loading, 4 h).

| Catalyst | $X_{acetone}$ [%] | $S_{MIBK}$ [%] | $Y_{MIBK}$ [%] | ICP-MS [ M wt.%] | TON [mol acetone converted/ mol M] |
|---|---|---|---|---|---|
| **ACH28 (Pd)** | 35.2 | 100 | 35.2 | 0.70 | 1839 |
| **A15-1%Pd** | 30.9 | 100 | 30.9 | 0.95 | 1190 |
| **A15-1%Ru** | 15.1 | 39.2 | 5.9 | 1 | 527 |
| **A15-1%Cu** | 10.3 | 9.8 | 1.00 | 0.91 | 244 |
| **Dow2-1%Pd** | 36.8 | 100.0 | 36.8 | 0.89 | 1500 |
| **Dow2-1%Ru** | 16.4 | 27.2 | 4.46 | 1 | 571 |
| **Dow2-1%Cu** | 16.1 | 5.329 | 0.861 | 0.92 | 385 |

By comparison of the prepared catalysts, it can be observed that gel-type (i.e, Dow2), achieved higher acetone conversion at the expense of lower selectivity, than for macroporous resins (i.e, A15). Comparing the different metals, the noble doped catalysts resulted in a better performance than the non-noble metal doped ones. Pd-doped ion exchange resins performed better than those doped with Ru because Pd can hydrogenate C=C groups while Ru is mainly used for hydrogenating CO groups. Furthermore, the palladium leaching hardly took place during the reaction while the copper content decreased significantly (above 80%), indicating that leaching was at play. Additionally, the acid capacity of the resins did not change, indicating that no loss of acidic sites took place during the reaction.

# Hydrogenation of 4-(2-furyl)-3-buten-2-one to jet-fuel precursors using hydrotalcites

Claudio C. Díaz[1*], Ana B. Dongil[2], Néstor Escalona[1]

[1]*Pontificia Universidad Católica de Chile, Santiago, Chile*

[2]*Instituto de Catálisis y Petroleoquímica, Madrid, España*

* *cicontreras6@uc.cl*

**Keywords:** Hydrogenation, hydrotalcites, ceria, zirconia, Jet-Fuel

**Introduction.** The use of lignocellulosic waste, such as forest residues and sawdust, is especially attractive as a sustainable and economically resource. Hemicellullose is one of the major components of non-edible biomass which can be transformed into $C_5$-$C_6$ sugars, and further used to produce several chemical reagents [1]. Furfural, which is obtained by dehydration of glucose, is widely used as platform molecule and one application is the aldol condensation with ketones to grow carbon chains and produce jet fuel or value-added products[2]. Hydrotalcites (HTC) are lamellar materials of general formula $Mg_6Al_2CO_3(OH)_{16}$, known as aldol condensation and hydrogenation catalysts. In this work we aim at studying the effect of Ce and Zr as modifiers, in the hydrogenation of 4-(2-furyl)-3-buten-2-one using isopropanol as green solvent.

**Experimental/methodology.** Modified hydrotalcites were prepared by co-precipitacion method using nitrates of $Cu_{1.5}$:$Mg_{1.5}$:$Al_{1-x}$:$M_x$ (M = Zr or Ce, X=0.1 or 1). Samples were then calcined in air at 500 °C for 2 h, and reduced at 500 °C under $H_2$. Catalytic experiments were conducted in a batch Parr reactor. Catalysts have been characterized by XRD, SEM, $H_2$-TPR, $N_2$-adsorption.

**Results and discussion.** The XRD of reduced hydrotalcites (Fig.1) show the characteristic HTC spinel peaks at 2θ = 43° and 63° which are sharper for CuMgZr and CuMgAlZr, this suggesting that these samples hold a more homogeneous structure. All the samples displayed the diffraction due to Cu(0) except CuMgAlCe. Interestingly, for this latter sample the incorporation of Ce leads to $CeO_2$, while this is not observed in CuMgCe. The initial rate (Fig.2) was estimated at 20% conversion and followed the trend: CuMgCe >CuMgZr>> CuMgAlZr ~CuMgA>CuMgAlCe. For all the catalysts, the C=C bond hydrogenation is the preferred path, while hydrogenation of C=O increases slightly with Ce. Selectivity towards D and $D_2$ (OH cyclation of D and hydrogenation of the ring) increases as Al in HTC is replaced by Ce or Zr. Overall, activity significantly improves by the incorporation of Ce or Zr into the HTC. Despite the selectivity differences are modest, they suggest that Ce favors the hydrogenation of the C=O bond. Nevertheless, the effect of the solvent seems to be critical in the reaction, and further investigations are being performed.

# Selective $H_2$ production from formic acid decomposition over Re and Mo supported catalysts

Claudio C. Díaz[1], N.Escalona[1], I. Rodríguez-Ramos[2], A. B. Dongil[2*]

**Keywords:** $H_2$ production, Formic acid decomposition, Rhenium Oxide

**Introduction.** Hydrogen is an energy vector and a main reagent to synthesize high value-added compounds. However, 96% of $H_2$ worldwide is obtained from non-renewable resources. In this context, biomass-derived compounds like HCOOH (FA) are interesting as a renewable source since it is easier to manipulate, transport and store than $H_2$ [1]. Recently, molybdenum carbide supported on carbon materials, has been evaluated as catalyst for FA decomposition with high selectivity to $CO_2$ at low temperatures [2]. So far, Re has been used successfully in several hydrodeoxygenation reactions, but no studies have been done in formic acid decomposition. In this work, we have evaluated the effect of the support morphology, i.e. Graphite (G) vs carbon nanotube (CNT), and synthetic atmosphere on the obtained metal phase. The catalysts were tested on the decomposition of formic acid.

**Experimental/methodology.** Catalysts were prepared by impregnation with 10% wt. metal over commercial carbon supports (CNT $O^+$ and HSAG 400 (G)), and treated under 3 different atmospheres: $C_2H_4/H_2$ (25/75), $H_2$ and $N_2$ at 650°C, 650°C and 350°C, respectively. Experiments were performed in a fixed-bed reactor using FA (3.25% vol.) diluted in He with a WHSV of 10.8 mL FA $g_{cat}^{-1}min^{-1}$ at different temperatures.

**Results and discussion.**

*In situ* XRD of Re/G-$H_2$ displayed characteristics peaks of Re(0) at 2θ=36°, 40° and 42° while Re/G-$N_2$ presented peaks at 37°, 54° and a broad hump at 43° due to ReOx. Mo/G-$H_2$ showed diffractions at 2θ = 37° and 53° which could be assigned to $MoO_xC_y$ and $MoO_2$ phases. From these results, it seems that Mo is carburized by gasification of the support while Re is carburized just under $C_2H_4/H_2$. Regarding reaction results, Re is the most active and most selective to $CO_2$ reaching ~94-98% selectivity while Mo-based catalysts reached 86-89%. Both Re/G-$H_2$ and Re/G-$N_2$ yielded similar results despite the different phase obtained. The support with better conversion was the graphite. In summary, unlike Mo, Re oxide which is synthetized at low temperature under inert gas can decompose FA at low temperatures. This is relevant to further use the obtained $H_2$ for hydrodeoxygenation reactions, for which ReOx has proved to be very active.

**Keywords:** Tall oil Epoxidation, Heterogeneous Catalysis, Catalytic Screening

**Introduction.** Epoxidized Vegetable Oils (EVOs), thanks to the highly reactive epoxy group are excellent molecular platforms. EVOs have already been used to obtain polyols, carbonates and plasticizers [1]. Industrially, epoxidation of vegetable oil is carried out in semi-continuous mode via the Prilezhaev process where a percarboxylic acid acts as the oxidant agent by shuttling an oxygen atom from the polar aqueous media to the organic apolar one [2]. Despite its wide application, the process suffers from several drawbacks due to the use of homogeneous mineral acids to catalyze the formation of the percarboxylic acid, sas well as low selectivity toward the target product, demanding separation steps and corrosion of the reaction and separation equipment. To overcome this problem, different heterogeneous catalysts have been tested in both the epoxidation via the Prilezhaev process and the presence of hydrogen peroxide, looking for a catalyst with activities and selectivity at least comparable to the homogeneous ones [3]. In the present project, we have focused our attention on the epoxidation of tall oil, a Scandinavian raw material originating from Kraft pulping process, in the presence of heterogenous catalysts and hydrogen peroxide as the oxidizing agent. The main aim is to find the best catalyst in terms of activity and selectivity as well as to work in presence of a bio-based, non-toxic solvent which can improve or at least replicate the performance of the selected catalyst replacing the environmentally unfriendly ones.

**Experimental/methodology.** The adopted strategy is at first select and synthesize several promising heterogenous catalysts after which all of them are tested in the epoxidation process with a fatty acid model compound looking for the most promising one. Finally, the selected catalysts are studied in the epoxidation of tall oil by changing several experimental parameters, i.e. temperature, double bond-to-$H_2O_2$ molar ratio and solvent, as well as the amount of catalyst and amount of specific active phase on it. The goal is to achieve good performances in terms of activity, selectivity and reusability of the selected catalyst by studying in depth the relationship between the physicochemical properties of it and the obtained performances in the reaction system.

**Results and discussion.** The present project aim to study a new promising catalyst for the epoxidation of vegetable oil (tall oil) in the presence of hydrogen peroxide as oxidizing agent and bio-based solvent. The final aim is to shift to a renewable reaction system where all the reaction elements, namely reactants, solvent and catalyst, are either by-products from other reaction system or are renewable, non-toxic and environmentally friendly compounds following the idea of green chemistry and circulary economy.

**Keywords:** Na-BEA zeolite; Catalysis; Biomass; carboxylic acids; Oxalic acid; Lactic acid; Levulinic acid

**Introduction**

The purpose of the process is to develop a method for obtaining C1–C5 carboxylic acids (levulinic acid, oxalic acid, lactic acid, and formic acid) from a mixture of C6 and C5 carbohydrates derived from waste lignocellulosic biomass – hemicellulosic fraction using the one-pot method. We present the conditions for the conversion of hemicellulose with different contents of C6 and C5 carbohydrates and uronic acids based on the OrganoCat process [3].

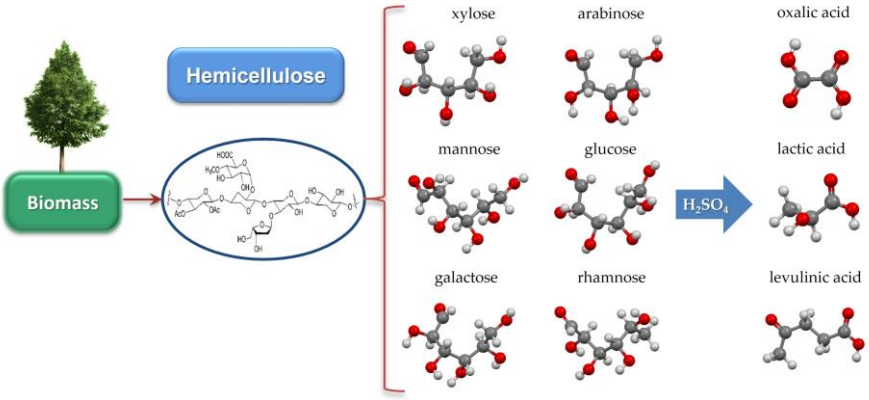

Fig. 1. Valorization of hemicellulose-derived mixture of sugars to carboxylic acids.

**Experimental/methodology.**

Three hemicellulose sugar mixtures were investigated, with different ratios of xylose, mannose, galactose, glucose, rhamnose, galacturonic acid and glucuronic acid (Figure 1). Three heterogeneous catalysts were used: Na-BEA zeolite and two ion exchange resins (AMBERLYST 15(H), DOWEX DRG8(H)). The one-pot catalytic conversion of fructose was performed in temperature ranges 100-250 °C for 1-5 h. Identification of products formed in the post-reaction mixture were identified with the participation of HPLC-RID.

**Results and discussion.**

Lactic acid (LAC) was obtained with the maximal yield of 86,4% (5 h, 250°C, DOWEXDR8X(H)) and levulinic acid (LA) with the yield of 44.1% 5 h, 250°C, DOWEXDR8X(H)) with the participation of DOWEXDR8X(H) as catalyst.

# One pot glycerol valorization of glycerol into acrylic acid: a catalytic and spectroscopic study

A. De Arriba[1], D. Delgado[1], P. Concepción[1], J. M. López Nieto[1,*]

[1]*Instituto de Tecnología Química, UPV-CSIC, 46022 Valencia, Spain*
[*]*jmlopez@itq.upv.es*

**Introduction.**
Multifunctional materials based on Nb/V-doped hexagonal tungsten bronzes (HTB) have demonstrated to be outstanding catalysts in the glycerol dehydration to acrolein [1]. Additionally, molybdenum based mixed oxides presenting the so-called M1 phase showed interesting properties in the partial oxidation of propane [2] and acrolein [3] to acrylic acid. Therefore, the aim of this work is to study the effect of using a single or double bed configuration by combining these two families of catalyts in order to optimize the selectivity to acrylic acid in a one pot aerobic transformation directly from glycerol.

**Experimental/methodology.**
Nb/V-doped HTB (*h*-$W_{0.71}Nb_{0.29}O_3$ and *h*-$W_{0.8}V_{0.2}O_3$) and M1 (MoVO, MoVTeO and MoVTeNbO) catalysts have been prepared hydrotermally at 175°C/72h and finally heat-treated afterwards at 550 (tungsten bronces), 400 (MoVO) or 600°C (MoVTeNbO) for 2h under $N_2$ stream. The physicochemical characterization of these oxides includes: XRD, $NH_3$-TPD, $N_2$-adsorption, Raman and XPS spectroscopies. *In situ* IR studies of adsorbed intermediates have been also carried out over selected catalysts. In addition, the catalytic tests were carried out in a fixed-bed reactor (alterning one or two subsequent catalytic beds) at 320°C and ambient pressure, with products being analyzed by both liquid and gas cromatography [3].

**Results and discussion.**
Characterization results indicate that both $Nb^{5+}$ and $V^{5+}/V^{4+}$ enter the HTB structure through isomorphic substitution of the $Me^{n+}$ cations for lattice $W^{5+}$ (**Fig. 1A**), while M1 oxides displayed differences in the XRD peaks, related to dissimilar shape of the crystals (**Fig. 1A**). However, regarding the catalytic results, for a single bed configuration, modified hexagonal tungsten bronces showed a selectivity to acrolein (*h*-$W_{0.71}Nb_{0.29}O_3$) and acrylic acid (*h*-$W_{0.8}V_{0.2}O_3$) notoriously higher than M1 catalysts (**Fig. 1B**). Nevertheless, by using a double bed configuration consisting of a first acidic bed (*h*-$W_{0.71}Nb_{0.29}O_3$) followed by an oxidizing bed (M1-phase catalysts), excellent catalytic performance can be achieved by modulating the second bed (**Fig. 1C**), with tetrametallic M1-MoVTeNb oxide presenting the best results (yield to acrylic acid up to 65%). The nature of active sites is also discussed by considering the *in situ* IR studies of adsorbed acrolein.

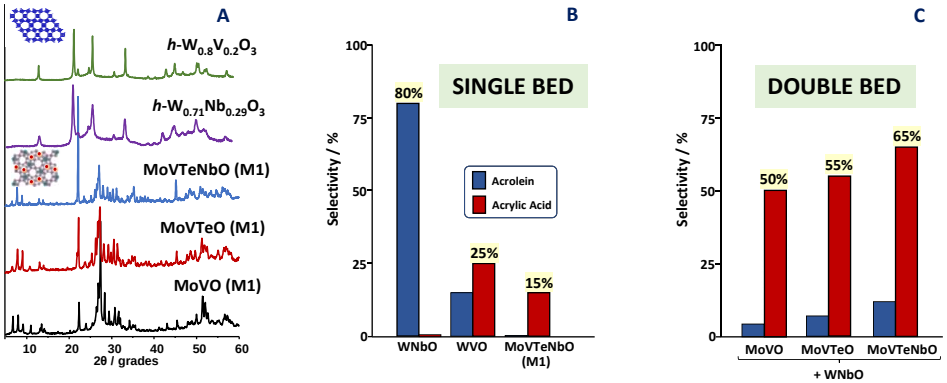

**Figure 1.** XRD patterns (**A**) of both Nb/V doped-Hexagonal Tungsten Bronze and M1-MoV(Te,Nb)O catalysts, and selectivity to acrolein/acrylic acid at 100% glycerol conversion of selected W- and Mo-based bronze catalysts in single (**B**) and combined bed (**C**) configurations.

# Efficient two-step production of biobased plasticizers: Dehydration-hydrogenation of citric acid followed by Fischer esterification

Anthony De Bruyne[1], Wouter Stuyck[1], Willem Deleu[2], Jarne Leinders[1], Carlos Marquez[1], Kwinten Janssens[1], Dimitrios Sakellariou[1], Ruben Ghillebert[2] and Dirk E. De Vos*

**Keywords:** Catalysis, Biomass to chemicals

**Introduction.** The increase in the global plastic consumption is accompanied by a growing concern about the safety of these plastics and their additives. For example, ortho-phthalates, which were the traditional plasticizers of polyvinyl chloride (PVC) plastics, are suspected to be bio-accumulating and endocrine disrupting.[1] A promising, safe and green alternative are derivatives of the renewable citric acid. Here, we focus on the production of propane-1,2,3-tricarballylate plasticizers, which possess excellent plasticizing properties.[2,3]

**Experimental/methodology.** In a first step, dehydration-hydrogenation reactions of a large amount of CA (20 mmol) were performed at relatively mild reaction conditions (150°C and 20 bar $H_2$) using $Al_2(SO_4)_3$ (homogenous) combined with $Pd^0$/C (heterogenous) as a catalytic system and water as a green solvent. In a second step, the reaction mixture was transferred to a Dean-Stark setup in order to perform a Fischer esterification with n-butanol, during which the previously used $Al_2(SO_4)_3$ could be recuperated. Reaction mixtures were anlysed *via* $^1$H-NMR.

**Results and discussion.** In this work, $Al_2(SO_4)_3$ in combination with $Pd^0$/C was found to be a cheap, stable and well-performing alternative to catalyze the dehydration-hydrogenation of citric acid. Citric acid and $Al^{3+}$ ions are known to strongly interact resulting in aluminum citrate (Al-citrate) complexes.[4] Both citric acid conversion and PTA yield were maximized at a pH value of 1.1 - 1.3. Through investigation by $^{27}$Al NMR and $^1$H-NMR, it was observed that under the applied conditions Al-citrate complexes are mainly present as $[Al\text{-}Hcit]^+$ and $[Al\text{-}cit]^0$. This may suggest that these species are the most active for the dehydration of citric acid. A maximum PTA yield (93%) was achieved for a reaction of 1 M citric acid (in 20 mL water), 1.25 mmol $Al_2(SO_4)_3$ and 0.5 mol% $Pd^0$ ($Pd^0$/C) with 20 bar $H_2$ at 150 °C for 20 hours (initial pH of 1.16). Only small amounts of methyl succinic acid (see Figure) were detected as side product. The stability of the $Al_2(SO_4)_3$ and $Pd^0$/C catalyst was confirmed by a fed-batch experiment and by CO chemisorption. Additionally, the catalytic system was proven to be robust, since the PTA yield remained largely unaffected when an industrial post-fermentation process stream (containing multiple organics and inorganics) of citric acid was used as substrate for the process.

**Keywords:** 2-acetyl furan, methyl 2-furoate, cross-ketonization, continuous-flow, gas-phase.

**Introduction.** In recent years, the ketonization of carboxylic acids has emerged as a main way to valorize multiple biomass-derived products. For instance, the coupling of light acids has been extensively investigated for the $H_2$-free deoxygenation of the bio-oils from fast-pyrolysis of lignocellulose [1], while the ketonization of fatty carboxylic acids (vegetable oils or waste fat) produces bio-based lubrificants and/or waxes [2]. However, the full potential of this reaction has yet to be suitably developed, in particular aimed to the alternative production of valuable asymmetric ketones.

In this work, the cross-ketonization between methyl 2-furoate (MF) and acetic acid (AA) was investigated with the aim of selectively synthesizing 2-acetyl furan (AF), a well-known flavour/fragrance and pharamaceutical intermediate [3]. This approach towards AF (depicted in figure 1), in respect to the traditional Friedel-Crafts acylations with homogeneous Lewis acid catalysts, would benefit from continous operation, a much easier work-up, and the use of bio-based feedstocks (e.g. AA and furfural-derived MF).

**Experimental/methodology.** All catalytic tests were carried out in the gas-phase using a continous-flow fixed-bed reactor. Unreacted reactants and products were quantified by means of GC-TCD (online) and GC-FID (offline). Unknown products were identified by means of GC-MS. Monoclinic $ZrO_2$ was prepared adapting a precipitation technique from the literature [4].

**Results and discussion.** The synthesis of AF was preliminarly carried out over $ZrO_2$ by feeding an AA/MF/$N_2$ = 1/1/98 mixture at 350 °C, contact time = 1 second. In these conditions MF conversion was ≈ 70 % and AF yield was ≈ 43 %; at the same time, AA conversion was complete, meaning that the homo-ketonization of AA towards acetone competed with the desired reaction, subtracting AA and limiting the achievable yield of AF. Therefore, the excess of AA in respect to MF was increased by increasing the molar fraction of AA in the feed up to 4 %: in these optimized conditions the conversion of MF was complete and a 70 % yield of AF in respect to MF was achieved. The versatility of this synthetic route towards acylfurans was further investigated by carrying out the cross-ketonization between MF and carboxyilic acid with different chain-lenghts (i.e. propionic and butyric acid), thus extending the substrate scope of the method to the propionyl- and butyryl-derivatives of furan, which were obtained with 70 and 80 % yield respectively.

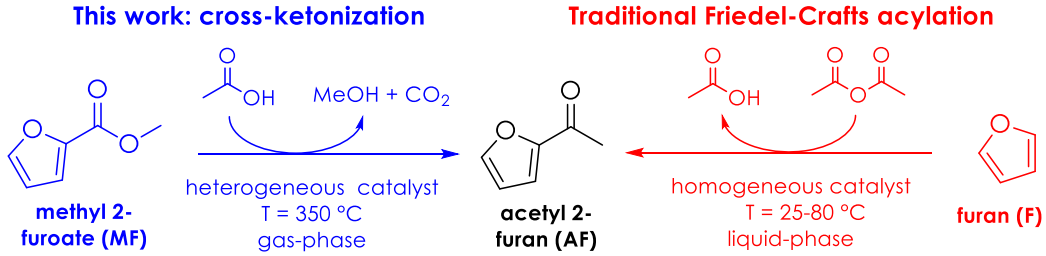

**Figure 1:** AC synthesis by means of cross-ketonization between MF and AA compared to the traditional synthesis by means of Friedel-Crafts acylation of furan with acetic anhydride.

**Keywords:** Biomass conversion, 2,5-dimethylfuran, Gallium, Ga-silicate, ZSM-5, BEA

**Introduction**

The growing demand for a sustainable chemical industry can be satisfied by utilizing renewable carbon sources like lignocellulosic biomass. One interesting model reaction is the conversion of biomass-derived furans into valuable aromatic building blocks such as benzene, toluene, and xylenes (BTX). Microporous solid acid catalysts, such as zeolites and zeotypes, are employed for their readily tuneable acidity and porosity, for example through incorporation of heteroatoms.

**Experimental/methodology**

For the conversion of 2,5-dimethylfuran (2,5-dmf) into BTX, a continuous fixed-bed powder reactor is used in which the effluent gases are analysed using using an online mass spectrometer (MS) as well as an online Fourier Transform Infrared (FTIR) spectrometer. Advantages of using this continuous reactor and on-line analysis is the high sampling frequency of at least 4 $min^{-1}$, as well as the ability to co-feed addends like ethene and propene in a stepwise manner. Zeolitic and zeotypic catalysts are prepared through a broad variety of synthesis methods. Structural analyses of fresh and spent catalysts and their acid sites include XRD, XRF, $N_2$/Ar-physisorption, SEM, TEM, EDX, TGA/DSC, $NH_3$-TPD, DRIFTS, and $^{29}$Si-, $^{27}$Al-, $^{71}$Ga-MAS NMR.

**Results and discussion**

To examine the effect of incorporating heteroatoms into the catalyst and its ability to convert furans into aromatics, aluminium and gallium have been isomorphously substituted into MFI framework silicalite-1, resulting in ZSM-5 and Ga-silicate, respectively [1]. These heteroatoms proved crucial for creating active sites and Ga-silicate demonstrated a superior BTX selectivity and catalyst lifetime, compared to ZSM-5 catalysts with both an equal or higher acid site density. The catalysts of relative low acid site densities remained active for isomerisation reactions even after 10 hours of 2,5-dmf conversion at 500 °C, whereas conversion to BTX was below 5% after 2 hours on stream. Acid site analysis before and after the reaction revealed deactivation of strong, extra-framework acid sites, associated with the cracking, decarbonylation and dehydration of the reactant 2,5-dmf which provided an unsaturated olefinic hydrocarbon pool (fig. 1). Co-feeding of ethene did not influence the BTX formation, suggesting the absence of a Diels-Alder Cycloaddition-Dehydration mechanism.

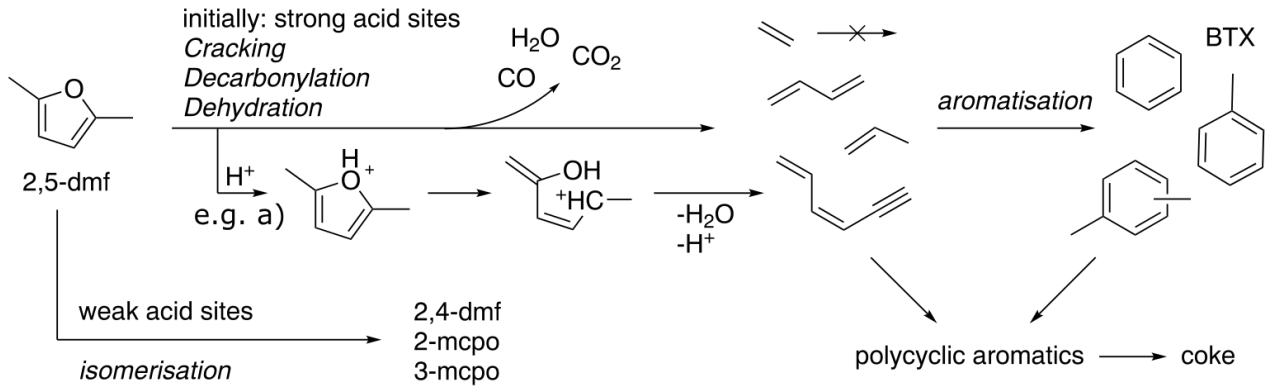

**Fig. 1: Reaction scheme for the conversion of 2,5-dmf [1]. Possible pathway a) was suggested by Uslamin et al [2].**

**Keywords:** Decarboxylation, Pd catalysts, Promotion effect, Alkali-metal compounds.

**Introduction.**Direct converting carboxylic acids into high-valued alkanes by hydrodeoxygenation is an effective way to achieve the upgrading of biomass-derived chemicals to high-value fuels. Developing efficient methodologies for conversion of carboxylic acids into alkanes under relatively mild conditions is essential for carboxylic acids utilization[1]. Alkali metals were found to be effective modifiers for the catalysts in various reactions by adjusting the surface acid-base property, increasing dispersion and stability of host metals (such as Pt, Pd, Cu, Co, etc.,), and participating in reaction[2,3] . Therefore, in this work, we report an efficient decarboxylation of carboxylic acids by modifying PdHx/C[4] catalyst with $KHCO_3$, which can greatly enhance the decarboxylation activity and is applicable to various carboxylic acids and the promotion mechanism is also investigated.

**Experimental/methodology.** Pd/C and alkali-metal compounds modified Pd/C catalysts were synthesized by the incipient wetness impregnation method. Catalytic decarboxylation reactions were performed in a high-pressure stainless-steel autoclave (300 mL) with a mechanical stirrer and a heating jacket. In situ sampling was carried out during the reaction by taking 1 mL of reaction liquid through a sampling tube with a filter. GC-MS analyzed the products. Reaction mechanism The physical and chemical properties of the catalyst were characterized by $N_2$ adsorption, $H_2$-Chemisorption, CO/$CO_2$-TPD, XRD and XANES.

**Results and discussion.** Decarboxylation of hydrocinnamic acid on $PdH_x$/C exhibited poor activity with a TOF of 5 $h^{-1}$. When introducing a small amount of alkali metal compounds to the Pd/C surface, the decarboxylation performance of $PdH_x$/C undergoes obvious changes (**Fig. 1**). By screening different potassium compounds including KOH, $K_2CO_3$, $KHCO_3$ and KCl, 1wt. % $KHCO_3$ modified $PdH_x$/C exhibits the highest decarboxylation activity (TOF of 96 $h^{-1}$) which is almost 20 times higher than the unmodified $PdH_x$/C catalyst. $CO_2$-TPD reveals that the introduction of $KHCO_3$ enhances the surface basicity. RCOO-K species was identified from XRD profile of used catalyst, deuterium labeling results indicate COOH group of the reactant is preferably adsorbed and dissociated on the $KHCO_3$–modified catalytic surface. Therefore, the promotion effect of $KHCO_3$ on the $PdH_x$/C catalyst could be ascribed to that $KHCO_3$ activates the COOH group by reversibly reacting with the proton in COO-H and forming hydrocinnamate anion intermediate (COO*). This dissociatively adsorbed hydrocinnamate anion is reported to be more preferable for the C-C bond cleavage than the molecularly adsorbed carboxylic acid, thus contributing to a higher decarboxylation activity on $KHCO_3$-modified $PdH_x$/C catalyst.

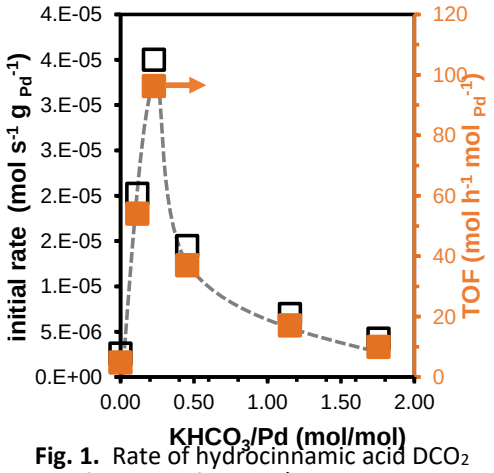

**Fig. 1.** Rate of hydrocinnamic acid $DCO_2$ as a function of $KHCO_3$/Pd molar ratio.

**Introduction.**
To mitigate climate change and decrease society's reliance on fossil resources, the industry must develop new processes to produce fuels and chemicals from renewable carbon resources. One of them is the hydrogenolysis of carbohydrates to ethylene glycol (EG). This reaction exploits a tandem catalyst system based on homogeneous $WO_x$ and heterogeneous Raney-Ni; the former cleaves the sugar to glycol aldehyde and the latter hydrogenates the glycol aldehyde to EG. This reaction proceeds with good selectivity with clean glucose and cellulose, but with lower yields with lignocellulose. We will discuss here this challenge and assign it to complex catalyst deactivation by feedstock contaminants, i.e., partly by lignin and more critically by ash and S/N. Catalyst deactivation is indeed a critical, though often neglected challenge in biorefining [1].

**Results.**
The yield loss observed with real lignocellulosic feedstock has been assigned to catalyst poisoning because it is avoided by using excessive amounts of $WO_x$ and Ni catalysts in batch operation.
The first suspected poison is lignin that accounts for ~25 wt.% of lignocellulose. Experiments with delignified feedstock and physical mixtures of cellulose/lignin confirmed some poisoning of the raney-Ni catalyst by lignin [2]. However, they could not assign the yield loss to lignin: some lignin-rich feed reached high EG yields while some lignin-lean ones did not.
We then turned to the ash that can account for <10 wt.% of lignocellulose. We removed part of the ash by various wash treatments and added some to clean cellulose [3]. Divalent cations, particularly $Ca^{2+}$, appeared to consume $WO_x$ by converting it to inactive $CaWO_4$ precipitate (fig. 1, left).
But the Ca content still failed to explain the very low EG yield measured with some grasses in the presence of excess $WO_x$. Beyond being rich in Ca (~0.1 wt.%), grasses can also contain ~1 wt.% of N and ~0.1 wt.% of S, e.g., bound in proteins. Deep removal of N and S by water/acid wash indeed allowed hay to deliver EG yields that are comparable to that of clean cellulose (fig. 1, right) [4].

This study allowed us to define quality criteria for hydrogenolysis feed. It also allowed us to propose a pretreatment scheme to help bringing real lignocellulosic feedstock up to specification [5].

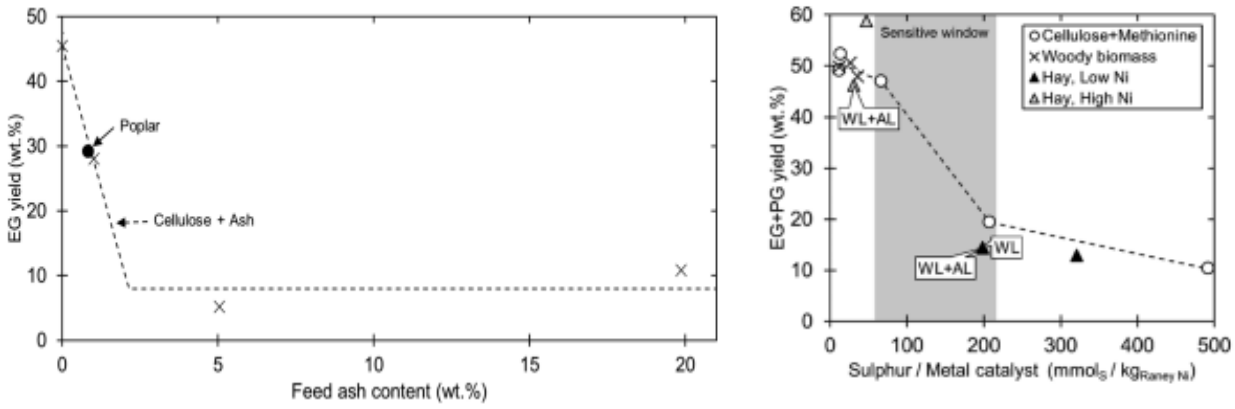

Figure 1 – Ash and S poisoning of cellulose hydrogenolysis to ethylene glycol (EG)

**Keywords:** Biofuels, hydrotreatment, marine biofuel, Jet biofuel, Triacylglycerides

**Introduction.**
The global aviation industry seems to be a constantly and rapidly expanding sector in recent years. The International Air Transport Association (IATA) claims that the request for air connectivity will continue to grow. In addition in April 2018, IMO's Marine Environment Protection Committee (MEPC) adopted an initial strategy on the reduction of greenhouse gas emissions from ships.The major challenge for thermochemical pathways is to develop conversion technologies with reduced energy consumption. In this direction, it is critical the incorporation of alternate approaches aiming to supply the demanding energy requirements of gasification process, syngas production, purification, hydrocracking etc. [1]. The BioSFerA concept aims to develop a combined thermochemical - biochemical pathway that minimizes the shortcomings of the existing technologies and takes advantage of their strong aspects in order to produce elevated yields of the desired fuels with limited energy consumption[2].

**Experimental/methodology.**
The overall process, combining thermochemical, biological and thermocatalytic parts is based on the gasification of biomass and other biogenic waste in a Dual Fluidized Bed gasifier and the 2-stage fermentation of the produced syngas. Through this process the syngas is converted to acetate (1st stage) and then the acetate is converted to TAGs (2nd stage). The produced TAGs contained medium and long fatty acids were hydrotreated and isomerized after the necessary separation and purification and the end-products are jet- and bunker-like biofuels, respectively. The current manuscript, will present the step of TAGs upgrading via hydroprocessing targeting jet- and bunker-like biofuels.

**Results and discussion.**
The results have shown that the most influential parameter during hydrotreatment, is the reaction temperature that strongly affects the mass recovery curve of the product. In general, higher reaction temperatures favour hydrocracking reactions leading to lighter hydrocarbons in jet fuel range. On the other hand, lower hydrotreating temperature leads to heavier hydrocarbons in bunker fuel range. Thus, the choice of reaction temperature is very important as it affects the final distillation range and thus the bunker fuel and jet fuel yields of the product. Pressure is also influencing the hydrotreating reactions and more specifically, the higher the pressure the lighter the product is. However, the effect of pressure is not as strong as that of temperature. Furthermore, as higher pressures and temperatures favour hydrocracking reactions, this result in higher hydrogen consumption. The hydrogen consumption increased as the heavier hydrocarbons are cracking to lighter ones. Thus, the choice of the optimum operating parameters is very important and depends first of all from the targeted products (bunker or jet range biofuels) and also from the optimum hydrogen consumption.

**Keywords: copper-cobalt ferrites; methanol decomposition, activated carbon, ceria-carbon hybrids**

**Introduction.**

Nowadays, methanol is considered as an important hydrogen precursor and carrier as hydrogen can be easy and safely released from it at relatively low temperatures by simple catalytic process of metanol decomposition. This reaction gives as products a gaseous mixture that can contain $H_2$ , CO, $CO_2$ and $CH_4$. In order to lead the reaction selectively to syngas production a very important role plays the used catalyst. Bulk transition metal containing ferrites show high ability to decompose methanol predominantly to syngas [1,2]. However, if we use a high surface area support, we could improve activity, selectivity and stability of the active phase using just a small amount of it. Carbon-based supports have many advantages, such as high surface area, well-developed porous structure and tunable surface chemistry, stability at high temperatures in inert or reduction atmosphere. Additional improvement of both textural and chemical functionality could bring the combination of nanostructured ceria with carbon materials (nanodiamond or graphene oxide). The aim of the present study is to show the advantages of using $Cu_{0.5}Co_{0.5}Fe_2O_4$ supported on various carbon-containing supports as catalysts for syngas prtoduction from methanol.

**Experimental/methodology.**

For the preparation of the catalysts were used as supports three activated carbon materials synthesized from various mixtures based on spent motor oil and sawdust, coal and fly ash, respectively, as well as ceria-carbon hybrids (ceria-graphene oxide and ceria-nanodiamond). The copper-cobalt ferrites ($Cu_{0.5}Co_{0.5}Fe_2O_4$, total metal content of 8 wt %) modifications were prepared by incipient wetness impregnation from the corresponding metal nitrate precursors. The obtained final catalysts were characterized by a complex of characterization techniques (X-ray diffraction, nitrogen physisorption, Moessbauer spectroscopy, and temperature-programmed reduction with hydrogen) and their ability to decompose methanol was studied as well.

**Results and discussion.**

The obtained results show a fine dispersion of the supported active phase in all studied samples, and it represents a complex mixture of species in different oxidation state. The active phase udergoes changes during the reaction due to the reductive influence of the reaction medium that reflects in both activity and selectivity of the catalysts. At low conversion temperatures (500-600 K) the selectivity to syngas production reaches above 90 % and gradually decreases to about 70 % with further temperature increase up to 750 K. At the same time the activity varies among the studied materials and seems to be significantly influenced by the support textural and functional characteristics.

**Keywords:** C5 sugars, xylose dehydration, furfural, acid catalyst, metal mixed oxide.

**Introduction.** Nowadays, the depletion of petroleum resources combined with the increasing demand for fuels and energy from emerging economies, and political and environmental concerns about fossil fuels, makes imperative to develop economical and energy efficient processes for the sustainable production of fuels and chemicals. Thus, plant biomass is the only renewable source of carbon and Hydrogen for biofuels and biochemicals production.[1] Furfural is a biomass-derived chemical considered as a platform chemical for fine chemicals industry, as well as useful for many other applications, such as extractant in the refining of lubricating oils, fungicide precursor, nematocide, adhesive, etc.[2] Furfural is produced from agricultural/waste raw materials rich in hemicellulose (pentosan polymers) by depolymerisation of pentosan to pentoses (mainly xylose) at high temperatures (150-250 ºC) in the presence of acid catalysts (i.e. sulfuric acid). Nevertheless, industrial processes suffer from serious drawbacks (i.e. corrosive and toxic catalysts or humins deposits), and technological improvements are needed to increase the possibilities of furan-based chemical industry. In this work, different metallic mixed oxides with controlled acid and textural properties are used as catalysts for selective dehydration of xylose to furfural, and their catalytic activity compared to homogeneous (i.e. $H_2SO_4$) and heterogeneous (i.e. zeolites) reference catalysts.

**Experimental/methodology.** Metal oxides and mixed oxides were prepared by co-precipitation or by hydrothermal synthesis from the corresponding metal precursors, characterized by ICP, XRD, $N_2$ adsorption isotherms, SEM and TEM, $NH_3$-TPD), and calcined in air at 450-550 ºC prior to their use as catalysts. Catalytic tests were performed in a 12 mL teflon-lined autoclave reactor equipped with a magnetic stirrer, temperature and pressure controllers and a valve for liquid/gaseous sample extraction. Typically, 10wt% xylose in water or $H_2O$/alcohol mixture and the solid catalyst were poured into the reactor. The reactor was closed and the xylose dehydration was performed at 160 ºC during 3 h under continuous strirring. After cooling to room temperature, the reaction mixture was filtered and liquids analysed by HPLC (Agilent 1200 with RI detector and a Bio-Rad Aminex HPX-87H column, with 5 mM $H_2SO_4$ as mobile phase at 60 ºC).

**Results and discussion.** Different solid acid materials based on transition metal oxides and mixed oxides were synthesized and essayed in the xylose dehydration to furfural, and their catalytic activity was compared to the both homogeneous ($H_2SO_4$) and heterogeneous (zeolites, commercial oxides) reference catalysts (Fig. 1B). The xylose dehydration goes through intermediates formation giving furfural as main product if the catalyst offer the adequate acidity, but intermediates rapidly undergo non-desired reactions (condensation, resinification) if active sites have lower or higher acidity than required (Fig. 1A). Among the different metallic oxides tested, Nb-based mixed oxides with adequate combination of Brönsted and Lewis acid sites give results (in terms of conversion and selectivity) similar to H-USY zeolite, higher than other single metal oxides, and close to those achieved with sulfuric acid industrial catalyst.

**Keywords:** molybdenum carbide, aqueous phase reforming, hydrogen production

**Introduction.** Recently, there has been a growing interest in revaluing residues generated by biorefineries in order to reduce their environmental footprint. Hydrogen production using biomass derivatives has been studied through vapor phase reforming or supercritical water reactions [1]. Ethanol is an atractive precursor and transition metal carbides, such as molybdenum, have catalytic potential to replace noble metals both in vapor and water phases [2]. In this work, aqueous phase reforming (APR) was studied to value ethanol in hydrogen, using molybdenum carbides in two cristaline phases (α y β) supported on zirconium. Carburization temperature (650-700°C), metal content (5-10-15% Mo) and reaction temperature (225-250-275°C) effects were studied.

**Experimental/methodology.** The zirconium support was prepared by precipitation at pH 9 and the catalysts by incipient wetness impregnation. Phase α and β carbides were synthetised using a $C_2H_4/H_2$ 25/75 mixture at 650°C, with a previous ammonia treatment for the α phase. The catalysts were caracterized by N2 physisorption, TPR-MS, DRX and XPS. Catalytic properties were studied in an agitated 25 mL batch reactor using water as solvent. The reactor was presurized with $N_2$ up to 6 bar and then heated to 250°C, reaching 46 bar. Reaction time was set at 90 min. Liquid products were analyzed by HPLC and gas products by gas chromatography (GC).

**Results and discussion.** Concerning catalytic performance, it was observed that ethanol conversion decreases with higher metal content (Figure 1a), which correlates with the carburization degree studied through TPR (Figure 1b). However, 10% Mo showed greater selectivity towards $H_2$, which might be explained by the oxicarbide presence detected through TPR (Figure 1b) and XPS. Reaction temperature has an effect on APR, being directly proportional to catalyst activity. $H_2$ production was favoured at 250°C. In addition, a higher ethanol conversion was observed for the α phase, in agreement with literature and which might be explained by a greater particle dispersion over the support. Nevertheless, $H_2$ selectivity was higher for the β phase.

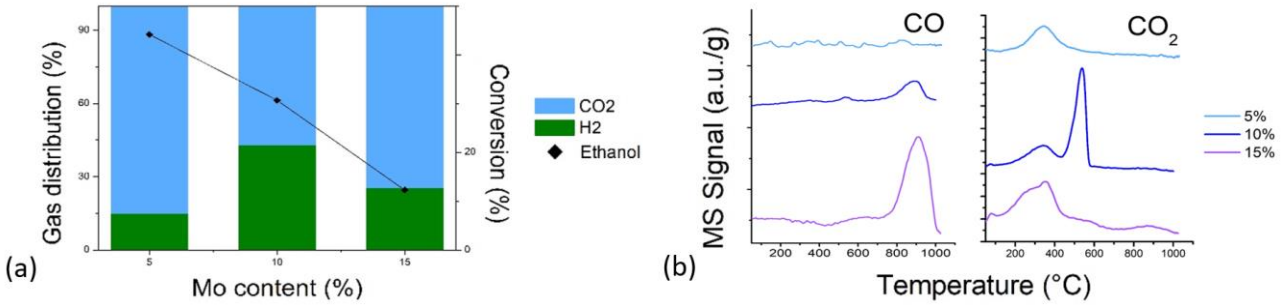

**Figure 1: (a) Effect of Mo content on catalysts' activity and (b) MS-Signal for the TPR analysis.**

**Keywords:** biomass, biocrude

**Introduction.**

The growing demand for energy resources and the need to reduce the consumption of fossil fuels in favour of more sustainable processes have led to an interest in the production of biofuels trough different routes, such as gasification, pyrolysis or liquefaction of biomass. In particular, the HTL (hydrothermal liquefaction) process allows the obtaining of a high-oxigeneted biocrude through the thermochemical conversion of wet biomass. This contribution aims to produce a high quality Biocrude that can be use in refinery by an assisted catalytic liquefaction.

**Experimental/methodology.**

To compare the properties of the biocrude obtained and the performance of the process, five different biomasses were used, divided into two categories: higher lignin content (sugar cane bagasse, rice husk and pine nut husk) and lipid-rich (Yellow Horn seeds and *Scenedesmus Al*. microalgae). HTL-D tests were carried out for 40 min in a 600 $cm^3$ Parr 4842 stainless steel pressure stirred reactor operating under subcritical water conditions at 600 rpm and 280 °C. Catalytic assisted process (HTL-CA) was analyzed under the same conditions, adding a short-chain alcohol that acts as a hydrogen donor (glycerol 3 wt %) and a Ni-Pt/$Al_2O_3$ catalyst that induces the aqueous phase reforming (APR) [1] of the glycerol. The catalyst with 9 and 0.09 atoms per $nm^2$ of support of Ni and Pt, respectively. was synthesised using pellets of 6 mm in length and 4 mm in diameter. The composition of the biocrude obtained was analysed by (GC-MS), Perkin-Elmer 2400 equipment, and Parr 6050 calorimeter. Were used for elemental analysed (C, N, H, S, O) an HHV (Higher Heating Value) estimation, respectively.

**Results and discussion.**

The biocrude yield registered by HTL-CA increases with respect to the direct process with values of about 18 % for lignocellulosic biomasses and values between 60 and 70 % for lipid biomasses. A higher HHV, with values between 35 and 50 $MJ \cdot kg^{-1}$, and an increase in H/C ratio and a decrease in O/C molar ratio in comparison with the direct HTL process were observed.

The HTL-D produces the depolymerisation of the biomass and the incorporation of the glycerol in the presence of the Ni-Pt catalyst promotes the production of $H_2$ by APR which produces the hydrogenation, decarboxylation and decarbonylation of the biocrude, these reactions in tandem tend to the formation of more saturated hydrocarbons in which the main fraction was found between C6 and C10.

[†]*These authors contributed equally*
[*]*alexis.bordet@cec.mpg.de; ar@kemi.dtu.dk*

**Introduction.** Metal nanoparticles (NPs) synthesized from organometallic precursors on molecularly modified surfaces (NPs@MMS) show benefitial properties for the design of multifunctional catalysts [1]. Variations of the support, the molecular modifier, as well as the employed NP precursors enable the preparation of tailor-made catalysts [2-4]. NPs@MMS catalysts have been found to exhibit excellent selectivity control in the hydrogenation of biomass-derived furfuralacetone (FFA, **1**). The different functional groups in FFA (*i.e.*, C=O, C=C and furan ring) have different reactivity and the product distribution upond hydrogenation depends on both the reaction conditions as well as the nature of the catalyst (Figure 1a). In this work, a NPs@MMS catalyst composed of Ru NPs immobilized on an aluminium phosphate (APO-5) [4] support modified with ionic liquid (IL) (Ru@SILP) was introduced for FFA hydrogenation, and its reactivity compared to an analogous Ru@APO-5 catalyst without IL-modifyer and Ru@$SiO_2$.

**Experimental/methodology.** Modified APO-5 support (APO-5-OH) was prepared by hydrothermal synthesis followed by grafting with ionic liquids (when used) and introduction of Ru NPs *via* a wet impregnation method using an organometallic precursor.

**Results and discussion.** Ru@SILP(APO-5-OH) and three reference catalysts Ru@APO-5-OH, Ru@SILP($SiO_2$), and Ru@$SiO_2$ were applied for the hydrogenation of FFA. The catalysts with the APO-5-OH support showed high selectivity for compound **3**, while the catalysts with $SiO_2$ support displayed high selectivity for compound **5** at 60 °C with 30 bar $H_2$ gas (Figure 1b), indicating that the adsorption mode of FFA might largely affect the product distribution. Furthermore, the selectivity of Ru@SILP(APO-5-OH) shifted from compound **2** to **3** and finally to **5** by increasing the reaction temperature from 20 to 200 °C (Figure 1c). Notably, the introduction of IL also made the Ru@SILP(APO-5-OH) more stable than the catalysts wihtout IL. In summary, the IL-modified APO-5-OH support generates a stable and highly durable Ru@MMS catalyst with temperature-controlled product selectivity for FFA hydrogenation and possibly also for alternative substrates with similar functionalities.

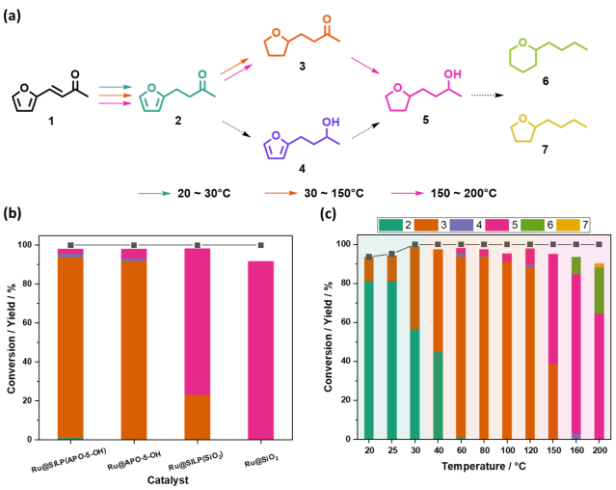

**Figure 1. (a) Hydrogenation network of furfuralacetone; (b) Catalytic performance of different catalysts at 60 °C; (c) Catalytic performance of Ru@SILPs(APO-5-OH) at different reaction temperatures.**

# Enhancing the bio-oil conversion using open cell foam structured catalytic reactors

E. Farah[1], E. Kantarelis[1, *]

[1] *KTH Royal Institute of Technology, Department of Chemical Engineering, Stockholm (Sweden)*
[*] *ekan@kth.se*

**Keywords:** open cell foam, structured reactors, process intensification, pyrolysis oil.

**Introduction.** A compelling step towards defossilizing current industrial processes is to replace fossil-based resources with biomass-derived ones. The catalytic upgrading of the biomass-derived oil, to produce important industrial feedstock such as light alkenes, emerges as an attracting alternative and takes place over microporous zeolites. Nevertheless, steric hindrances and diffusion limitations at particle scale combined with conventional packed bed reactor arrangement, that induces large pressure drop, temperature gradients, low external mass transfer and possibility of channeling [1], result in poor control of the mass (and heat) transfer at different scales promoting secondary reactions and altering the product distribution. Deposition of hierarchically ordered zeolite coatings on well-defined structures, such as open cell foams could enhance the overall mass transfer of the reactants to the active sites of the catalyst, control their reaction time, and thus improve conversion and selectivity to desired products [2-4].

In this study, the effect of different ZSM-5 coatings supported on an aluminum open cell foam catalyst on the catalytic cracking of biomass-derived oil is investigated. The catalytic performance and the deactivation behavior of the tested catalysts are compared to their activity in a packed bed configuration. More specifically selectivity to primary products (e.g., light olefins) and coke type and amount are of interest.

**Experimental/methodology.** Hierarchical ZSM-5 catalysts were prepared and coated on aluminum foam by hydrothermal treatment. The catalytic performance was evaluated at 600 °C and WHSV 1-7 $h^{-1}$ and compared to runs using a fixed bed arrangement. The pyrolysis oil was injected in a pulse mode totaling 4 pulses of 15 mins each (Figure 1). The gas and liquid products were analyzed using gas chromatography.

**Results and discussion.** The conversion of bio-oil in a packed reactor revealed a fast decrease in the activity of the hydrothermally synthesized hierarchical HZSM-5 compared to the desilicated ones. The coke content (20%) was also higher than the Ds-HZSM-5 (14%) and the Fe-doped one (18%). The experiments using a foam supported catalyst are ongoing.

[3]*Laboratory for Chemical Technology, Ghent University, Belgium*
[*]*bert.sels@kuleuven.be*

**Keywords:** B-ZSM-5 zeolites, Direct dehydration, 1,3-Butanediol, 1,3-Butadiene

The most important and fundamental conjugated diene is 1,3-butadiene (BD), which is a key intermediate for the production of a variety of synthetic rubbers and polymeric resins [1]. Currently, over 98% of 1,3-BD is obtained as a by-product in ethylene plants during naphtha cracking or through the oxidative dehydrogenation of *n*-butane and *n*-butene [1,2]. However, the depletion of these non-renewable feedstocks increases the demand of BD production via greener and more sustainable routes based on bio-based renewable resources [3]. Butanediol isomers (BDOs) (such as 1,3-, 1,4- and 2,3-) can be produced in high yields from biomass by fermentation, therefore, the acid-catalyzed dehydration of such $C_4$ alcohols paves the way to alternative routes for bio-BD synthesis [3].

Our work aims to stably produce BD with a very high yield from the catalytic dehydration of 1,3-BDO in the gaseous phase. To realize this goal, the catalytic behaviour of several acidic commercial zeolites with different topologies were tested at 300°C under atmospheric pressure in a fixed-bed flow reactor. Results revealed that the framework structure of zeolites plays a crucial role in governing butadiene selectivity. In addition to topology, active site accessibility, acid strength and acid site density can have a prominent impact on conversion rate, selectivity as well as stability in such dehydration reactions. While better sites accessibility may lead to shorter diffusion paths in the catalyst particle and lower cokes formation, hence, higher conversion and higher butadiene selectivity may be achieved; weak acid sites might decrease propylene formation by hindering carbon-carbon catalytic cracking. To tackle these properties, new dehydration catalysts such as Boron-incorporated MFI zeolites were synthesized, and their catalytic activity was evaluated. The catalytic results of B-ZSM-5 compared to its proton analogous revealed the positive effect of Boron on the dehydration reaction. At a comparable Si/Al ratio, B-ZSM-5 displayed a superior activity and BD selectivity compared to the parent ZSM-5.

**Keywords:** Succinic acid, Catalytic Transfer Hydrogenation, Pd/C, XPS, XRD, Rietveld analysis, TEM

**Introduction.** Succinic acid (SAc) and its dehydrated anhydride form, succinic anhydride (SA), which production mostly relies on the hydrogenation of maleic acid (MAc) or maleic anhydride (MA) derived from fossil oil, are used by the chemical industry in a number of applications, such as the production of 1,4-butanediol (BDO), γ-butyrolactone, pharmaceuticals, food and agrochemical products and in the production of polymers such as polybutylene succinate. A renewable route based on fermentation of sugars, currently at a demonstration level, presents several drawbacks associated with the separation and purification of SAc from the fermentation broth. This fossil route can become fully renewable if MAc is derived from biomass feedstock (like oxidation of furfural) and if it is hydrogenated with green $H_2$, like for instance that obtained from biomass-derived formic acid (FAc), that can also be obtained from biomass.[1]

**Results and discussion.** In this communication, we present our investigation to find an efficient catalytic technology to produce SAc from MAc in aqueous phase and using formic acid as a source of $H_2$ (the catalytic transfer hydrogenation (CTH) of MAc to SAc). Among all the catalysts tested, the catalyst system based on Pd particles supported on carbon (Pd/C) was found to be very active and selective for this reaction: neither extra organic solvents nor excess of FAc beyond the stoichiometric amount are needed. Besides SAc precipitates at the exit of the reactor which facilitates its separation. Interestingly the Pd/C system is very stable. Deactivation could only be detected when the WHSV of MAc was larger than 13 g MAc g $cat^{-1}$ $h^{-1}$, but even at these conditions, the increase of the reaction temperature and/or the contact time (decreasing the flow rate) can mitigate the deactivation and still achieving very high SAc productivity. After 400 h on stream, the productivity was above 5300 g of SAc per g of catalyst.[1]

We also present the studies of the effect of the Pd particle size and of the type of C support (activated carbon, charcoal, mesoporous carbon, carbon nanotubes, graphene oxide, etc.) on the reaction rate. It was found that the reaction is sensitive to the structure. The intrinsic reaction rate of SAc formation increases with the particle size but for (average) diameter of particles size larger than 6 nm the intrinsic rate decreases (Fig 1).

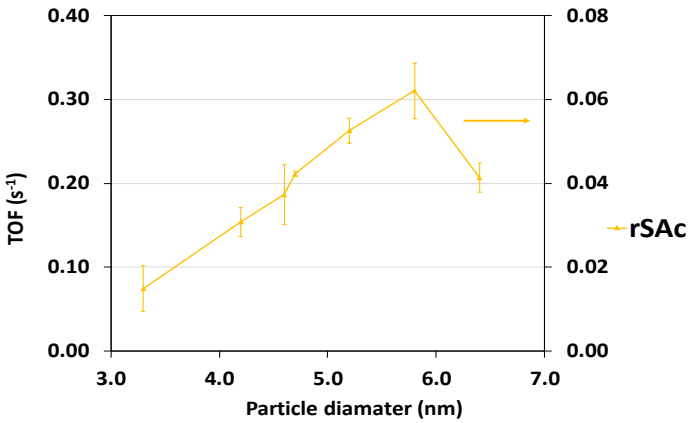

**Fig 1. Intrinsic reaction rate of formation of SAc as a function of the Pd particle size**

**Keywords:** hydrolysis of cellulose, molten salt hydrate, solid acid catalysts

**Introduction.** A promising cellulose solvent is a highly concentrated aqueous solution of inorganic salts (molten salt hydrates – MSH) in the presence of inorganic acids, which can interact with the hydroxyl groups of cellulose, weakening and breaking the hydrogen bonds and then, leaving the β-(1-4) glycosidic units exposed and accessible to catalysts. However, these inorganic acids are highly corrosive, require steps of neutralization, and are not recyclable. In spite of their advantages, heterogeneous catalysts have not been used with MSH for cellulose depolymerization [1]. Hence, this study aimed to investigate the performance and stability of heterogeneous catalysts for cellulose one-pot solubilization and depolymerization, in lithium bromide (LiBr) reaction media.

**Experimental/methodology.** Four different commercial catalysts were used in this study: Ion-exchange polymer resin (Amberlyst-15, Sigma), modified sulfonated silica (SiliaBond®-PSA endcapped, Silicycle), zeolite (HZSM-5, Si/Al = 11.5, Zeolyst) and a metal oxide ($NbOPO_4$, CBMN). To measure the acidity of these catalysts, a titration with NaOH in aqueous phase was performed following a method described by Kim *et al.* [2]. Concerning hydrolysis studies, 50 mg of cellulose (Sigmacell Type 50, with a Dp = 1181) and 50 mg of catalyst were added to 2.5 g of LiBr solution (water/salt molar ratio = 3.25), in a reaction flask containing a stirring bar. The flask was sealed, heated to 90 °C and kept at this condition for 2 h, under stirring (600 rpm). Catalysts were separated and the resulting hydrolysates were analyzed by HPLC.

**Results and discussion.** The experiment without a catalyst produced only gluco oligomers (10%) and most of cellulose remained unreacted (90%). The addition of catalyst strongly decreased the yield of oligomers, which were converted into glucose, fructose, levoglucosan (LGA), HMF, and furfural, regardless of the catalyst (Table 1). Furthermore, the yield of glucose followed the order of total acidity of the catalysts and the nature of its acid sites. These results revealed that the Brønsted acid sites were responsible for the hydrolysis of gluco oligomers to glucose and its conversion to LGA and furfural, as well as, the dehydration of fructose to HMF. The Lewis acidity of the MSH performs the isomerization of glucose into fructose. Regarding the catalysts stability, it was observed a significant deactivation for the resin and the zeolite, while the metal oxide and the modified silica remained stable under the reaction conditions.

Table 1. Catalyts acidity and products distribution observed after hydrolysis screening on LiBr media.

| Catalyst | Acidity (μmol $g^{-1}$) | Products Yield (%) | | | | | |
|---|---|---|---|---|---|---|---|
| | | Glucose | Gluco-oligomers | Fructose | Levoglucosan | HMF | Furfural |
| LiBr | - | - | 10.0 | - | - | - | - |
| Amberlyst-15 | 5223 | 50.9 | 43.2 | - | 0.70 | 3.40 | 0.80 |
| SiliaBond-PSA | 813 | 47.0 | 39.0 | 11.0 | 1.00 | 1.00 | 0.50 |
| HZSM-5 | 668 | 42.5 | 46.0 | 10.0 | 1.30 | - | - |
| $NbOPO_4$ | 538 | 39.0 | 47.0 | 10.4 | 0.80 | 1.60 | 0.30 |

# Aqueous phase hydrogenolysis of glycerol over Ni-Cu/Al catalysts with in-situ produced hydrogen

D. Gallego-García, M. Laria-Alonso, U. Iriarte-Velasco, M.A. Gutiérrez-Ortíz, J.L. Ayastuy*

*Department of Chemical Engineering, University of the Basque Country UPV/EHU, Bilbao, Spain*

**Keywords:** spinel, glycerol, aqueous phase, HDO, 1,2-propylene glycol.

Glycerol is an important candidate for the next-generation bio-feedstocks. It is an abundant coproduct in biodiesel production (around 10 wt.% of biodiesel) and a highly functionalized molecule so it can be transformed into an array of value-added chemicals. Generally, the glycerol hydrogenolysis involves the addition of $H_2$ from an external source, mainly produced from fossil resources. Glycerol, being an oxygenated molecule can undergo aqueous-phase reforming (APR) to generate hydrogen. Therefore, the use of hydrogen generated in-situ by APR would provide an alternative to external, high-pressure fossil-derived hydrogen and make the process safer and more sustainable [1]. Nevertheless, the objective to produce 1,2-propylene glycol by glycerol hydrogenolysis with $H_2$ generated by APR is quite challenging because of the design of bifunctional catalysts. These catalysts have to present the proper balance of metal and acid sites to reach a high selectivity toward 1,2-propylene glycol by using in-situ generated hydrogen.

In this work, a series of Ni-Cu aluminate spinels have been synthesized by one-pot sol-gel method, with a Ni/Cu molar ratio of 1/0, 0.95/0.05, 0.875/0.125, 0.75/0.25 and 0/1. For all the cases the Metal/Al=1/2 ratio has been kept. The synthesized solids have been characterized by different techniques to evaluate their metal and acid functions, textural properties, structure, morphology, reducibility, among others. Glycerol hydrogenolysis has been carried out in a fixed bed reactor at 235 °C and 45 bar (catalyst reduced in-situ at 800 °C, for 2 h) feeding a 10 wt.% glycerol/water solution and with a space velocity of 12 $h^{-1}$. The gas product of the reaction was analyzed by GC and the liquid product, at different reaction times, was analyzed by GC-FID and TOC.

**Table 1. General properties of reduced catalysts.**

| Catalysts | $d_{Metal}$ (nm) | $S_{BET}$ ($m^2/g_{cat}$) | DoR (800 °C) |
|---|---|---|---|
| **NiAl** | 8.6 | 14 | 88.1 |
| **$Ni_{0.95}Cu_{0.05}Al$** | 9.2 | 57 | 81.8 |
| **$Ni_{0.875}Cu_{0.125}Al$** | 8.7 | 27 | 65.8 |
| **$Ni_{0.75}Cu_{0.25}Al$** | 9.5 | 58 | 37.1 |
| **CuAl** | 16.0 | 6 | 99.5 |

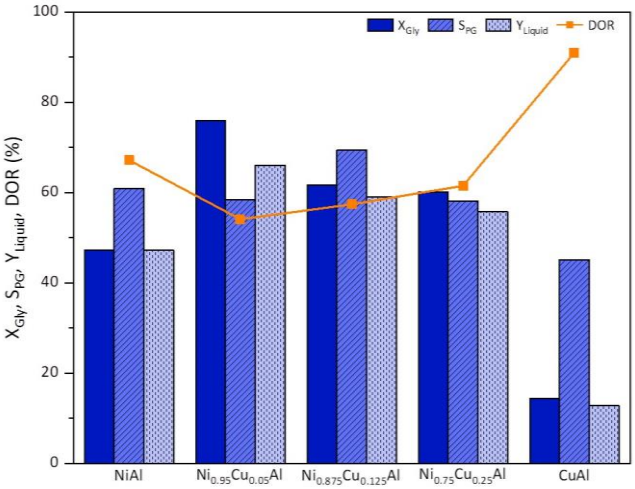

**Figure 1. Glycerol conversion, Selectivity to Propylene Glycol, C-yield to liquids and Deoxygenation degree. Data at TOS (4 h).**

Ni-containing spinel derived catalysts produced nanosized metallic particles upon reduction (< 10 nm). Also, bimetallic solids showed Ni-Cu alloy formation (XRD). Compared to monometallic solids, bimetallic reduced catalysts presented enhanced $S_{BET}$. The Degree of Reduction (DoR) of bimetallic solids decreased substantially upon Cu doping, due to the enhancement of the Cu-Ni-Al interaction. Therefore, less metallic Ni could be exsoluted from the spinel phase by reduction at 800 °C. The CuAl catalyst was not active to produce $H_2$ by APR; however, the presence of Ni enhanced $H_2$ production. Moreover, the $H_2$ generated by APR was consumed in-situ giving rise to HDO products, such as 1,2-PG. Bimetallic catalysts improved the reaction indices of the monometallic NiAl, being $Ni_{0.875}Cu_{0.125}Al$ catalyst the most selective to 1,2-propylene glycol.

# Engineering the surface configuration of AgPd alloy catalysts for highly selective oxidation of 5-hydroxymethyl-furfural at room temperature

Yichao Jin[1], Huai-Yong Zhu[1*]

[1]*School of Chemistry and Physics, Queensland University of Technology, 2 George Street, Brisbane 4001, Australia*

**Keywords:** aerobic HMF oxidation, room temperature, bimetallic sites

**Introduction.** The production of 2,5-furandicarboxylic acid (FDCA) plays a pivotal role in chemical synthesis as it serves as a highly valuable and renewable platform chemical with diverse applications. FDCA is a key building block for the synthesis of bio-based polymers and materials, such as polyethylene furanoate (PEF), which offers a sustainable alternative to conventional plastics derived from fossil fuels. The selective oxidation of 5-hydroxymethyl-furfural (HMF) to FDCA is a promising pathway to efficiently obtain this valuable compound. However, achieving high selectivity/yield of FDCA at low temperatures is challenging with the currently available catalysts. To address this challenge, our research proposed both thermalcatalysis and photocatalysis systems using AgPd alloy NPs supported on $CeO_2$.

**Experimental/methodology.** A 20 mL Pyrex glass tube was used as a reaction container. The reactants and catalyst were added, and the tube was sealed with a rubber septum cap under the $O_2$ atmosphere. The reaction mixture was stirred using a magnetic stirrer while keeping a temperature of 20 °C. The filtered samples were analyzed using high-performance liquid chromatography (HPLC) and an LTQ Orbitrap Elite mass spectrometer at a temperature of 30 °C.

**Results and discussion.** The $Ag_{1.5}Pd_{1.5}/CeO_2$ catalyst exhibited a remarkably high yield of FDCA at 20°C, making it a promising method for room temperature production of FDCA from sustainable sources. Both the experimental results and DFT simulations indicate that the selective oxidation process is strongly influenced by the appropriate chemisorption strength of reactants, intermediates, and products on the metal NPs. Adjusting the Ag/Pd ratio allows for finely tuning the surface configuration to modify its adsorption capabilities. The bimetallic boundary sites of $Ag_{1.5}Pd_{1.5}$ NPs exhibit a moderate adsorption capacity for reactants and intermediates, surpassing the activation energy barriers involved in the oxidation of carbonyl and alcohol groups, while efficiently avoiding side reactions. The scale-up results demonstrated a remarkable FDCA yield at the 100g level, indicating the significant potential of this catalyst for industrial applications. Our recent exploration involves designing a low Pd content AgPd photocatalyst, achieving an FDCA yield exceeding 99% under low-flux light illumination. The results provide an alternative approach for sustainable and environmentally friendly production of FDCA.

# Hydrogen-driven Deoxydehydration of Vicinal Diol Compounds over Anatase-titania-supported Molybdate-Copper Catalyst

J.X. Gan[1], Y. Nakagawa[1,*], M. Yabushita[1], K. Tomishige[1,*]

[1]*Department of Applied Chemistry, School of Engineering, Tohoku University, Sendai, Japan*

[*]*yoshinao@erec.che.tohoku.ac.jp; tomishige@tohoku.ac.jp*

**Keywords:** deoxydehydration, biomass-based platform chamicals, selectively reduction

**Introduction.** Biomass-based platform chamicals such as sugar alcohols are highly oxygened, and deoxydehydration (DODH) reaction is useful which converts vicinal diols into corresponding alkenes in one step (**Fig. 1**). In pervious study[1], Re-based catalysts such as $ReO_x$-Au/$CeO_2$ achieved high yield in DODH reaction. Meanwhile, application of noble metal based catalysts is limited by the high cost. Therefore, the development of new DODH catalysts that do not contain noble metals was targeted in this research. We have recently reported $MoO_x$-Au/$TiO_2$ catalyst for DODH reaction[2]. To further decrease the cost of this catalysts, non-noble additive metal instead of Au was explored (Fe, Co, Ni, Cu) for $MoO_x$/$TiO_2$ (anatase) catalysts.

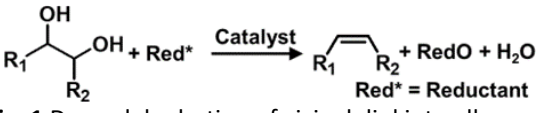

**Fig. 1** Deoxydehydration of vicinal diol into alkene.

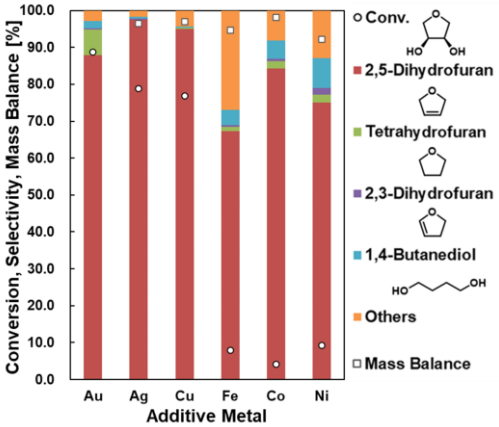

**Fig. 2** Effect of additive metal (M) on the catalysis of $MoO_x$-M/$TiO_2$ (anatase) for DODH of 1,4-anhydroerythritol. Condition: $MoO_x$-M/$TiO_2$ (Anatase) (Mo: 1 wt%, M: 2 wt%) 0.15 g, 1,4-anhydroerythritol 0.5 g, 1,2-dimethoxyethane 4 g, 463 K, $H_2$ 8 MPa, 4 h.

**Experimental/methodology.** Sequential impregnation method was used in preparation of catalysts with uncalcined $TiO_2$ (anatase), $(NH_4)_6Mo_7O_{24}{\cdot}4H_2O$ (AHM) and metal nitrates as support, Mo precursor and additive metal percurosr, respectively. Autoclave with an inner glass vessel was used as reactor. The products were analyzed with by GC-FID.

**Results and discussion.** The effect of additive metal (M) is summerized in **Fig. 2**. Cu showed the highest conversion and selectivity to the DODH product among first-row transition metals as additives. In the activity test with various loading amounts of Cu and Mo, the catalyst with 2 wt% Cu and 1 wt% Mo showed the highest conversion up to 78.8% with selectivity of 98.2% to DODH product in the condition of 463 K and 4 h. However, after 8 hours in the time course experiment, the catalyst began to produce by-product (1,4-butanediol). Referring to earlier research[3], the carbonaceous species accumulated on the catalyst can promote the conversion of 2,5-dihydrofuran to 1,4-butandiol. Acidity of catalyst can be responsible to the formation of carbonaceous species. To increase the selectivity of DODH product, basic Mo precursor ($NaMoO_4$) was added in the catalyst preparation process. As a result, the selectivity of 24 h reaction was successfully increased to 88.6% from 36.4% obtained with single AHM as precursor (**Fig. 3**). The Mo precursor weight ratio of 9:1 showed the best conversion and selectivity in activity tests using various ratio of Mo precursors. Additionally, the $MoO_x$-Cu/$TiO_2$ (anatase, mixed Mo precursor) catalyst was stable for at least 4 uses according to the reusability test. The reaction order was around 0.1 with respect to both the substrate concentration and the $H_2$ pressure which suggests that the extrusion of the alkene is the rate-determining step. Besides, XAS and TEM tests were performed to characterize the catalysts.

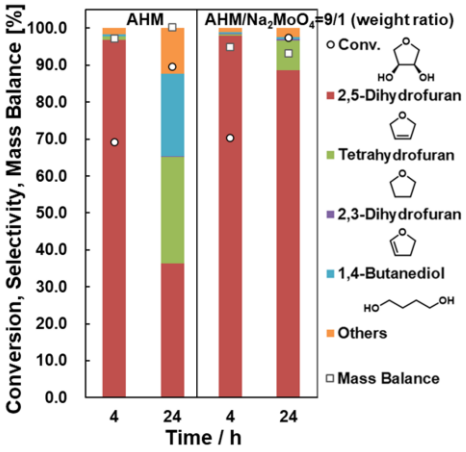

**Fig. 3** Effect of Mo precursor on the catalysis of $MoO_x$-Cu/$TiO_2$ (anatase) Condition: $MoO_x$-Cu/$TiO_2$ (anatase) (Mo: 1 wt%, Cu: 2 wt%) 0.15 g, 1,4-anhydroerythritol 0.5 g, 1,2-dimethoxyethane 4 g, 463 K, $H_2$ 8 MPa.

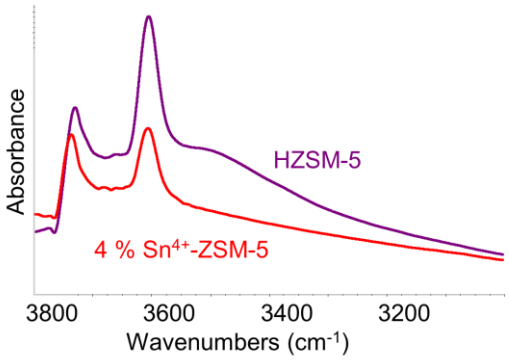
# Zeolite catalysts for the (bio)ethanol to (bio)hydrocarbons process

G.Busca[1*], E.Spennati[1], E.Finocchio[1], P.Riani[2], G.Garbarino[1]



[1*]*Department of Civil, Chemical and Environmental Engineering, University of Genoa, Genoa, Italy*
[2]*Department of Chemistry and Industrial Chemistry, University of Genoa, Genoa, Italy*

**Keywords:** zeolite; tin; zinc; biohydrocarbons.

**Introduction.** The production of hydrocarbons, such as e.g. olefins [1] and aromatics [2], from renewable sources will likely be of interest in the near future, to produce sustainable fuels and to manufacture sustainable intermediate chemicals for the chemical industry. Bioethanol, either produced by fermentation of ligneocellulosic matter or algae [4], by $CO_2$ hydrogenation with green hydrogen [3], or even by fermentation of biosyngas [5], according to its low toxicity and limited volatility, is an interesting intermediate. The conversion of ethanol to hydrocarbons using zeolite catalysts was proposed years ago [6], and is of renewed interest today [7,8]. In the present communication a study of protonic and of tin, zinc and iron based ZSM5 zeolite for the ethanol-to-hydrocarbon processes is proposed.

**Experimental/methodology.** Zeolyst (CBV 5524 G) $NH_4$-ZSM5 was used as the starting material for catalyst preparation, including parent zeolite. Cationically exchanged ZSM5 zeolite catalysts (1 and 4 wt. % of $Fe^{3+}$, $Zn^{2+}$, $Sn^{2+}$, $Sn^{4+}$, and, a 1:1 wt ratio, 2 wt.% $Zn^{2+}$-$Sn^{2+}$ bimetallic sample) have been prepared by incipient wetness impregnation technique from Fe and Zn nitrates and Sn chlorides, followed by calcination in air at 773 K for 4 h. Characterization was realized using X-Ray Diffraction, UV-vis-NIR and skeletal FT-IR spectroscopies. Surface characterization and surface activity tests were realized by FT-IR spectroscopy with a home-made gas adsorption and reaction cell. Steady state catalytic activity was investigated with a fixed bed flow microreactor with 0.5 $g_{catalyst}$, 170 cc/min of 2.4 vol.% ethanol/nitrogen mixture. Product analysis was realized by GC and GC-MS. TPSR experiments were also realized with continuous on-line IR analysis.

**Results and discussion.** For all investigated catalysts, in steady state conditions, diethylether is the main reaction product at T ≤ 473 K when conversion is still incomplete. On the other side, in most cases, ethylene yield approaches 100% at around 523 K. Higher hydrocarbons yield grows up to a maximum in the range 623-723 K, and most frequently decreases at higher temperature with reincrease of ethylene yield. 1 wt% tin-impregnated zeolites and the protonic form appear to be the most active in the production of hydrocarbons $C_{3+}$. Maximum yield to $C_{3+}$ hydrocarbons is 70 % observed at 673 K on 1 wt% $Sn^{4+}$-impregnated ZSM5 zeolite and 67% at 673 K on the protonic form. Maximum propylene yield is observed at 723 K over the protonic form, 35 % and on 1% $Sn^{4+}$ impregnated zeolite, 30 %. Maximum $C_4$ yield (32%) is observed at 623 K on 1% $Sn^{2+}$-impregnated zeolite. 1% $Sn^{2+}$ and $Sn^{4+}$ impregnated zeolites are also the best catalysts for the production of "biogasoline" ($C_{5+}$), up to 30 % yield, and of $C_{6+}$ hydrocarbons, including aromatics. Characterization results, in particular those arising from IR spectroscopy of adsorbed species, allow us to discuss the catalytic data in terms of activity of residual Brønsted acid sites (see the figure) and Lewis acidity of the impregnated cations.

FT-IR spectra of the surface -OH groups of zeolite catalysts

# Sequential Hydrogenolysis and Guerbet Reaction of Bio-carboxylic Acids to Plasticizer Alcohols (C8-C12) over Dual-Functional Heterogeneous Catalysts

Mahlet N. Gebresillase [1a], Jeong Gil Seo [a]*

[a] *Department of Chemical Engineering, Hanyang University, 222 Wangsimni-ro, Seongdong-gu, Seoul 04763, Republic of Korea*

[*] *Corresponding author: jgseo@hanyang.ac.kr*

**Keywords:** Bio-carboxylic acid Hydrogenolysis, Guerbet reaction, Plasticizer alcohol,

**Introduction:** Plasticizers are low-volatility liquid or solid substances that are added additives to increase the flexibility or workability of materials[1]. Almost all plasticizers are synthesized from acids and alcohols[2]. Plasticizer alcohols are primarily synthesized from Alkenes via hydroformylation to aldehydes, followed by aldol condensation and hydrogenation[3]. Given the environmental issues associated with fossil fuel feedstock, developing new methods for efficiently synthesizing plasticizer alcohols from renewable biomass sources is crucial.

**Experimental/methodology :** Ru-based monometallic and bimetallic catalysts supported on SBA-15 were synthesized using a one-pot co-precipitation method for the catalytic hydrogenolysis of butyric acid, and hexanoic acid conducted using a high-pressure continuous reaction system. The guerbet reaction was performed in a Parr batch reactor over Ni-MgAl-LDH catalyst. After the catalyst was filtered out, liquid products were analyzed using liquid chromatography (HPLC).

**Results and discussion:** The continuous high-pressure reaction proceeds via the hydrogenolysis of butyric/ hexanoic acid to the intermediate aldehyde, followed by the subsequent hydrogenation of the aldehyde to alcohol. The obtained alcohol is subjected to Guerbet reaction where the *in situ* coupling over MgAl and hydrogenation over Ni to attain C8 and C12 plasticizer alcohols are completed. Butyl butanoate and Hexyl hexanoate are formed in trace amounts from the esterification of butyric acid, butanol, hexanoic acid, and hexanol, respectively, catalyzed by the $SnO_x$ and the SBA-15. Ru/SBA-15 exhibits low activity due to the difference in the reactant adsorption sites (Ru). $Ru_3Sn_7$ alloy was the active center for hydrogenation. $SnO_x$ was determined as an adsorption site for C=O because of its positive charge (acidity), whereas Ru bonds with Cα and provides hydrogen transfer. The association between catalyst properties and reaction pathway and yield was further studied. It was possible to obtain a yield of up to 86% C8 and 74% C12 plasticizer alcohols directly from butyric acid and hexanoic acid, respectively.

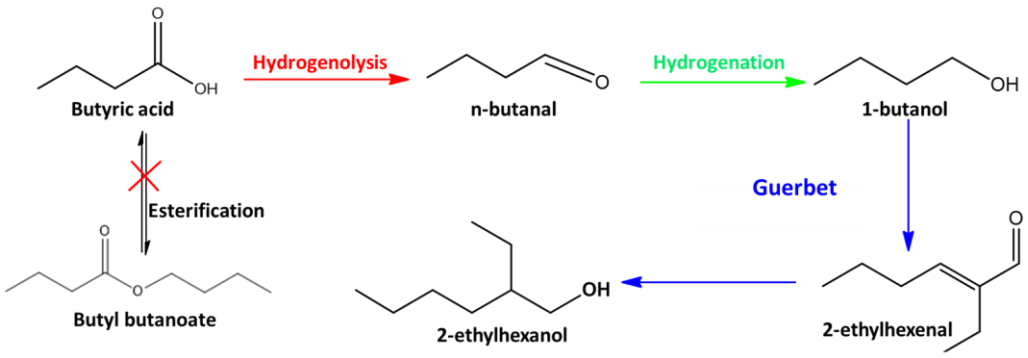

**Figure 1: Reaction scheme for the synthesis of plasticizer alcohol from bio-carboxylic acid.**

**Introduction.** Aldol condensation of biomass derived molecules is highly attractive for the upgrading of biomass to value added chemicals. While Aldol condensation can be promoted by acid or a base catalysts efficient acid-base cooperative interactions can facilitate lower activation barrier, lower reaction temperature, and better control over reaction selectivity. $MgAlO_x$ based Layer double hydroxides (LDH) act as a base catalyst for aldol condensation. If the LDH is deposited as thin (order of 1 nm) layers on the surface of an acidic metal oxide the material can have acid-base properties at the interface between the two oxides. In the current work, we study the acid-base functionalities of MgAlOx thin particles deposited on an underlying support (i.e., $ZrO_2$). The catalysts are tested for the Henry reaction as a model reaction and the condensation of Furfural with Cyclohexanone.

**Experimental/methodology.** The catalyst was prepared through the synthesis of LDH thin sheets according to Leib, E. W. *et al.*[1] and depositing them on either commercial oxides or dedicated zirconia and yttrium doped zirconium (YSZ) were prepared based on the protocol of Yu et al.[2] Reaction testing was performed on a particulate catalyst while single particle characterization was performed by depositing the LDH thin particles on a zirconia coated Si-wafer. Reaction testing are performed in a batch mode and were analysed using $^1$H-NMR and GC-MS.

**Results and discussion.** Following catalyst preparation, we compared the performance of the calcined hierarchical catalyst (LDH/$ZrO_2$, HOX) to that of the calcined native LDH (LDO) and $ZrO_2$ oxides and their mechanical mixture in the Henry reaction, **Figure 1**. We find that the LDO (layered double oxide) is the most active with 0.032 mol/$mg_{cat}$, the $ZrO_2$ is the least active with 0.002 mol/$mg_{cat}$ and the mechanical mixture of LDO and $ZrO_2$ is 0.003 mol/$mg_{cat}$. The HOX catalyst per gram catalyst was slightly more active with 0.008 mol/$mg_{cat}$. However, normalizing the conversion levels to the amount of LDO in each sample we find that the HOX out performed the LDO by almost 20-fold, **Figure 2**. This difference cannot be explained by surface area as the $ZrO_2$ and HOX have roughly 10 $m^2$/g and the LDO is about 140 $m^2$/g. Hence, as the $ZrO_2$ is almost inactive the higher activity of the HOX and mechanical mixture is postulated to originate from specific active sites generated at the interface between LDO and $ZrO_2$. To better understand this effect we performed kinetic analysis, acid/base chemisorption at the macroscopic level and at the single particle level using AFM-IR. Work on the aldol reaction is in progress as well as additional analytical characterizations.

**Keywords:** nickel, zirconia, alumina, co-pyrolysis, lignocellulosic biomass, waste, polymers, hydrogen

**Introduction.**
The problem of waste disposal and the need to become independent of fossil fuels encourages researchers to develop new methods of the production of renewable energy. Thermal conversion of lignocellulosic biomass and waste plactic turns out to be one of the most promising among them [1]. Simultaneous use of both types of feedstock results in the increase in the production of valuable products (including hydrogen), which is related with synergic effect between lignocellulose and polymer. Unfortunately, the efficiency of the mentioned process is still unsatisfactory. The yield of produced hydrogen can be improved by the use of catalysts [2]. However, their catalytic performance can be limited due to carbon deposition or thermal instability [3]. Therefore, the main goal of this study was to develop active and stable catalyst for co-pyrolysis of lignocellulosic biomass and waste plastic to hydrogen-rich gas.

**Experimental/methodology.**
In the first step mixed $Al_2O_3$-$ZrO_2$ supports with various alumina content were synthesized. Then nickel was deposited on their surface by impregnation method. For comparison $Ni/Al_2O_3$ and $Ni/ZrO_2$ were prepared. Catalytic activity tests were conducted under atmospheric pressure at 700°C with the use of cellulose, real biomass samples and waste polymers. Co-pyrolysis was performed in a two step fixed bed quartz reactor. The feedstock was decomposed at 500°C. Then, formed pyrolysis intermediates were upgraded in catalyst bed at 700°C. The gaseous products were analyzed by gas chromatograph equipped with TCD detector. Physicochemical properties of prepared catalysts were characterized using TPR, TPD-$NH_3$, TPD-$CO_2$, XRD, ToF-SIMS, FTIR and microscopic techniques. TG-DTA was used for the evaluation of coking rate and catalyst stability.

**Results and discussion.**
The obtained results showed that both selectivity and activity of Ni catalysts depends strongly on the composition of support. Preliminary results showed that nickel supported on mixed $Al_2O_3$-$ZrO_2$ (with the ratio 1:1) allowed for the most efficient production of hydrogen. The catalytic performance of the studied materials was affected by porosity, acidity, crystallographic structure of support and reducibility of active phase, among others. $Al_2O_3$ possessing higher number of acid sites showed promising activity, but at the same time, was more susceptible to progressive deactivation due to coke deposition. The addition of $ZrO_2$ lowered acidity, but increased resistance against carbon deposit formation and catalyst stability. It can be related to its redox properties and higher oxygen storage capacity. Moreover, zirconia is able to adsorb water molecules present in the reaction mixture and facilitate their decomposition. This may result in the formation of hydroxyl groups on the catalyst surface participating in gasification of deposited carbon [4].

[*] *Mouad.hachhach@abo.fi*

**Keywords:** Oxidation, Arabinose, Gold catalyst, Extrudates.

**Introduction.** Catalytic oxidation of monomeric sugars extracted from hemicelluloses appearing is biomass is regarded as an attractive way to valorise biomass. Hemicelluloses can be easily hydrolysed to sugar monomers and oligomers, which can be converted to valuable products. From this perspective, the catalytic oxidation of arabinose sugar which is present in large amount in the hemicellulose arabinogalactan is studied, focusing on the effect of liquid flow rate on the arabinose conversion.

**Experimental/methodology.** Gold on alumina (3%) catalyst extrudates were used in the experiments. The catalyst was reused for all the performed experiments. The experimental device was a combination of a packed bed reactor, a pH controller to ensure a constant pH, a recycling tank and a recycling pump. The first set of experiments was performed using a recycling flow of 200ml/min, then the second one using the 250ml/min and the last one 150 ml/min flows. Some experimental results are collected in Figure 1. The results show that for all the flows have a high conversion rate (95% for the 150 ml/min flow and 99% for the other ones) was reached fpr all the front rates. However, it is also observed that the higher the flow rate the conversion rate is slightly higher.

**Results and discussion**.

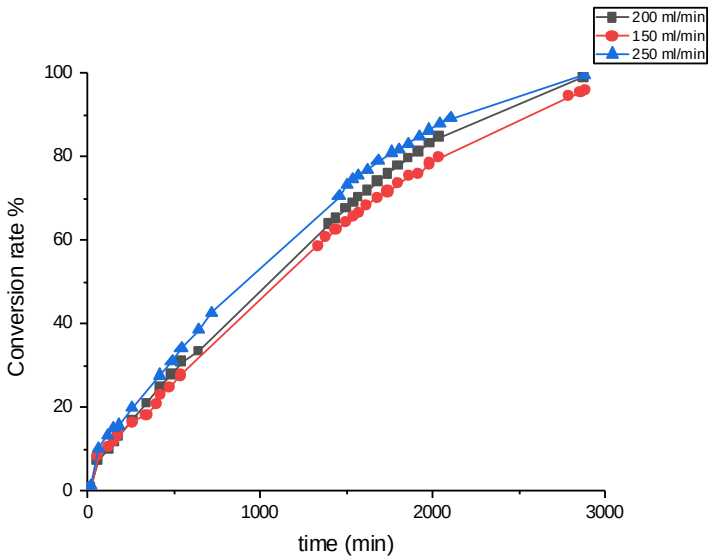

*Figure 1: Conversion rate of arabinose to arabinonic acid at various liquid flow rates in recycled packed bed.*

The results revealed that the flow rate has a slight impact on the arabinose conversion, which can be attributed to the fact that since the reactor system is a closed one, so the contact time between reactants and catalyst can be proportional to the liquid phase flow which increased the conversion of arabinose and even suppressed the external mass transfer resistance around the catalyst extrudates.

**Keywords**
Mixed metal oxides, Guerbet reaction, alcohols, transesterification

**Introduction**
The metal mixed oxides are acid-base catalysts used for many reactions such as transesterification (ester formation), Guerbet reaction (higher alcohol formation) or aldol condensation, i.e., preparation of fuels or chemicals from biomass. The non-edible *Camelina sativa* oil (second generation) was used for transesterification.

The mixed oxides were prepared by heating of double layer hydroxides to the temperature of 450 °C. The formula of hydrotalcite is $[M^{2+}_{1-x}M^{3+}_{x}(OH)_2]^{x+}A^{n-}_{x/n}\cdot zH_2O$, where *M* represents bivalent (Mg, Ca and Zn) or trivalent metallic cations (Al and Fe), $A^{n-}$ is an anion (inorganic or organic) and *x* is the stoichiometric coefficient of $M^{3+}$. The type and molar ratio of metallic cation and the way of synthesis influence the properties and structure of formed hydrotalcite. The catalyst activity is also influenced by impurities remaining in hydrotalcites, especially sodium ions.

**Experimental**
For the transesterification, the Mg-Al hydrotalcites (constant molar ratio Mg to Al 3:1) were prepared by the coprecipitation method from nitrates of aluminum and magnesium with various types of anions. The transesterification was carried out at different weight hour space velocities and different reaction temperatures, with tested every parameter for 32 h. Moreover, the stability of the catalysts was tested by the determination of the metal content in the reaction mixture.

The Guerbet reaction was catalysed by Mg-Al mixed oxides (i) pure and (ii) with addition of transition metals such as Co, Ni, Cu, Mn and Cr (synthesized by coprecipitation). The transition metals were added to increase the redox properties. The catalytic synthesis of butanol from ethanol proceeded in a microflow reactor at a constant weight hour space velocity (4.5 $h^{-1}$) and different reaction temperatures (280, 300 and 350 °C). Other products, such as ethylene, 1,1-diethoxyethane, ethyl acetate, 1-hexanol, etc. were also determined and the reaction pathway for their formation was examined.

The synthesized materials (hydrotalcites and mixed oxides) were characterized by several experimental techniques such as XRD, TG-MS, TPD-$CO_2$, DRIFT and SEM.

**Results and discussion**
The presentation will introduce and compare the use of Mg-Al mixed oxides as heterogeneous catalyst for (i) the transesterification of non-edible *Camelina sativa* oil and (ii) ethanol conversion to higher alcohols such as butanol, hexanol (Guerbet reaction). It was found, that sodium impurities were bonded predominantly in the form of sodium nitrates (nitrates were used for hydrotalcite synthesis). The sodium influenced especially acid-base properties and so the ester yield, because the sodium nitrates blocked the pores and also disturbed the TPD determination. For Guerbet reaction, the relationship between structure, activity and stability was described. It was found that the presence of nickel, copper and cobalt positively influenced the catalyst activity. Moreover, some results were statistically evaluated.

**Keywords:** Sonocatalysis, Carbon-based materials, Selective oxidation, Catalysis, Porous materials, C-C reductive coupling, Biomass valorization

**Introduction.**

Sonocatalysis is one of the most important and effective advanced oxidation processes for destruction and mineralization refers to the chemical process realized by passing ultrasonic waves through liquid environments [1,2]. Focusing on sonocatalytic valorization of lignocellulosic biomass and their platform molecules by carbonaceous materials can be regarded as a key route enabling technology for pretreatment and conversion of lignocellulosic biomass [3]. The unique physicochemical properties and abundancy of carbon-based materials lead us to use the porous carbon materials doped with N, P, or B in our research for sonocatalysis which is rarely reported compared to traditional carbons [1,4]. It is worthy to mention that the alternation in the substrate from benzyl alcohol in other studies to syringic alcohol and assesment of the selective oxidation and C-C coupling of mentioned substrate is also the matter of concern in this study.

**Experimental/methodology.**

In the current investigation, the sonocatalytic activities were studied for the selective oxidation and C-C coupling of syringic alcohol. Various frequencies (22 kHz, 100kHz, 340 kHz, 500 kHz, and 800 kHz) were *used for evaluating the sonocatalytic activity of the four carbon-based catalyst namely C-meso, Chit-1, CN*-800-3, and C6-800-W [1]. After sonocatalytic tests in batch system, the collected samples were analyzed by *HPLC and reported as conversion, selectivity, and yield for favorable products which were syringaldehyde* and syringic acid. Finally, the best catalyst was chosen as sonocatalytic-active carbon material.

**Result and Discussion**

Properties of C-meso, as the best sonocatalytic-active catalyst, were examinated by $N_2$ sorption which showed the high specific surface area (more than 800 $m^2/g$). In the XRD pattern, all heteroatom-doped mesoporous carbons show two broad reflections at around 25°C and 43.5°C,which can be assigned to the (002) and (100) lattice planes [1]. After sonocatalytic tests, the conversion of 73% and selectivity to synergaldehyde was 40%. The Raman spectra show the defective structure and graphitic sites. The D-band results from the imperfect sites in sp2 carbon lattice such as edges/vacancies, topological defects, functionalities, and the presence of heteroatoms. The control reactions were performed by normal stirring on all porous carbon materials and the only sonocatalytic active catalysts was C-meso that has different selectivity for aldehyde while using lower frequencies and in higher ones toward acid. The morphological features of C-meso are investigated by TEM. SEM analysis shows that the materials present a non-uniform particle size and morphology; however, the chemical mapping (EDS) shows a homogeneous distribution of heteroatoms throughout the particles.

**franziska.heck@heraeus.com*

**Introduction.** The negative impacts of global warming and greenhouse gasses, including the $CO_2$ emission, are widely recognized by society, politics, academia, and industry as complex challenges. [1-3] To move away from the dependence on petroleum-based chemistry, the cooperation program "Competence Centers for Excellent Technologies (Comet)" focuses on the valorization of organic materials and the total biomass utilization into sustainable products and energy. The native biopolymers from woody biomass are separated to obtain 5-hydroxymethyl (5-HMF) as starting material for bio-based products. In this paper, we highlight the development of an efficient oxidation of 5-HMF into 2,5-Diformylfuran (DFF) using new Ruthenium-based catalysts to produce biobased formaldehyde free phenolic resins from biomass. [4, 5]. Also, the attractiveness of precious metal (PM) catalysts, when applying recycling strategies, are presented.

**Experimental/methodology.** For the investigations, different ruthenium-based catalysts were synthesized. In a 450 mL stainless-steel autoclave (Parr Instrument Company), HMF (500 mg) was dissolved in 100 mL solvent (toluene, ethanol, *n*-hexane). After adding the catalyst $Ru/Al_2O_3$ (500 mg), the suspension was stirred vigorously (300 rpm) at RT while purging with molecular oxygen (flow rate 100 mLmin-1) for 10 min. After the reaction temperature was reached, the desired oxygen pressure was set via a gas inlet valve. The samples were analyzed with an Agilent 1100 series HPLC connected to a UV-vis detector, an AminexR HPX 87P column (300×7.8 mm, 9 µm particle size) and aqueous sulfuric acid (5 mM) as the mobile phase at of 298 K (flow rate 0.6 mLmin-1, injection volume 10 µL). The concentrations of HMF, DFF, FFCA, HMFCA, and FDCA were determined by external calibration at a detection wavelength of 280 nm.

**Results and discussion.** We developed the heterogeneous catalytic oxidation of 5-HMF with molecular oxygen for the efficient formation of DFF using new Ruthenium-based catalysts. The catalyst performance depends not only on the used solvent, but also strongly on the PM precursors, e.g., Ruthenium chloride or Ruthenium nitrosyl nitrate, and on the intrinsic support characteristics. To investigate the support influence, different $3\%Ru/Al_2O_3$ catalysts were synthesized on different alumina and were tested. It is noteworthy, that no 5-formyl-2-furancarboxylic acid (FFCA), 5-hydroxyme-thyl-2-furancarboxylic acid (HMFCA) or 2,5-furandicarboxylic acid (FDCA) were detected as over-oxidation products with none of our catalysts. After washing, the $Ru/Al_2O_3$ catalyst can be reused several times. Nevertheless, after the catalyst is deactivated, the PM recovery plays a key role from both an ecological and economical point of view. The full "PM loop" consists of the PM winning, PM solution production as well as the catalyst synthesis, followed by the performance as active catalyst. Finally, the deactivated catalyst is separated from the reaction mixture to close the loop with the PM recycling. The recycled secondary PM can reduce the carbon footprint up to 98% in comparison to primary PM from mining.

**Keywords:** furfural, hydrogenation, perovskites

**Introduction.** The reduction in the availability of oil reserves and emerging environmental changes have generated interest in developing economic, efficient, and environmentally friendly technologies to transform biomass-derived molecules. Furfural is a promising platform molecule of biomass to obtain, through catalytic processes, high value-added chemicals such as furfuryl alcohol (FUR-OH), 2-methylfuran (2-MF) and tetrahydrofurfuryl alcohol (THF-OH), among others [1,2]. The catalysts of interest are perovskites due to their versatility of structural conformation[3]. In this work the synthesis, characterization, and catalytic evaluation of three pure ($ABO_3$) perovskites, $LaCoO_3$, $LaNiO_3$, $LaFeO_3$ and three substituted ($AB_{0.5}B'_{0.5}O_3$) perovskites, $LaFe_{0.5}Co_{0.5}O_3$, $LaFe_{0.5}Ni_{0.5}O_3$ and $LaCo_{0.5}Ni_{0.5}O_3$ previously reduced at 500°C in the hydrogenation of furfural is reported.

**Experimental/methodology.** The materials were characterized by X-Ray diffraction (XRD), physisorption of $N_2$ at 77 K, thermal programmed reduction (TPR $H_2$) and thermal programmed desorption of $CO_2$ (TPD $CO_2$). The hydrogenation of furfural was carried out in a batch reactor at 30 bar of $H_2$ pressure and 200 °C using n-dodecane and n-hexadecane as a solvent and internal standard, respectively.

**Results and discussion.** The characterization results show that the presence of Fe in the B cation in both pure and the substituted perovskites gives it great stability in a reducing atmosphere, avoiding the formation of metallic nanoparticles. On the other hand, in the $LaCoO_3$, $LaNiO_3$ and $LaCo_{0.5}Ni_{0.5}O_3$ perovskites, metallic Co and Ni species were detected, which also induce the formation of basic sites. Only in the $LaCoO_3$, $LaNiO_3$ and $LaCo_{0.5}Ni_{0.5}O_3$ catalysts a 100% of furfural conversion after 4 h of reaction was observed, detecting significant differences in the selectivity at 40% for furfural conversion (Figure 1). For $LaNiO_3$ and $LaCo_{0.5}Ni_{0.5}O_3$ the main product was THF-OH and FUR-OH as secondary compound, while in $LaCoO_3$ the main product was FUR-OH, followed by 2-methylfuran (2-MF) as a secondary product. These results indicate that the conversion of furfural in $LaNiO_3$ and $LaCo_{0.5}Ni_{0.5}O_3$ perovskites follows the route of hydrogenation of the C=O bond to FUR-OH and then hydrogenation of the C=C bond of the aromatic ring to form THF-OH, while in $LaCoO_3$ the hydrogenation of the C=O bond occurs to form FUR-OH, followed by the process of hydrogenolysis of the C-O bond of the hydroxyl group to form 2-MF.

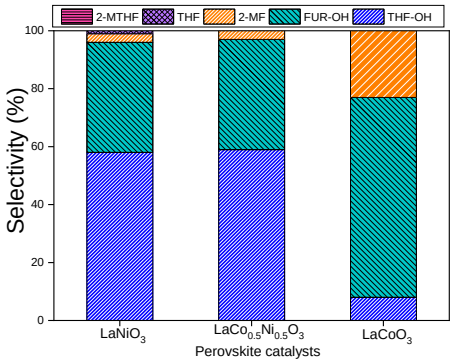

Figure 1: Selectivity at 40 % of furfural conversion.

**Keywords:** *Biomass, Heteropolyacids, Catalyst recycling*

**Introduction.** In times of climate change and diminishing fossil resources, the transition to renewable raw materials such as lignocellulose is indispensable. Still, their transformation into fuels and valuable platform chemicals is challenging. Herein, the acid-catalyzed hydrolysis of xylan to the platform chemical xylose is investigated using heteropolyacids (HPAs) as catalysts.[1] They exhibit a particularly high Brønsted acidity, possess tunable redox activity and are soluble in water and most organic solvents. The latter makes them ideal for homogeneous applications but impedes their recycling and thus industrial application. To meet this challenge, the immobilization of HPAs on suitable heterogeneous supports is of high interest.[2]

**Results and discussion.** Initially, commercially available HPAs were tested in the hydrolysis of xylan to xylose whereby phosphotungstic acid (PTA) showed the highest activity with 90% conversion in 2 h and 81% selectivity to xylose under omtimized reaction parameters. Therefore, PTA was chosen for the impregnation on porous activated carbons (AC). Although some studies have been carried out using carbon supports for the immobilization of HPAs[3], it is not fully clarified yet whether the HPA-carbon interaction is of physical or chemical nature, which can take  take place by i.e. electrostatic or acid-base-interactions of with oxygen moieties on the carbon surface. In this regard, PTA was impregnated on an oxygen-rich carbon with a high specific surface area of 1749 $m^2/g$. TEM analysis and EDX mapping revealed a molecular distribution of PTA on the surface. In the $N_2$-physisorption a significant decrease in the specific surface area to 780 $m^2/g$ was found after impregnation. ICP confirms a high PTA-loading of 473 mg/g, which is in accordance with a significant increase of acidic sites found by $NH_3$-TPD. In the hydrolysis of xylan to xylose (Figure 1), PTA/AC showed a high activity with 91% conversion. The selectivity to xylose of 99% was even higher than in the homogeneous system. Furthermore, the long-term stability of the catalyst was demonstrated in batch recycling experiments, in which the catalyst could be easily seperated from the reaction system. The observed loss in activity correlates with a moderate PTA-leaching of 2–3%. Nevertheless, a moderate conversion of 44% was still achieved after 20 recycling runs. The stability of PTA/AC was further confirmed by IR and solid-state NMR-spectroscopy of the recycled catalyst. In summary, oxygen rich carbon materials were found to be promising supports to heterogenize HPAs for an efficient biomass valorization in aqueous medium.

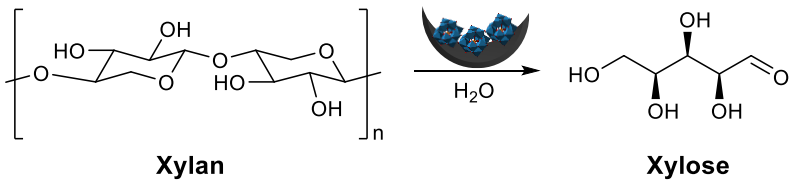

**Figure 1:** Hydrolysis of xylan to xylose catalyzed by PTA/AC.

# Preparation of biodiesel from spent coffee ground over hydrotalcites

M. Horňáček, M. Mališová, A. Peller

*Slovak University of Technology in Bratislava, Faculty of Chemical and Food Technology, Radlinského 9, 812 37 Bratislava, Slovakia*
*michal.hornacek@stuba.sk*

**Keywords:** SCG, coffee, biodiesel, hydrotalcites, transesterification

Critical global energy-related issues such as scarcity of fossil fuel resources, increasing price of diesel fuels, global warming and climate change crisis have necessitated the search for greener alternative fuels from renewable sources. To date, biodiesel has been regarded as one of the most viable renewable energies due to its non-toxic nature, renewability, biodegradability, favourable properties and eco-friendliness. However, about 95% of the current world biodiesel supply are produced from edible oil crops making them unfavourable and unsustainable for large scale production [1]. In this regard, there is a direct need for an alternative feedstock to avoid such controversy as well as to make large scale production economically feasible and non-competitive to food supply.

Coffee is currently the world's second largest commodity, and its consumption produces an estimated six million tons of Spent Coffee Ground (SCG) each year. For instance, approximately 650 kg of SCG are produced from one ton of green coffee beans. SCG is known to contain various organic compounds such as fatty acids, lignin, cellulose, hemicellulose, and other polysaccharides and is a suitable bio-source to produce biodiesel, activated carbon, fertilizer, sugar and even adsorbents for heavy metal ions removal [2]. Therefore, the large amount of solid waste generated from SCG which can be used for valuable product synthesis requires the development of waste management plan to ensure that it is properly utilized.

Biodiesel is commonly produced via the transesterification reaction of oil with methanol and a base catalyst which results in a fuel containing a mixture of fatty acid methyl esters (FAME) ranging from C6 to C22. However, base catalyst can only be used for transesterification of oils with FFA less than 1% to avoid saponification which can cause difficulty of ester separation [3].

Therefore, it is necessary to look for a catalytic system where the esterification of FFA and then the transesterification of triglycerides with methanol would take place. Thus, the catalyst must contain both acidic and basic centers. Hydrotalcites appear as a potentially suitable solid catalyst.

In this work, we prepared Mg/Al hydrotalcites with the addition of metals such as $Ni^{2+}$, $Cu^{2+}$, $La^{3+}$ and $Ce^{3+}$. Hydrotalcites were prepared by simultanous co-precipitaion at pH = 10 and the temperature was 30 °C. Prepared hydrotalcites were characterized by available physico-chemical methods such as XRF, XRD, SEM, adsorption of nitrogen, TPD of ammonia and carbon dioxide and skeletal vibration of FTIR spectra. Mixed oxides were prepared by calcination of hydrotalcites at the temperature of 450 °C. Mixed oxides were used as a catalyst in transesterification of coffee oil with methanol. Coffee oil was obtained from spent coffee ground by Soxhlet extraction with n-hexane like a solvent. Coffee oil was treated by refining – water, acid and TOP degumming. The composition of refining coffee oil was determined by TLC, HT-GC and GC-MSD. Parameters such as conversion of acylglyrides and FAME content in the product were evaluated. Mixed oxide Ni+Mg/La+Al/HT showed the content of FAME over 99 wt. % after two step transesterification of coffee oil with methanol.

**Keywords:** Heteropolyacids, Alumina, Surface Chemistry, Low-Field NMR, NMR Relaxation

**Introduction.** The catalysed conversion of glycerol (GLY) to acrylic acid (AA) is a highly desirable process owing to the large abundance of GLY produced as a waste by-product of biodiesel and the usefulness of AA as a platform chemical to produce high-value chemicals and commodities.
In this work, a multi-technique surface study of promising solid catalysts used for the conversion of GLY to AA is reported. In particular, γ, θ and α alumina ($Al_2O_3$) were modified by (i) grafting with 5 wt.% zirconia, (ii) doping with 30 wt.% silicotungstic acid (STA), and (iii) using both zirconia and STA. The aim is to rationalise the effect of these different parameters on the catalysts' structural and chemical properties and relate these properties to their catalytic activity.

**Experimental/methodology.** 30 wt.% STA or 5 wt.% Zr were doped onto the different alumina phases using an incipient wetness impregnation method described elsewhere. [1]
30 wt.% STA was doped onto the 5 wt.% Zr grafted aluminas using the same incipient wetness impregnation method.
Chemical and structural properties of the catalysts prepared were analysed using low-field NMR relaxation, $N_2$ adsorption-desorption, XRD, Laser Raman spectroscopy and differential thermogravimetry.

**Results and discussion.** XRD and laser Raman spectroscopy confirmed a strong interaction between STA and the γ-/θ-$Al_2O_3$ resulting in a distortion of the supported STA Keggin structure relative to that of bulk STA. Conversely, a much weaker interaction between the supported STA and α-$Al_2O_3$ was measured.

NMR relaxation demonstrated that the STA doping increases the adsorption properties of the catalyst, particularly for γ-/θ-$Al_2O_3$. For catalysts based on α-$Al_2O_3$, such effect was negligible.
Thermogravimetric/differential thermogravimetry (TGA/DTG) analysis suggested that zirconia-grafted and non-grafted θ-$Al_2O_3$ and γ-$Al_2O_3$ are suitable materials for increasing the thermal stability of STA whereas α-$Al_2O_3$ (both grafted and non-grafted) does not improve the thermal stability of STA.

**Keywords:** glucose hydrogenolysis, biomass, trickle bed reactor

**Introduction:** Due to the global population growth and the advancing industrialisation, fossil resources are the major source of carbon dioxide emissions, that can only be avoided by developing closed carbon cycles, e.g., by utilizing renewable ressources. One promising alternative is biomass, which partly consists of cellulose.[1,2] Glucose formed by the depolymerization of cellulose is a water-soluble starting material for biobased products, which is why it is well suited to study the complex network of hydrogenolysis reactions. To obtain propylene glycol and ethylene glycol, retro aldol reactions followed by hydrogenations must occur. The balance between these reaction rates is decisive for maximum yields of glycols. If the hydrogenation proceeds too fast, undesired hexitols are formed. For this reason, the interaction between the hydrogenation metal (e.g. Pd, Ni, Ru, Pt) and the retro aldol catalyzing species (e.g. $WO_x$) is crucial.[3] In our work, we aim at the selective synthesis of propylene glycol. Because of that, the isomerization to fructose has to occur first. For this reaction pathway, the Pd-$WO_x/Al_2O_3$ catalyst was shown to be suitable.[4] Hence, in our study besides palladium as hydrogenation metal, also ruthenium, platinum and copper were investigated. Furthermore, by the usage of the Pd-$WO_x/Al_2O_3$ catalyst, a complex kinetic study was performed in order to gain insights into the complex reaction network.

**Experimental/Methodology:** The bifunctional catalysts are prepared by the stepwise incipient wetness impregnation of gamma-alumina spheres with ammonium metatungstate and the metal precursor. After the calcination and reduction of the catalysts, they are tested in the glucose hydrogenolysis. The reactions are carried out in a continuously operated trickle bed reactor with an aqueous solution of glucose. For the kinetic study, reaction temperatures between 150 and 200 °C were chosen.

**Results and discussion:** By the usage of the Metal-$WO_x/Al_2O_3$ catalysts in the glucose hydrogenolysis, different product distributions were observed. With the ruthenium catalyst, the direct hydrogenation to the hexitols was favored which shows the high hydrogenation ability of ruthenium. When copper, platinum and palladium were used, hydroxyacetone (the precursor of propylene glycol) was obtained as main product. With the Pd-catalyst, the highest selevtivity for hydroxyacetone with 37 % was reached (at 190 °C and 40 bar), while 96 % of glucose was converted. In general, the hydrogenation of hydroxyacetone to the desired product propylene glycol could not be achieved. Because of that, an additional catalyst bed of the ruthenium catalyst was placed after the palladium catalyst. In this way, an almost complete conversion of hydroxyacetone was achieved. The selectivity of propylene glycol was increased from 2 % to 37 % by the usage of the combined catalysts. With respect to ethylene glycol, a selectivity of only 2 % was reached, showing the preferred reaction pathway via fructose. Besides propylene glycol, also 1,2-butanediol ($S$ = 7 %) and glycerol ($S$ = 2 %) were obtained. For the kinetic study, the use of various intermediates and by-products was investigated. Overall, a better understanding of the complex reaction network was achieved. By fitting the experimantal data, kinetic parameters such as activation energies were obtained.

**Keywords:** Nickel bifunctional catalysts, HDO, microalgae lipids, fatty acids, green diesel

**Introduction**

Due to its high lipid content, algae are a renewable feedstock with high potential for the manufacture of green fuels and has gained widespread acceptance as energy source worldwide[1]. The hydrodeoxygenation (HDO) of (micro)algae shows a potential yield of liquid hydrocarbons of up to 60% depending on reaction conditions, reactor design the quality of the feedstock and the selected catalyst[2]. Ni-based catalysts were found to function better than many noble-metal catalysts[3], being also of higher abundance and lower cost. In this study, metal Ni catalysts supported on various types of micro/mesoporous materials were tested in the hydrotreatment of model fatty existing in microalgae lipids/oils to elucidate the mechanism of their conversion to the respective n-/i-paraffins via HDO, hydroisomerization and hydrocracking pathways.

**Experimental/methodology**

Nickel was loaded on various micro/mesoporous zeolites based on Beta, Ferrierite, ZSM-5, USY as well as ordered mesoporous aluminosilicates (MCM-41, SBA-15, etc.) with different acidic and porous characteristics, via simple incipient wetness methods followed by reduction under hydrogen. The fatty acids studied as model feeds were oleic, arachidic, linoleic and palmitoleic, being abundant in the lipid fraction of *Chlorella vulgaris* strain. The tests were performed in high pressure batch autoclave reactor and the reaction parameters (solvent, temperature, pressure, time) were optimized with regard to the different pathways, ca. decarbonylation, decarboxylation, HDO, isomerization, etc. The products were analyzed by GC-MS/FID, Karl Fischer, etc. and the catalysts were characterized by XRD, BET, XPS, TPR, etc.

**Results and discussion**

Analysis of the products by GC-MS showed that in the HDO of oleic acid at relatively low temperature of 250°C with 10%Ni/Beta catalyst, aliphatic n/i-alkanes in the range of hydrocarbon fuels (kerosene, diesel; C9-C18) are formed at high percentages (74-86%). In general, alkane production is favored at relatively longer reaction time (ca. 60-90 min) and with shorter chain solvents, as can be seen in Figure 1.

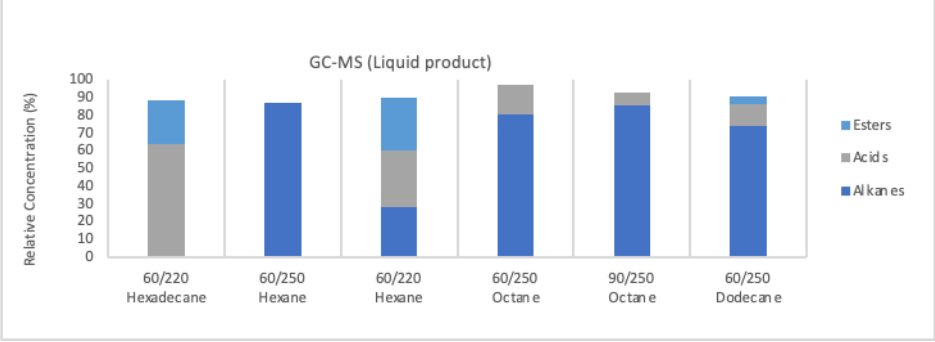

**Figure 1. Relative concentrations (GC-MS) of liquid products in the hydrodeoxygenation of oleic acid over 10%Ni/Beta catalyst, at 50 bar $H_2$ in different solvents and varying time and temperature conditions**

**Keywords:** Hydrogenolysis, Photocatalyst

**Introduction.** Reactions that selectively cleave C-O bonds are important in organic synthesis[1]. Lignin is an amorphous polymer comprising aromatic monomers connected via oxygen bridges (C–O bonds)[2], and aromatic compounds can therefore be produced by selective cleavage of the bridges. Therefore, various catalysts have been investigated for the cleavage of lignin C-O bonds to produce aromatic compounds[3]. These reactions require severe reaction conditions (i.e., high temperatures and high $H_2$ pressures), which result in poor selectivity for the target materials owing to the production of by-products. Irradiation of $TiO_2$ with UV light results in the formation of electrons and holes, which can then participate in reduction and oxidation reactions, respectively. These redox reactions proceed at room temperature under atmospheric pressure. In this study, photocatalytic cleavage of C-O bond in benzyl phenyl ether as a model compound for lignin.

**Experimental/methodology.** Bare $TiO_2$ (50 mg) was suspended in 5 $cm^3$ of alcohols containing benzyl phenyl ether (50 μmol) in a Pyrex test tube, which was then sealed with a rubber septum under argon and photoirradiated at $\lambda > 300$ nm by means of a 400-W high-pressure mercury arc with magnetic stirring in a water bath maintained at 298 K. The amounts of unconsumed benzylphenylether and generated toluene and phenol were determined with a gas chromatograph.

**Results and discussion.** When bare $TiO_2$ was used as the photocatalyst, no reaction of benzyl phenyl ether occurred. We investigated Cu, Ru, Rh, Pd, Ag, Pt and Au as co-catalyst. When we used Ru-, Rh-, Pd-, or Pt-loaded $TiO_2$, toluene and phenol were obtained in a 1:1 molar ratio by cleavage of the C–O bond of benzyl phenyl ether without the need for $H_2$ gas. The Pd-$TiO_2$ catalyst showed much higher yields of toluene and phenol than did the other photocatalysts (scheme 1).

**Scheme 1 Time courses of the amount of 1-phenylethanol remained and acetophenone formed in photocatalytic hydrogenation using glucose instead of $H_2$ gas.**

**Introduction**

The valorization of hemicellulose sugar streams derived from the pretreatment and fractionation of lignocellulodic biomass comprises an important sustainability pillar in various 2nd generation biorefinery schemes. The main reactions/processes involved are the hydrolysis of oligmeric carbohydrates towards monomer sugars such as xylose, arabinose, etc. and their dehydration to the respective furans (i.e. furfural and HMF) by homogeneous or heterogeneous acid catalytic systems. The obstacles to be overcome are the tendency of furanics to rehydrate towards organic acids, i.e. formic, levulinic, etc. and/or to condensate to polymeric humins, thus decreasing their selectivity and yield. When real hemicellulose streams are involved, for example originating from the hydrothermal/mild acid or organosolv pretreatment of biomass, the co-presence of organic acids needs also to be considered.

**Experimental/methodology**

An optimization study was initially conducted using model xylose feed solutions in neat water, as well as in biphasic systems, e.g. water/THF, GVL, in the presence (or not) of NaCl to induce the salting-out effect and "protect" the formed furfural via in-situ extraction from the aqeuous to the organic phase. Both homogeneous (dilute $H_2SO_4$, $H_3PO_4$, HCl) and heterogeneous (ZSM-5, BETA, USY zeolites) acid catalytic systems were tested, at different reaction conditions (time, temperature and pressure). Mechanistic studies focusing on furfural stability and effect of co-presence of organic acids in the hemicellulose streams were also performed. Real hemicellulose streams, isolated from the organosolv pretreatment of beechwood sawdust, were then investigated as feed at the optimum conditions towards maximizing furfural production. Feeds and products were analyzed by HPLC, GC-MS, GC-FID, NMR, while solid catalysts were characterized by XRD, BET, ICP, acidity measurements, etc.

**Results and discussion**

The optimum reaction conditions towards maximum furfural yield (61% at ~100% xylose conversion) using model xylose in water were 175°C, 15 min, 10 bar $N_2$, with the reaction temperature being the dominating parameter in comparison to time. Sulphuric acid ($H_2SO_4$) was most effective compared to HCl and $H_3PO_4$, at low concentrations in order to minimize the subsequent conversion of furfural to acids and humins. Solid acid zeolite catalysts (ZSM-5, BETA, USY) were also very active (~100% conversion) with ZSM-5 (Si/Al=11.5) showing the highest furfural yield of 40%. Co-feeding ethanol, being present in real organosolv hemicellulose streams, led to slightly lower conversion and yield, depending on the addition level, inducing at the same time the formation of furfural diethyl-acetals. Furthermore, the reactivity of various organic acids, i.e. formic, acetic, levulinic, lactc, being also present in real hemicellulose streams was also high towards furfural formation, reaching 50-70% yield at the studied conditions. The use of biphasic systems, afforded organic solvent fractions containing essentially only furfural. The results obtained from the model xylose tests were adopted and verified with the hemicellulose aqueous streams derived from the organoslv pretreatment of beechwood sawdust, where the existing $H_2SO_4$ (from the organosolv pretreatment) was utilized as the acidic catalysts.

**Introduction.**
A one-pot catalytic hydrolysis-decarboxylation reaction is one of the potential route to produce green diesel or value-added chemicals such as α-olefins by using natural fats and vegetable oil-based feedstocks. Nickel and/or palladium catalysts are good candidates to carry out both reactions sequentially in the same conditions. However, the decarboxylation of the fatty acids, which are in the feeding or produced in the hydrolysis reaction, in an aqueous reaction media is less effective and described in the literature than the organic one. Then, the main goal of this work is to investigate the stearic acid (SA) hydrothermal deoxygenation by using palladium supported on different supports (C, $Al_2O_3$, $SiO_2$, $Nb_2O_5$).

**Experimental.**
The catalysts (1 wt.% Pd) were prepared by incipient wetness impregnation of an aqueous $[Pd(NH_3)_4](NO_3)_2$ solution, dried at 120 °C and calcined at 300 °C (except on C). They were characterized by $H_2$-TPD, CO-chemisorption, and other techniques. The reactions were performed in a 500 mL-stirrer batch reactor at 25 bar and 250 °C during 3h by using SA/H2O/catalyst mass ratio of 1/100/5.

**Results and discussion.**
Heptadecene was the main organic molecule observed in the GC-FID analysis after reaction, indicating a selective decarboxylation reaction. Figure 1 reveals that the final decarboxylation conversion was reached at less than 1.5 h with all catalyst. It also exhibits the maximum specific rates after 1.5 h and the turnover frequency (TOF) as well. The results can be explained by the metallic sites density and strength.

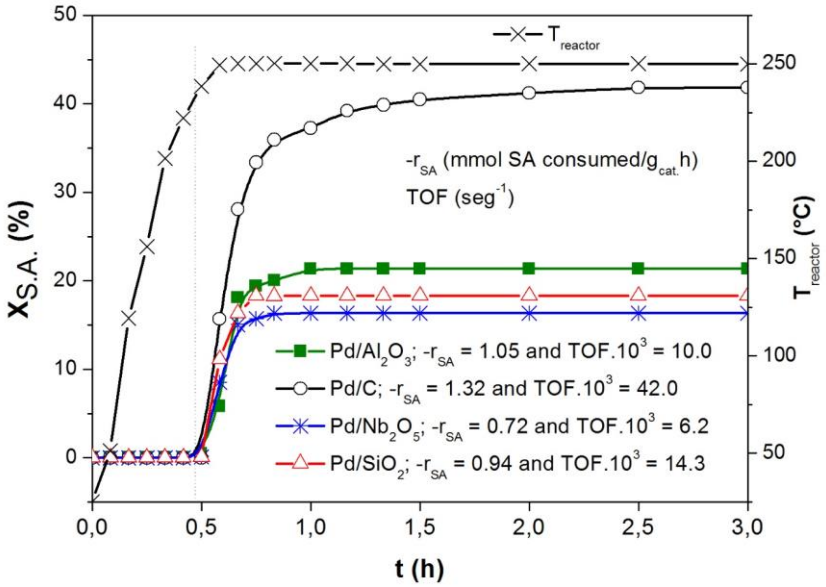

**Figure 1 - SA decarboxylation/decarbonylation catalytic activities**

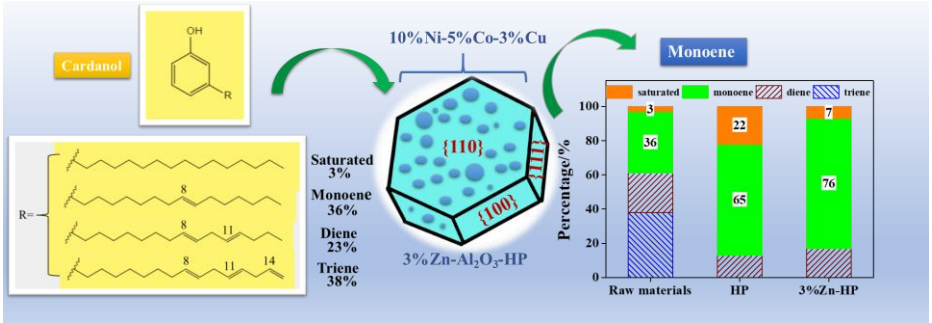
# Selective hydrogenation of polyenes in biomass-derived cardanol over the trimetallic Ni-Co-Cu catalyst supported on morphologically controlled alumina



J. Ding, Z. S. Xu, H. J. Fang, X. Z. Feng, W. J. Ji*

*Key Laboratory of Mesoscopic Chemistry, MOE, School of Chemistry and Chemical Engineering, Nanjing University, Nanjing 210023, China*
**jiwj@nju.edu.cn*

**Introduction.** The biomass-based molecules usually contain unsaturated organic groups, and catalytic hydrogenation is an effective way to achieve value-added chemicals. The effectiveness of hydrogenation process is highly defined by the selectivity toward the specific product(s). Morphology control is considered to be an effective tactic to design high performance catalyst system. [1] Cardanol can be naturally obtained from cashew nut shell liquid. The long chain hydrocarbon group of cardanol can be fully saturated, monoene, diene, or triene with different content. Renny Ni can fully hydrogenate the long chain hydrocarbon group. [2] This is unfavorable, however, to achieve high degree of cross-linking and coupling between resin and curing agent. Although the homogeneous $RuCl_3$-catalyzed transfer hydrogenation can achieve selective conversion of polyenes to monoene in cardanol, [3] the reaction is kinetically sluggish. Herein, we reported a transition metal-based Ni-Co-Cu catalyst effective for the target reaction.

**Experimental/methodology.** $Al_2O_3$ hexagonal plates ($Al_2O_3$-HP) and stacked hexagonal plates ($Al_2O_3$-SHP) were synthesized through the ion-liquid assisted hydrothermal approach. The commercially obtained spherules of $Al_2O_3$ ($Al_2O_3$-CS) was also used for comparison. The Ni-Co-Cu constituents were introduced by incepeinte wetness impregnation. The characterizations of XRD, SEM/TEM, EDS, XPS, $H_2$-TPR were performed for understanding the physico-chemical properties of catalysts. All the catalysts were evaluated in a small-sized high pressure continuously stirred tank reactor under a set of conditions.

**Results and discussion.** We reported a heterogeneous non-precious trimetallic catalyst for the first time for selective hydrogenation of polyenes in cardanol. By controlling morphology plus Zn doping of $Al_2O_3$ support, we accomplish highly selective hydrogenation of triene/diene into monoene with variable ratio. The larger sized Ni entities with higher electron density on $Al_2O_3$-HP are more favorable for activating triene/diene responsible for a high potential of selective hydrogenation. The $Ni^0$ fraction is comparatively lower while the mean particle size of $Ni^0$ is the smallest with lower electron density on commercially obtained γ-$Al_2O_3$ spherules ($Al_2O_3$-CS). The latter kind of Ni entities is more favorable for activating hydrogen to generate highly reactive H species accounting for a strong potential of full hydrogenation. Over a fine-tuned 10%Ni-5%Co-3%Cu/3%Zn-$Al_2O_3$-HP under the optimized conditions (7.5% cardinal in *n*-butanol, 2.5 MPa $H_2$, 80°C, 3.5 h), as high as 76% monoene can be obtainable. Note that the reaction over the current catalyst system becomes kinetically much faster (within 3.5 h). Ni-Co-Cu synergism and low content Zn-modification of $Al_2O_3$ (110) facet are recognized to be essential to achieve the aim of this study.

**Keywords:** Porphyrin, Cobalt-porphyrin, Biomass conversion, Furfural, succinic acid.

**Introduction:** Metallo-porphyrins are fascinating macro-molecules due to their applications in industrial and academic research, especially due to their significant role in biological reactions.[1,2] Transition metal-based organo-metallic complexes have a wide range of catalytic applications due to their immense redox potential.[3] However, some problems associated with the homogeneous metallo-porphyrin catalyst are oxidative degradation of porphyrin and the difficulty in separating the products and recovering catalysts. Further to achieve the improved stability and efficiency of these complexes, it can be immobilized solid supports such as carbon nanotubes due to its unique structural characteristics, high surface area, and the lack of solubility in most solvents.[4] In this work we introduced $Co^{2+}$ in porphyrin and covalently immobilized on multi-walled carbon nano-tube (CNT), and explored its catalytic activity for the oxidation of furfural to succinic acid.[3,5] Currently succinic acid is producible by oxidation of butane and 1,4-butanediol, carbonylation of ethylene glycol, and fermentation of saccharides. Therein, synthesis of succinic acid through the oxidation of furfural is examined by as-prepared eco-friendly catalyst of cobalt porphyrin-based catalyst.

**Experimental methods:** The meso-tetrakis (carboxyphenyl) porphyrinatocobalt(II) (Co-TCPP) was prepared and characterized by FT-IR, UV-Vis, TGA, powder XRD, $^1$H NMR, and mass spectroscopy. Subsequently, the CNT-supported Co-TCPP was screened for its activity at the oxidation of furfural with $O_2$ molecule.

**Results and discussion:** The amino-functionalized CNT-supported Co-TCPP (Co-TCPP/CNT-$NH_2$) exhibit promising catalytic properties for oxidation of furfural to succinic acid with excellent conversion of 76.0 % with 78.9% selectivity at moderate reaction conditions, as listed in **Table 1**. The product was confirmed by HPLC and GC-TOFMS studies. Further, the catalyst was reusable for several cycles and succinic acid was obtained as the major product constantly. In summary, the simple cobalt-porphyrin-supported catalyst was successfully able to proceed the selective aerobic oxidation of furfural to succinic acid with molecular oxygen without any co-catalysts, which generally required for the activation of molecular oxygen by metal complexes.

**Table 1: Furfural oxidation using various Cobalt-porphyrin catalysts in the presence of molecular oxygen.**

| Catalyst | Conv. /% | Yield (Selectivity for succinic acid) /% | | | Carbon mass balance /% |
|---|---|---|---|---|---|
| | | Succinic acid | Maleic acid | Fumaric acid | |
| Co-TCPP/CNT-$NH_2$ | 76.0 | 60.0 (78.9) | 3.0 | 4.3 | 53.9 |
| Co-TCPP/CNT | 73.5 | 41.0 (55.8) | 1.9 | 2.8 | 36.6 |
| Blank | 5.4 | 0 ( 0) | 4.7 | 1.8 | 5.2 |

**Reaction conditions: Furfural (1.0 mmol), Catalyst (20 mg), 100°C; 20 h, $O_2$ (1.0 MPa), water (3 mL).**

**Keywords:** Brønsted-Evans-Polanyi (BEP), Catalysis, Density Functional Theory (DFT), Furan hydrodeoxygenation (HDO), Microkinetic Modeling (MKM).

**Introduction:** Rising crude oil prices and depleting fossil fuel reserves have led to the search for alternative sources of fuel and chemicals. Biomass pyrolysis derived bio-oil is a promising alternative, but the bio-oil is rich in oxygen and requires a catalytic hydro-deoxygenation step (HDO) to transform it into valuable fuels and chemicals. In this work, a combined Density Functional theory (DFT) and microkinetic modeling (MKM) based approach is employed for understanding the HDO activity of large bio-oil molecules (example furan) on mono and bimetallic transition metal (TM) surfaces. A similar approach has been previously applied to small molecules, but not for heterocyclic molecules like furan. In this work, using furan and O binding energy as descriptors in the MKM model, suitable HDO catalysts for the formation of oxygenates, ring saturated compounds and deoxygenated products are identified.

**Experimental/methodology:** For developing energetics of the reaction network spin-polarised DFT calculations were performed as implemented in Vienna Ab-initio Simulation Package (VASP)[1,2]. An energy cut-off of 450 eV and the revised PBE (revPBE)[3] exchange-correlation functional were implemented with vdW corrections[4,5] that account for weak long-range dispersion interaction. The energetics obtained was used in an MKM to obtain selectivity and rate plots for the different HDO products as a function of the furan and O binding energies.The MKM was developed using the descriptor-based analysis approach as in CatMAP[6] developed at Stanford university.

**Results and discussion:** Brønsted-Evans-Polanyi (BEP) relationships were developed for all elementary steps of furan activation to tetrahydrofuran (THF), open-chain alcohols, aldehydes and olefins on mono and bimetallic TM surfaces. Open-chain oxygenates were the dominant product on Pt, Ir, Pt, Rh and Pd while metals with strong oxygen binding energies (Ru and Co) facilitated C-O scission to form deoxygenated products. MKM analysis revealed the product selectivity to be a strong function of the reaction temperature. The range of binding energies of the descriptors which gave the maximum turnover frequency (TOF) for each product was also identified. The combined DFT and MKM analysis allows for accelerated catalyst discovery for HDO of biomass-derived bio-oil.

# Effect of zeolite framework on the efficiency of implanted Ti active sites for methyl oleate epoxidation

S. Klinyod[1], T. Sooknoi[2], C. Wattanakit[1*]

[1]*Department of Chemical and Biomolecular Engineering, School of Energy Science and Engineering, Vidyasirimedhi Institute of Science and Technology, Rayong 21210, Thailand*

[*]*Corresponding Author's email; chularat.w@vistec.ac.th*

**Introduction.** The development of isomorphically substituted transition metals, especially the Ti atom, in a zeolite framework is one of the most promising perspectives for Lewis acid catalysis. In this contribution, we demonstrate the effect of the zeolite framework on the efficiency of incorporated Ti active sites in different zeolite topologies, such as MFI and BEA. It is observed that the zeolite framework can affect the structure of embedded Ti active species, confirmed by the UV-Vis DRS technique. The isolated tetrahedrally coordinated Ti active species has been successfully incorporated into the BEA zeolite framework (Ti-BEA). In contrast, the ZSM5 (MFI) framework primarily composes of tetrahedrally polymeric Ti species.[1] To demonstrate the effect of the zeolite framework on the catalytic performance in methyl oleate epoxidation, the isolated tetrahedral Ti active sites in the BEA framework show superior catalytic activity in terms of methyl oleate conversion and epoxide selectivity compared to polymeric tetrahedral Ti-containing in ZSM5 zeolite (Ti-ZSM5). Noticeably, the product distribution obtained from Ti-BEA and Ti-ZSM5 catalysts is completely different. These observations relate to the fact that the differentiation of the electronic property of Ti active species could be obtained when incorporating in the different zeolite framework, eventually changing the catalytic activity of the catalyst.

**Experimental/methodology.** The isomorphic substitution of the Ti atom in the ZSM5 and BEA zeolite framework is achieved by using the post-synthesis method. The consecutive chemical reactions of the dealumination and titanation reaction are applied for implanting the Ti atom into different zeolite frameworks. The catalytic activity of as-synthesized catalysts is evaluated in methyl oleate epoxidation.

**Results and discussion.** The differentiation of the zeolite framework can induce the formation of different incorporated Ti active structures. The UV-Vis DRS spectra point out that the Ti active species in the BEA framework are mainly isolated four-coordinated Ti sites, verified by the strong adsorption band of 214 nm. On the other hand, the tetrahedrally polymeric Ti active sites mostly contained in the ZSM5 framework are confirmed by the adsorption band of 248 nm,[1] as shown in Figure 1A. To illustrate the effect of zeolite framework and Ti species in a catalytic activity, the obtained catalysts are employed in the catalytic transformation of methyl oleate to their corresponding epoxide compounds. Obviously, the product selectivity derived from different Ti active species is remarkably changed. The further transformation of the epoxide product to the hydrolyzed product can be suppressed when the isolated Ti active site in BEA zeolite is applied as a catalyst. In contrast, the polymeric tetrahedral Ti sites in the ZSM5 catalyst facilitate the conversion of epoxide product to methyl 9,10-dihydroxystearate (MDI) compound through consecutive hydrolysis reaction, as illustrated in Figure 1B. These observations inspire the rational design of the Ti active species toward controlling the catalytic activity of the catalysts.

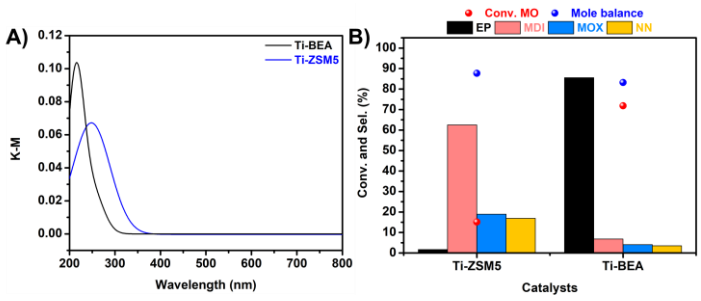

**Figure 1.** A) UV-Vis spectra of Ti-ZSM5 (blue) and Ti-BEA (black) and B) the catalytic performance of different catalysts.

# Production of biomass-derived polyalphaolefin-grade lubricant through aldol condensation reactions

Sang Hyeok Ko, Dinesh Kumar Mishra, Young-Woong Suh*

*Department of Chemical Engineering, Hanyang University, Seoul 04763, Republic of Korea*
**ywsuh@hanyang.ac.kr*

**Keywords:** lubricant, aldol condensation, hydrodeoxygenation

**Introduction.** As the world population increases, the usage and production of lubricants tend to increase every year. Most lubricants are produced from mineral oil, but due to raw material depletion and environmental problems, the technology for producing lubricating oil from unused biomass has recently been getting attention. However, the development is currently in an early stage [1,2], and it is necessary to develop a lubricant manufacturing technique with different physical properties suitable for the purpose. Thus, we developed a strategy to obtain polyalphaolefin-grade lubricants (PAOL) through a series of reactions using homogeneous and/or heterogeneous catalysts in a batch reactor.

**Experimental/methodology.** As depicted in Figure 1, C16 synthesis was conducted through self-condensation of octanal produced by chemical conversion of pentose and hexose derived furan derivatives. The synthesized C16 was condensed with ketones followed by aldol condensation and hydrodeoxygenation, affording PAOL product. All aldol condensation reactions were conducted in a glass reactor and autoclave batch reactor using homogeneous and heterogeneous catalysts, respectively. Hydrodeoxygenation experiments were performed in a batch reactor with heterogeneous catalyst.

**Results and discussion.** The optimal octanal self condensation reaction conditions were chosen to achieve a high yield of C16 ketone ($Y_{C16}$ = 80%). The synthesized C16 ketone was condensed with C11 ketone, and then hydrodeoxygenated over Pd/$NbOPO_4$ to the target product, C27 alkane. The hydrodeoxygenation product of C27 alkane was analyzed through GC-MS (Figure 2) and $^1$H-NMR techniques, confirming the successful synthesis. The high-purity C27 alkane was recovered by being separated from the hydrodeoxygenation product.

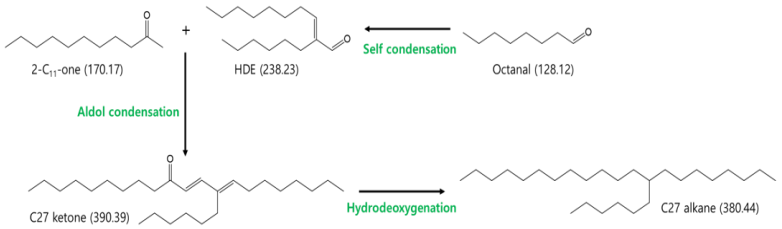

**Figure 1. Reaction pathway for the synthesis of polyalphaolefin lubricant (C27)**

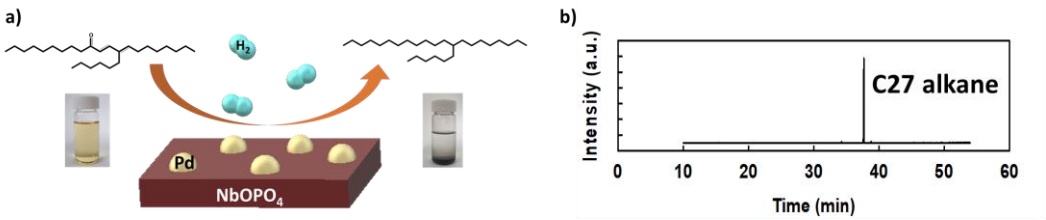

**Figure 1. a) Hydrodeoxygenation of C27 ketone and b) GC-MS result of the hydrodeoxygenation product.**

**Keywords:** Ethanol, butanol, Guerbet reaction, mixed oxides, Tishchenko reaction

**Introduction.** The decreasing amount of fossil resources and climate change lead to the intensification of research in the field of the use of renewable raw materials and waste recycling. One of the promising starting materials may be an ethanol. Today,ethanol is obtained through a fermentation process from sugar containing substances . Commonly, ethanol is mainly used as a biofuel in gasoline. However, its potential can be found in the preparation of important chemicals such as ethylene, butanol, hexanol, ethyl acetate and butyl acetate. These substances are important solvents and components in the preparation of plastics. In case of higher alcohols such as butanol and hexanol which can be prepared by the multistep Guerbet reaction, consisting of: dehydrogenation, aldol condensation and hydrogenation, respectively., The Tishenko reaction can be utilized for the acetates synthesis. . Both reactions require the presence of an acid-base catalyst. Therefore, the catalyst plays a key role, as its properties strongly influence the selectivity to the desired products.

**Experimental/methodology.** The mixed oxides based catalysts were prepared by co-precipitation method, where the calcination temperature was foundby TGA analysis. The structure of the catalyst was studied by XRD and the chemical composition by ICP-OES. $N_2$-physisorption and Hg-porosimetry were used to study of the catalyst pore size distribution. A key parameter was the study of the active sites, where acid-base centers were determinated by TPD techniques and reduction properties by TPR-$H_2$. The catalysts were tested in stainless steel fixed bed reactor under different reaction conditions. The catalysts activity was evaluated based on the conversion of ethanol and selectvity to main products.

**Results and discussion.** The presence of transition metals significantly increased the conversion of ethanol. However, the transition metals influenced the selectivity to desired products. It was found, that the presence of the copper enhanced the acetates formation,while the presence of nickel and cobalt improved the selectivity to butanol and hexanol. Besides the transition metals impact, it was found that acid-base properties influenced the selectivity, as the catalysts with higher total basicity showed higher selectivity to butanol.

**Keywords:** PdIr catalyst, hydrogenation, acetalization, furfural, furfuryl alcohol, furfural diisopropyl acetal

**Introduction.** Furfural (FU) platform molecule is derived from lignocellulosic biomass and can be used for sustainable synthesis of chemicals and fuels. FU hydrogenation may lead to furfuryl alcohol (FA, used for fine chemicals, lubricants, polymers, pharmaceuticals) which can be further hydrogenated to tetrahydrofurfyl alcohol (THFA, green solvent) while acetalization with alcohol solvent produces acetal (AC, potential Diesel fuel additive). The evaluation of Pd-Ir/C catalysts with various Pd:Ir surface concentration and $Ir^0/IrO_x$ ratio for driving the reaction toward hydrogenation or acetalization is discussed.

**Experimental.** The catalysts were prepared by reverse water-in-oil micromulsion method. The series of nanoparticles with different Pd:Ir molar ratios were syntesized using Pd,Ir-salts solutions ($c^0$=0.02M) and deposited on carbon support (2%PdIr-X X=5-50mol%Ir). PdIr-26/C catalyst was also synthesized with more concentrated precursors solutions $c^0$ = 0.08 and 0.2M. 2%Pd/C and 2%Ir/C were also prepared. The catalysts were characterised by XRD, SEM, EDS, HRTEM/STEM, XPS, TPR, $H_2$ and $NH_3$ sorption. FU hydrogenation in 2-propanol in batch reactor under mild conditions (6 bar $H_2$, 35°C) was performed.

**Results and discussion.** The Pd/Ir bulk proportion determined surface Pd/Ir ratio, Pd-Ir alloying degree which changed the strength of hydrogen adsorption, e.g. influenced the carbonyl group hydrogenation. The highest activity (Fig. a) with the highest FA selectivity and almost no AC formation was obtained over PdIr-26/C (26%Ir) with Pd-Ir alloyed surface structure (Fig. b). On the contrary, formation of AC by FU acetalization with 2-propanol was promoted by bimetallic particles of high surface share of oxidized amorphous iridium species like $IrO_x$ and almost without alloyed structure e.g. PdIr-5 and PdIr-9 (Fig. c). The monometallic Ir/C catalyst was also active for FU acetalization (Fig. c) but only when the active sites were generated in situ during preactivation of catalyst with $H_2$. There was no reactivity of Ir/C in acetalization under $N_2$. The change of Pd- and Ir-precursors solution concetration ($c^0$, Fig. d) strongly affected the Pd/Ir nanoparticles surface structure influencing the catalysts reactivity toward hydrogenation vs. acetalization.

**Keywords:** sustainable fuels, pyrolysis oil upgrading, catalytic hydrodeoxygenation, catalytic stabilization

**Introduction.** Fossil fuels are a major contributor to the high carbon emissions today and more sustainable alternatives are needed, especially in the transportation sector [1]. While electric cars are being implemented instead of conventional passenger cars, more sustainable alternatives remain to be found for aviation and heavy transport purposes, as these require a more energy-dense fuel source [1].

Biomass-derived hydrocarbon fuels have gained increasingly more attention as a sustainable alternative to conventional fossil fuels, as they can easily be implemented in today's engines, either by blending with fossil fuels or completely replacing them. Unfortunately, the oil produced from pyrolysis of biomass has a high content of oxygen-containing organic compounds, which leads to unwanted properties, such as poor stability and a corrosive nature [1]. Therefore, a two-step hydrotreating process is needed to remove the oxygen from the oil; the oil is first stabilized at a lower temperature to avoid reactor plugging and catalyst deactivation, before the actual HDO at elevated temperatures [2,3].

Hydrotreating catalysts can be divided into three categories: conventional sulfided catalysts, noble metal catalysts, and reduced base metal catalysts. The last two categories have been heavily investigated, but little attention has been given to the sulfur tolerance of these catalysts. As biomass-derived pyrolysis oils will contain small amounts of sulfur, it is important to take the sulfur tolerance into account, when looking for the optimal catalyst [1]. In this contribution, we will present our research into the activity and sulfur sensitivity of a range of catalysts for stabilizing pyrolysis oils.

**Experimental/methodology.** Catalyst screening experiments for stabilization of pyrolysis oils have been conducted on a benchscale batch autoclave setup. The catalysts were tested using the model compound furfural at high pressure and at temperatures of up to 200 °C. Addition of an organic sulfur compound to some of the experiments was used to test the sulfur sensitivity of the catalysts. The gas phase was analyzed using gas chromatography (GC) with a flame ionization detector (FID) and two thermal conductivity detectors (TCD), the liquid phase was analyzed by GC with a mass spectrometry detector (MSD) and a FID. The catalysts were characterized using XRF.

**Results and discussion.** An overview of the activity of a wide selection of catalysts was created from the catalyst screening experimental series. The use of the model compound furfural instead of real pyrolysis oil provided clarity on the reactions taking place during the stabilization. The experiments with sulfur addition provided insight into the sulfur tolerance of the catalysts in question. Research is ongoing to determine the catalyst best suited for stabilization purposes of pyrolysis oils.

**Introduction.**
The development of catalysts with prolonged and enhanced activity is a crucial aspect of improving and adding environmental value to the industrial hydrotreatment upgrading of lignin-based oils. It is a major challenge to develop an efficient catalyst that does not suffer from short-term deactivation due to, e.g. surface coke formation and subsequential blockage of pores and active sites [1]. The effects of rare earth metals in catalyst-support systems used in, e.g. oxidative reforming processes, have been recognized to decrease coke formation [2]. However, less attention has been given to the corresponding enhancement of the hydrodeoxygenation (HDO) process of lignin oils. The three synergistic aims of the work described in this study were: (i) to investigate the effect of adding Ce and La to the δ-$Al_2O_3$ support prior to thermal pretreatment in relation to textural and structural surface properties, (ii) to assess the performance in terms of activity and selectivity towards cresol in the HDO of vanillin over Ce- and La-doped NiMo/$Al_2O_3$ catalysts under continuous-flow conditions, (iii) and to evaluate the catalytic performance in relation to the addition of sulfur during activation of the catalyst and/or during the HDO process.

**Experimental/methodology.**
The catalysts were prepared using incipient wetness impregnation. Ce and La were initially added to $Al_2O_3$ prior to being thermally exposed to 1100 °C, whereas Ni and Mo were impregnated in separate subsequent steps and calcinated at 500 °C. HDO of vanillin was performed under continuous-flow conditions at 314 °C, 5 bar, and a WHSV 35 $h^{-1}$ for 8 hours. The resulting liquid and gas product distribution was analyzed using GC-FID. Elemental analysis was used to evaluate carbon deposition on the used catalysts. The support and catalyst surface characteristics were evaluated using physisorption, chemisorption, XRD, TPD and TPR.

**Results and discussion.**
Less sintering of the doped $Al_2O_3$ was observed after thermally induced (1100 °C) transformation from δ- to θ-structure, suggesting a material stabilization effect by mainly La. A relative decrease in the number of tetrahedral $Al_2O_3$-structural sites was observed for the doped support, and blockage of such sites by mainly Ce is suggested. The addition of Ce and La resulted in a less acidic NiMo catalyst and is proposed to enhance the metal dispersion. The HDO activity tests showed sulphur dependency for both catalysts. However, enhanced selectivity of the direct HDO of vanillin was observed over the doped catalyst, and less coke was formed (Fig 1). This suggests improved characteristics and prolonged activity by doping $Al_2O_3$ with Ce and La.

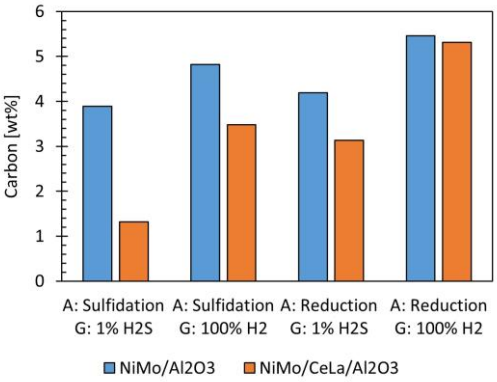

**Fig 1.** Carbon deposition on the used catalysts.

**Keywords:** etherification, fructose, microwave reactor

**Introduction.** Catalytic upgradation of biomass-based feedstock into chemicals and biofuels is possible via several methods such as oxidation, hydrogenation, etc. The methods reported typically require high pressure environment or presence of various gases thereby increasing the cost of process and handling issues. In this regard, the etherification process has emerged as an efficient process for conversion of bio-renewable resources into 5-ethoxymethylfurfural (5-EMF) via various catalytic systems [1], [2]. Herein, we report metal-free, low cost and green heterogeneous catalytic system for developing a mechanistic study on conversion of fructose into 5-EMF. The catalyst is able to be tuned according to the demands of reaction pathway in order to increase selectivity of the reaction.

**Experimental/methodology.** Silica was prepared via hydrothermal method which was modified by grafting functional groups over its surface post its synthesis. The catalytic activity reactions were done in a microwave reactor via microwave heating method where quartz glass vial was charged with a known amount of fructose, ethanol and catalyst. The reactions were carried out by varying the parameters such as temperature, time, catalyst loading and substrate amount. Finally, the reaction product was filtered to separate the catalyst and quantification of products was done in HPLC, GC-FID and GCMS and kinetic studies were also done.

**Results and discussion.** The PXRD patterns in figure-1a show a wide peak at 22.5° indicating the formation of amorphous silica in pristine as well as in functionalized catalyst which shows that pristine structure of silica is preserved. The structure formation of silica and grafting of functional group can also be validated from FTIR spectrum in figure-1b from the Si-O-Si bond stretching of silica and bond stretching vibrations of surface functional groups. The catalytic activity studies were done at varying temperature and time in a microwave reactor which resulted in maximum 99% conversion of fructose. Furthermore, catalyst amount and substrate amount were varied which resulted in a yield of 64.39% 5-EMF at optimized conditions. Notably, time taken in microwave reactor was very less in comparison to that reported in conventional heating methods where up to 24 hours have been taken for reaction to reach maximum conversion and yield. The active acidic sites in the catalyst were mainly responsible for the reaction to occur and proceed towards equilibrium.

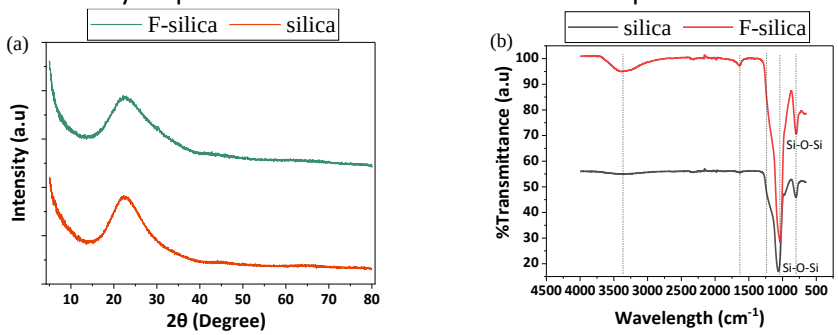

**Figure 1. (a) PXRD patterns of silica and functionalized silica (b) FTIR spectrum of silica and functionalized silica**

**Introduction.**
The production of 5-hydroxymethylfurfural (HMF) is of great importance because it is a platform molecule of industrially significant fine chemicals[1]. In this work, glucose has been chosen as the starting material because of is the most abundant hexose contained in lignocelullulosic biomass as cellulose. The production of HMF from glucose needs two different catalysts: a Lewis-type catalyst for glucose isomerization to fructose and a Brønsted-type catalyst for fructose dehydration and obtaining HMF. For this reason, Metal Organic-Frameworks (MOF) as Lewis acid catalyst[2] and polyoxomethates (POM) as Brønsted acid catalyst have been chosen, which are respectively active for each reaction. The study of this reaction will be carried out in two ways: in the first, the MOF and POM catalysts will be added separately (MOF+POM) and in the second one, the POM encapsulates inside the MOF (POM@MOF)[3].

**Experimental/methodology.**
Different MOF catalysts were used in these reactions MIL-101(Cr), MIL-53(Cr), MIL-53(Al), MIL-100(Fe) and CuBTC. The inmobilization of POM in the MOF was carried out using a previously described method.[4] The reactions were performed in stirred tank reactors with a solution of 1 % glucose (0.05 g) in 5 mL of GVL-10%$H_2O$ with the appropriate amount of catalysts.[3] The reactions were carried out at 140 °C for different reaction times (15, 30, 60, 120, 240, 360 and 480 min) and were analyzed by HPLC.

**Results and discussion.**
The HMF yields versus time for the two different reaction studies (MOF+POM and POM@MOF) were studied. In both cases, the formation of HMF was observed with similar yield profiles, although with some slight improvements for the POM@MOF. The best and most relevant data were those obtained with MIL-101(Cr) and MIL-53(Al) in both studies, which present an increase in performance over time up to 40 % after 480 reaction min. However, the other combinations of the different catalysts present a lower yield increase that does not exceed 20 % in any case, with stabilization from short times regardless of the method studied. Catalyst reuse studies were carried out and the most efficient was HSiW@MIL-101(Cr) with up to 6 reuse cycles. In each consecutive study cycle, a loss of POM catalyst was observed in the catalyst structure, resulting in decreased yield to HMF and increased yield to fructose in the medium.

**Introduction.** The development of processes for obtaining industrially important chemicals based on renewable raw materials is an important area of research in the sustainable chemistry. One of these processes is the dehydration of bio-isobutanol into butene isomers. The latter are the raw materials for the synthesis of various important chemicals (polybutenes, ETBE, methyl methacrylate, etc.). It is known that the production of butene isomers is possible by catalityc dehydration of isobutanol over oxide and zeolite systems [1, 2]. In particular, FER zeolites show high selectivity for linear butenes. The distribution of isobutanol dehydration products on zeolite catalysts is mostly associated with zeolite topology. We focused on elucidating the influence of the acid-base properties of FER, MFI, FAU and BEA zeolites on the conversion of isobutanol to butene isomers. Also, the deactivation behavior of the most selective catalyst was investigated.

**Experimental/methodology.** Commercial zeolites of FER, MFI, FAU and BEA structural types with a Si/Al ratio of 10÷68 (specified in the name of the samples) were investigated in the work as catalysts for the conversion of isobutanol. Physico-chemical characteristics of zeolite catalysts were studied by FE-SEM, XRD, $N_2$-ad/desorption, $^{27}$Al, $^{1}$H, $^{29}$Si MAS NMR, $^{1}$H-$^{29}$Si CP MAS NMR, FT-IR with pyridine, TPD-$NH_3$/$CO_2$/$H_2O$ with MS control. The catalytic properties of zeolites were investigated in a flow-type quartz reactor unit at atmospheric pressure in the temperature range of 175-300 °C with chromatographic analysis of reagents and products.

**Results and discussion**. In the process of isobutanol conversion over FER, MFI, FAU and BEA zeolites the distribution of butene isomers significantly depends on structural type (see Table) of the zeolite catalyst, strength and nature of the surface acid sites. The highest selectivity toward linear butenes of 83.2 % (but-1-ene, trans-but-2-ene and cis-but-2-ene) is achieved over the FER-10 catalyst at 225 °C. Selectivity for linear butenes is more than twice as low, but also quite significant (36.8 %) is observed on MFI-40 catalyst at 175 °C after 4 h of reaction. This may be due to the presence of a larger number of strong Brønsted acid sites on FER-10 surface compared to the MFI-40 and other catalysts, which are active sites for both alcohol dehydration and alkene skeletal isomerization. The catalyst under study retains a fairly high activity after above 45 hours. The reasons for a decrease in catalyst activity were studied using $^{1}$H-$^{13}$C CP MAS NMR and NAP-XPS methods.

**Indices of isobutanol conversion over zeolite catalysts (T = 175 °C, W = 1 g/($g_{cat}$·h), TOS = 2.7 h)**

| Catalyst | Conversion, % | $S_{linear\ butens}$, % | Selectivity, % | | | | |
|---|---|---|---|---|---|---|---|
| | | | Isobutene | But-1-ene | trans-But-2-ene | cis-But-2-ene | Others |
| FER-10* | 18.5 | 72.5 | 23.8 | 8.1 | 42.8 | 21.6 | 3.7 |
| MFI-40 | 30.0 | 35.3 | 57.1 | 4.2 | 19.7 | 11.4 | 7.6 |
| FAU-15 | 52.8 | 14.0 | 36.4 | 1.9 | 7.0 | 5.1 | 49.6 |
| BEA-19 | 37.6 | 18.1 | 38.4 | 3.1 | 7.9 | 7.1 | 43.5 |
| BEA-68 | 23.7 | 21.1 | 50.0 | 3.4 | 9.5 | 8.2 | 28.9 |

# Catalytic Co-pyrolysis of Beech Wood and Polyamide-6

W. de Rezende Locatel, C. Mohabeer, D. Laurenti, Y. Schuurman, N. Guilhaume*

*IRCELYON, Univ. Lyon1-CNRS, UMR5256, Villeurbanne, France*
** nolven.guilhaume@ircelyon.univ-lyon1.fr*

**Keywords:** Biomass, polyamide, catalytic upgrading, co-pyrolysis, HZSM-5

**Introduction.** Biomass residues and wastes can be converted into bio-liquids by pyrolysis, which can contribute to both the production of renewable fuels and the recycling of wastes. In this work, the pyrolysis of pure beech wood (BW) and of BW mixed with polyamide-6 (PA6), a nitrogen-containing plastic, little studied in pyrolysis but ubiquitous in particular in the building industry, was investigated to assess the effect of PA6 on the properties of bio-oils, obtained either by thermal pyrolysis or by pyrolysis with ex-situ catalytic treatment.

**Experimental.** The catalytic treatment was applied to the pyrolysis vapors that are driven across a HZSM-5 catalyst bed before their condensation into liquid products in a dedicated reactor already descibed [1].

**Results and discussion.** The presence of 20 wt.% PA6 in the blend affected the pyrolysis products yields and distribution (gases, liquids, chars), but also the composition of the bioliquids. In absence of a catalyst, the production of phenolic, sugar and furan compounds decreased significantly with the BW+PA6 blend compared to pure BW, and N-containing compounds derived from PA6 were found in the bioliquids (Fig. 1). When HZSM-5 catalyst was used for the treatment of vapors, the production of sugars and furans decreased and a small production of fully deoxygenated compounds was observed with pure BW. This effect was mitigated with BW+PA6 blends and the formation of deoxygenated compounds was almost totally suppressed, suggesting that the strong catalyst acid sites were poisoned. Caprolactam was by far the main product of PA6 degradation found in the bioliquids, but the N-containing by-products were different depending on the absence or presence of HZSM-5 catalyst. Mixtures of BW and PA6 in different ratios were also co-pyrolyzed in the presence of the HZSM-5 catalyst. With increasing PA6 concentrations, less gaseous products were formed, evidencing a catalyst deactivation (less cracking activity). In the liquid phase products, the production of oxygenated aromatic compounds and of fully deoxygenated compounds decreased with increasing PA6 concentrations, while the average molar mass of bio-oils and their N-content increased. It was also observed that the amount of coke deposited on the catalyst decreased as the PA6 concentration increased.

# Catalytic depolymerization of *γ*-valerolactone organosolv processed lignin

Saravanan Kasipandi,* Sari Rautiainen, Silja Känsäkoski, Taina Ohra-aho, Juha Lehtonen

*VTT Technical Research Centre of Finland Ltd, P.O. Box 1000, FI-02044 VTT, Espoo, Finland*
**saravanan.kasipandi@vtt.fi*

**Keywords:** Depolymerization, molybdenum, organosolv lignin, phenolic monomers

**Introduction.** Modern biorefineries focus on valorizing cellulosic fractions of lignocellulose and major part of lignin is still used as a fuel. EU project FRACTION proposes aqueous *γ*-valerolactone (GVL) organosolv process for fractionation of different lignocellulosic feedstocks to valorise the lignin as well as hemicellulose fractions of biomass [1]. Lignin is an abundant source of aromatics and is an ideal complement or substitute to petroleum-based feedstocks [2]. In the catalytic depolymerization, lignin is depolymerized initially with solvents to form oligomers, which can be further converted into stable monomeric products via catalytic route. Herein, the lignins produced by the FRACTION fractionation process (*ie*., GVL lignin) are depolymerised via catalytic ethanolysis and ethanolysis enhanced by gaseous $H_2$ (hydrogenolysis) into low molecular weight products. The results of GVL lignin-derived products were compared to that of eucalyptus organosolv Fraunhofer lignin.

**Methodology.** Two types of catalysts namely $MoC_x$ and MoP were synthesised and characterised using XRD, BET, XPS and SEM-EDS. The catalytic ethanolysis and hydrogenolysis were carried out in a batch reactor. Reaction parameters such as temperature, and with and without catalysts/external gaseous $H_2$ were studied. The depolymerised lignin oil samples were analysed using GC/MS and further information was obtained from GPC and NMR analyses.

**Results and discussion.** The nature of lignin properties such as interunit linkages, molecular weight, monolignol ratio and hydroxyl groups were thoroughly characterised. Non-sulfided Mo-based catalysts were prepared and studied for lignin depolymerisation reaction. As shown in **Fig.1**, $MoC_x$ showed relatively higher monomer yields than MoP under identical reaction conditions. Moreover, use of external $H_2$ pressure and catalyst in the reaction system reduces char formation considerably and increase the yield of ethanol soluble oil fraction. Up to 19 wt% of monophenolics and 90 wt% of ethanol soluble fraction were achieved under supercritical ethanol reaction conditions, though increasing the reaction temperature (>280 °C) led to lower monomer yield and increase char formation. GVL lignins displayed relatively higher amounts of ethanol soluble fraction as compared to that Fraunhofer ethanol organosolv lignin.

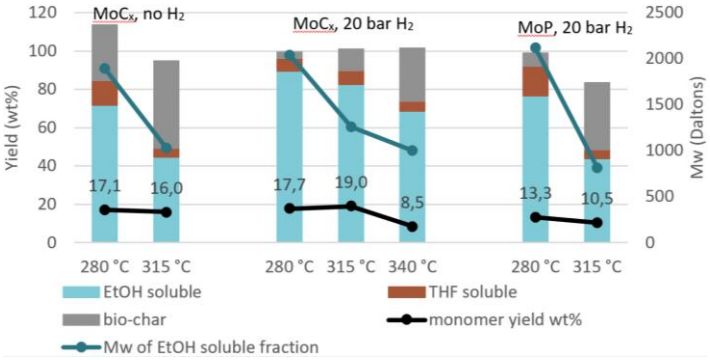

**Fig.1 Comparison of catalysts and reaction conditions in depolymerisation of Fraunhofer lignin. Reaction conditions: 2 g lignin, 80 ml ethanol, 100 mg catalyst (5 wt%), 4 h**

# Maximizing sustainable aviation fuel production through optimized hydroprocessing of bio-oils

Kasper Hartvig Lyng Lejre*, Jostein Gabrielsen and Magnus Zingler Stummann
*Topsoe A/S, Kgs. Lyngby, Denmark*
**KHLJ@topsoe.com*

**Introduction**

Achieving climate neutrality in the transportation sectors requires large volumes of truly sustainable bio fuels to provide long-term solutions for sectors where direct electrification is not viable. Biomass can be used as a raw material for the production of fuels with low (potentially zero) carbon footprint [1]. Biofuel processes such as hydrotreating of vegetable oils can convert biomass into fuel through well-established technologies [2]. Topsoe A/S has been developing and refining the HydroFlex™ technology since 2004 to tailor the product and optimize the yields of both renewable diesel (RD) and sustainable aviation fuel (SAF) from bio-oil feedstocks.

**Experimental/methodology**

In this study, the target was to produce maximum SAF yield while minimizing the loss of overall liquid fuels, SAF+RD, yield. Experiments were carried out in Topsoe's hydrotreating pilot plant facilities, using hydrotreated vegetable oil (HVO) and commercially available hydroprocessing catalyst. The tests were conducted in a once-through, fixed-bed, high-pressure pilot plant setup, loaded with 22 g of TK-920 D-wax™ which is specifically designed for dewaxing HVO and gas oil. The temperature was varied between 280 and 340°C, and the pressure applied was in the range of 40-80 barg. At each condition, gas and liquid samples were drawn and analyzed after reaching line-out. Gas and liquid analyses were carried out in order to close mass balance calculations and giving the basis for calculating yields and hydrogen consumption.

Furthermore, the feed and liquid products were subjected to a range of analytical methods to determine properties such as freezing point, simulated distillation, and density. The liquid products were fractionated to investigate the properties of the SAF and RD fractions separately. More comprehensive methods such as GC×GC-MS/FID/AED and GC-VUV were employed to give in-depth understanding of the chemical reactions taking place over the catalyst.

**Results and discussion**

The HVO was successfully converted to SAF and RD meeting the ASTM D7566 and ASTM D975 specifications, respectively. HVO is a liquid consisting mainly of normal paraffins with carbon numbers in the range C15-C18 resulting in poor cold flow properties. HVO produced by hydrotreating of vegetables oils or animal fats typically has a freezing point in the range of 22-28°C depending on the specific feedstock used. In order to meet SAF specifications both isomerization, to meet freezing point, and hydrocracking, to meet density and boiling point requirements, must be carried out. This is best done in hydroprocessing using a bi-functional catalyst or catalyst system tailor-made to minimize yield loss [3]. In Figure 1, transportation fuel yield, SAF and RD, is plotted as a function of SAF yield. Very high transportation fuel yields are obtained even for SAF yields larger than 20 vol% of fresh feed. The HydroFlex™ process can be applied to advanced bio fuel production where the feedstock is based on e.g. lignocelloulosic- or sewage waste. Recent pilot plant test results show that it is possible to produce SAF based on advanced bio fuel feedstock.

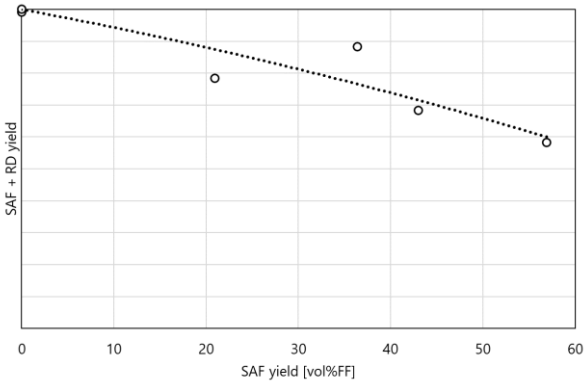

**Figure 1. The overall SAF+RD yield in vol % FF as a function of the SAF yield in vol % FF.**

# Reductive Amination of 5-Hydroxymethyl-2-furaldehyde catalyzed by Supported Ni-Co Bimetallic Catalysts

X. Li[1], S. Nishimura[*]

[1] *Japan Advanced Institute of Science and Technology, Nomi, Ishikawa, Japan*
[*] *E-mail: s_nishim@jaist.ac.jp*

**Keywords:** Reductive amination, 5-Hydroxymethyl-2-furaldehyde, Ni-based bimetal catalyst

**Introduction.** The manufacturing of bio-based chemicals from renewable bio-resources is an important step toward a more sustainable business. Nitrogen-containing chemicals, particularly primary amines, have long been regarded as crucial in the bulk and fine chemical industries.[1] While, in order to offer the target primary amine with a significant amount in a cost-effective and environmentally friendly method, it is crucial to design highly-efficient and selective catalysts since primary amines are more active nucleophiles than secondary and tertiary amines.[2] Herein, the reductive amination of 5-hydroxymethylfurfural (HMF), a one potential lignocellulosic biomass-derived platform chemical, to produce 5-hydroxymethyl furfurylamine (HMFA), is studied over Ni-based bimetallic catalyst by using aqueous ammonia ($NH_3$ aq.) and hydrogen ($H_2$) as nitrogen sources and reductants, respectively.

**Experimental/methodology.** Ni-based catalysts were prepared with a co-impregnation method, and pre-reduced in 5 vol.% $H_2/N_2$ flow (50 ml $min^{-1}$) at 500°C or 800°C for 2 h before use. A pressurized batch reactor system was conducted at the reductive amination reaction under 100°C and 0.6 MPa $H_2$. Reactive activity was evaluated by a GC-FID. A continuous liquid flow system was also applied for stability test.

**Results and discussion.** The effects of Ni:Co ratio are screened as shown in **Figure 1**. It is observed that there is an optimum ratio of Ni:Co, and then the 3wt%Ni-2wt%Co-loaded HAP (denoted as Ni3Co2HAP) catalysts is found to be the best one to afford the corresponding primary amine of 5-hydroxymethy-2-furfurylamine (HMFA) from HMF with 49% yield. It was also discovered that the decrease of reducing treatment from 800°C to 500°C (denoted as Ni3Co2HAPr500) served much higher activity (60% yield). According to TEM and XPS analysis, it indicated that not only the smaller particle size of as-gerenated CoNi but also the smaller binding energy at Ni 2*p* play a key for HMFA production with high yield, and strong interaction between Ni and Co metallic species induced these characters to be more effective. The higest HMFA yield was observed as 82% at a flow system, but stability of reactivity is still remained as next challenging subject of NiCo-catalyzed reductive amination of HMF to HMFA.

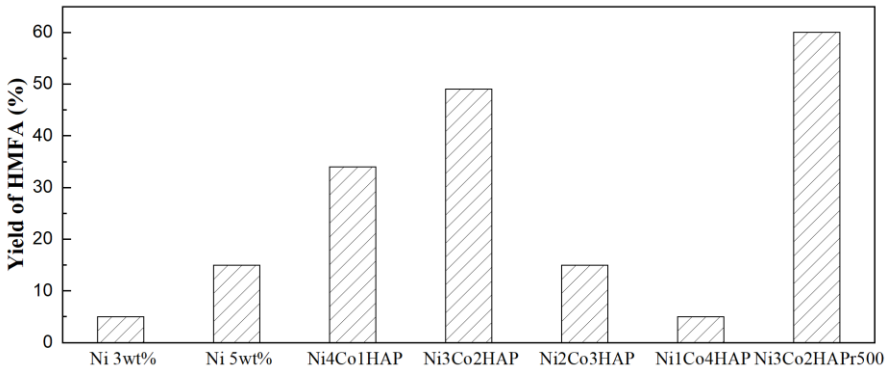

**Figure 1**. Yield of HMFA over HAP supported Ni-based catalysts. Reaction condition: HMF (2 mmol), 25% ammonia water (3 mL), ethanol (3 mL), catalyst (50 mg), 0.6 MPa $H_2$, 100 °C, 24 h.

# Enzymatic hydrolysis lignin dissolution and low-temperature solvolysis in ethylene glycol

Yushuai Sang, Yongdan Li*

*Department of Chemical and Metallurgical Engineering, School of Chemical Engineering, Aalto University, Espoo, Finland*

**Keywords:** Catalysis, Lignin, Ethylene glycol, Dissolution, solvolysis

**Introduction.** Lignocellulose, the natural composite of cellulose, hemicellulose and lignin, is the most abundant form of biomass [1]. Different from cellulose and hemicellulose, lignin is composed of aromatic units. Nowadays, cellulose and hemicellulose are fully utilized in pulping and the second-generation (2G) bioethanol industries. The 2G biofuel industry produces enzymatic hydrolysis lignin (EHL) as a low-value and large-volume byproduct [2]. As a renewable resource of aromatic molecules, EHL is an ideal feedstock for the sustainable production of commercial aromatic chemicals and fuels. Ethylene glycol is a green solvent that can be produced from the conversion of cellulose and has been widely used for the production of chemicals and fuels. In this work, EHL dissolution at room temperature and solvolysis at 200 °C in different solvents are examined, and the mechanisms of EHL dissolution and solvolysis in ethylene glycol are proposed

**Experimental/methodology.** EHL solvolysis was carried out in a 50 mL batch reactor. The Gaussian simulation was carried out with the Gaussian16 package using M062X simulation method in conjunction with the 6-31 g(d) basis set. The non-covalent interaction (NCI) analysis is carried out with software Multiwfn and VMD. The Forcite module in materials studio was used for molecular dynamics simulation.

**Results and discussion.** Ethylene glycol shows high EHL solubility and achieves complete EHL dissolution at room temperature, while methanol only dissolves part of EHL with high content of hydroxyls and β-O-4 linkages. The Gaussian simulation results indicate that ethylene glycol forms strong Van Der Waals interactions with EHL, including C-H···O and lone pair···π interactions, and these interactions break original π-π stacking in EHL, achieving complete EHL dissolution. The total monomer yields obtained from non-catalytic EHL solvolysis at 200 °C under 3 $H_2$ for 6 h show a positive correlation with EHL solubility, and ethylene glycol gives the highest total monomer yield, i.e., 5.5 wt%, among the solvents examined. With Ni and NaOH as co-catalysts, the total monomer yield in ethylene glycol reaches 18.8 wt% under the same reaction condition. EHL is partly depolymerized at 200 °C without a catalyst due to the strong interactions between EHL and ethylene glycol. NaOH as the homogeneous catalyst directly attracts C-O bonds in EHL and depolymerizes EHL into active monomers and intermediates. The adsorption of lignin fragments over Ni catalyst via C-O bond is hindered with ethylene glycol, and Ni catalyst mainly plays a role in supplying active hydrogen atom to stabilize the active intermediates, suppressing repolymerization side reactions.

# Co-pyrolysis of biomass and plastic to produce high-quality liquid

Zhihui Li[1*], Kishore Rajendran[2], De Chen

[1]*Norwegian University of Science and Technology (NTNU), Trondheim, Norway*
[*] *de.chen@ntnu.no*

**Keywords:** Co-pyrolysis, biooil, clay.

**Introduction.** Bio-oil is considered a potential alternative to traditional energy petroleum [1]. The most widely applied method to obtain bio-oil is pyrolyzing, however, bio-oil directly converted from biomass has drawbacks of low heating value, corrosion problems during storage and transfer and instability, because of the high oxygen content in the biomass. The oxidation content in biomass can reach 20-60 wt%, which comes from the main components of biomass, lignin and cellulose [2, 3]. Hydrodeoxygenation (HDO) process is one of the most widely used [4], whil upgrading bio-oil by HDO method has a high requirement of plant, and the catalysts for HDO are easily to be deactivated due to the coke formation. In this work, the addition of plastic into biomass in the feedstock can be considered as a hydrogen donor to achieve in-situ HDO process. At the same time, clay, a very cheap material was applied as an in-situ catalyst during pyrolysis. Aluminum pillared bentonite clay showed the potential of an alternative to commercial fluid catalytic cracking (FCC) catalyst, clay catalyzed bio-oil showed low oxygen content (6 wt%) and high liquid yield (60 %).

**Experimental/methodology.** Biomass was beech wood sawdust from Denmark, which contains 40wt% cellulose, 18wt% hemicellulose and 24wt% lignin. Plastic was low-density polyethylene from Sigma Adrich. Bentonite was from Sigma Aldrich and contains montmorillonite mostly. FCC catalyst was offered by Equinor, an oil company.

Experiments were carried out in a lab-scale plant, which is a semi-batch reactor in 10g scale. Gas products and liquid products were collected for further offline analysis. GC-MS and GC-FID from Agilent were applied for qualitative and quantitative analysis respectively. Additional characterization methods for catalyst, XRD, BET, SEM were applied.

**Results and discussion.** Aluminum pillared bentonite has a very significant improvement than raw bentonite both in surface area and acid sitee, which can benefit cracking and enhance synergic effects between biomass and plastic during pyrolysis.

Spent FCC catalyst was selected as a reference catalyst for it was found to have the very outstanding cracking ability. Aluminum pillared bentonite was found to be very competitive with FCC catalyst, both from oil quality(76.6 % and 69.9 %) and oil quantity (both lower than 10wt% of oxygen). The product oil content is mainly composed of hydrocarbon can aromatics which are also the main component of transport fuels. The comparison of biooil catalyzed by Al-pillared clay and spent FCC catalysts were shown in Table 1.

Further modification of aluminum pillared clay can be carried out to achieve even higher liquid oil yield and product distribution control.

Table 1. The comparison of liquid oil yield and components catalyzed by different catalysts.

**Keywords:** Ru/C catalysts; spherical carbon materials; levulinic acid; gamma-valerolactone.

**Introduction.**

Transformation of lignocellulosic biomass residues allows obtaining useful platform chemicals, such as levulinic acid (LA), which can be catalytically transformed into other products of interest like gamma-valerolactone (GVL) [1]. The present study is focused on the development and application of 1 wt. % Ru/C catalysts for the transformation of AL into GVL, using as catalysts supports carbon materials with different textural and chemical properties, and morphology (powder, granular and spherical). The influence of the support properties on the interaction with the metal phase has been analyzed. With the aim of designing a simpler and cheaper process, the effect of skipping the catalyst reduction treatment has been investigated.

**Experimental/methodology.**

The following carbon materials have been used as supports for the Ru/C catalysts: i) spherical carbons named IC-1 and IC-2, provided by Immutrix Therapeutics (USA), with a mean size of 0.1-0.2 mm and 0.5 mm, respectively, ii) an spherical carbon, named ACGE, from Gun-Ei Chemical Industry (Japan) (mean size 0.1-0.5 mm), and iii) commercial activated carbons named SA-30 (fine powder, <0.1 mm) and WV-1100 (granular, >1.0 mm) from Ingevity Corporation (USA). The spherical samples have been also used after milling in order to determine any influence of the support's morphology. Analogous catalysts have been prepared using $TiO_2$ supports, both commercial and prepared for this purpose.The supports and catalysts have been characterized by physical adsorption of gases ($N_2$ at -196 °C and $CO_2$ at 0 °C), programmed temperature desorption and reduction (TPD and TPR, respectively), X-ray photoelectron spectroscopy (XPS) and transmission electron microscopy coupled to EDX (TEM-EDX). The catalysts have been tested under the following reaction conditions: 0.445 mL LA, 0.130 g catalyst, 15 bar $H_2$, 1 h and 70 °C.

**Results and discussion.**

All the reduced Ru/C catalysts give very good GVL yield (60-70%). However, in the case of the unreduced catalysts, a very important effect of the carbon material properties on the catalytic activity has been found. Surprisingly, the catalysts prepared from the spherical supports are as active as the reduced counterparts. TPR and TEM-EDX results reveal that under the mild reaction conditions, the *in situ* metal reduction takes place, being the size of the resulting particles very strongly dependent on the content of surface oxygen groups on the carbon support [2]. Such surface oxygen content is lower in these spherical carbons than in the studied activated carbons. Data obtained using the milled spherical supports show that the morphology *per se* is not responsible for the good catalytic properties. Thus, efficient catalysts with high activity, reusability, and convenient handling can be prepared using appropriate carbon materials as supports.

Reduced Ru/$TiO_2$ (prepared with commercial $TiO_2$) catalysts lead to 77% GVL yield, being as competitive as Ru/C reduced ones, however the unreduced samples show a low activity similar to that of Ru/C prepared with activated carbons. This fact has encouraged the study, still in progress, of using non-reduced Ru/$TiO_2$ catalysts to better understand the role of the support surface chemistry in the metal support interaction and particle size.

# Syngas conversion to oxygenates over $Co_2C$ and Co-$Co_2C$ catalysts: CO insertion mechanism

Y. Yao*, J. Chang, Y. Zhang, N. C. Shiba, X. Liu*

*Institute for Development of Energy for African Sustainability (IDEAS), University of South Africa, Roodepoort 1710, South Africa*
**Corresponding Author's E-mail address: yaoy@unisa.ac.za or Liux@unisa.ac.za*

**Keywords:** Cobalt carbide, hydroformylation, Fischer-Tropsch synthesis, CO insertion mechanism, oxygenate

**Introduction.** Syngas conversion via Fischer-Tropsch synthesis (FTS) reaction system is a sustainable route for the conversion of liquid fuels and valuated chemicals and mitigation the dependency of fossil fuels [1]. Metallic cobalt (Co) is efficient for long chain hydrocarbon production, while $Co_2C$ plays a pivotal role for the production of lower oxygenates [2]. It was reported that synergistic effect between Co and Co2C promotes the formation of higher oxygenates [3].

It generally believes that the complex FTS reaction system may not be controlled by a single reaction mechanism. Among them, CO dissociation mechanism and CO insertion mechanism are the two distinct classes of mechanisms. Our research group has experimentally improved that both the CO insertion and dissociation mechanisms may exist, by controlling the operating conditions and the cobalt species [3-5].

In addition, the structure, the dispersion and the amount of the cobalt species on the catalyst surface can be adjusted by catalyst pretreatment processes, which enhances the catalyst activity and stability and product distribution [4]. Although syngas conversion has been widely discussed, there is lack of discussion to understand the correlation of each possible reaction mechanism under different active phases of catalysts and /or reaction conditions. Therefore, it is worthwhile for the investigation of the linkage between the reaction environment and the reaction pathways.

**Experimental/methodology.** Typical industrial supports ($SiO_2$, $TiO_2$ and $Al_2O_3$) and reduced graphene oxide (RGO) were used for the preparation of the cobalt based catalysts. The catalyst preparation methods have been reported in our previous published papers [1, 2]. Large groups of experimental runs were conducted in changes the catalyst activation atmosphere ($C_2H_4/H_2$, CO, syngas and $H_2$), operating conditions (reaction temperature varied from 120 °C to 260 °C), and the compositions of the feed mixtures ($H_2/CO$, $H_2/C_2H_4$ and $H_2/CO/C_2H_4$).

**Results and discussion.** Comparison of the experimental results (activity and selectivity) and the characterization results (active phases and nanoparticle morphology), the reaction pathways (such as, chain growth reaction, hydroformylation reaction and oligomerization, etc.) have been discussed. A successive pretreatment method may be an effective, easy and cheaper tool to tune the product spectrum towards the aim products without the expensive upgrading of the existing catalyst system. The catalysts pretreated with $C_2H_4/H_2$, syngas and CO may control the formation of Co and $Co_2C$. Co2C promotes the formation of oxygenates via CO insertion mechanism. Co promotes the formation of long chain hydrocarbons via CO dissociation mechanism. The multiphase of Co-$Co_2C$ demonstrated the production of higher oxygenates. This research attracts attention to the field of biomass/municipal wastes/coal/natural gas to value-added products including synthetic fuels, light olefins and oxygenates etc.

**Keywords:** Dehydrogenation, dehydration, isopropanol, $SrTiO_3$, DFT, mechanism.

**Introduction.**

Alcohols are one of the most relevant biomass precursors, which may be used as platform molecules for sustainable production of several value-added chemicals and biofuels, as well. One of the potential routes to achieve this goal is the dehydrogenation and dehydration of alcohols over acid-base catalysts. In this study, the dehydrogenation and dehydration of isopropanol on the SrO and $TiO_2$ terminated surfaces, of the $SrTiO_3$ perovskite, is addressed by periodic DFT calculations in order to shed light on the involved mechanisms. This study reports the reaction pathways, including identification of the transition states and intermediates, and evaluation of the respective energy barriers, as well. Thus, this study provides significant insights about the mechanisms of dehydrogenation and dehydration of isopropanol on the $SrTiO_3$, not reported earlier in literature.

**Methodology.**

All calculations were carried out with Quantum Espresso v.7.0 software using the PBE functional as DFT method. A kinetic energy cutoff for wave functions was set at 50 Ry. A 3x3x1 Monkhorst−Pack scheme was considered for the supercell. Grimme-D3 corrections were used to account a good description of dispersion interactions. The systems for this study were built from the replication of the unitary cell of the cubic $SrTiO_3$ perovskite (spatial group 221 Pm-3 m, cell constant a = 3.905 Å) in a dimension of 4X3X1, involving a surface area of about 15.7x11.8 $Å^2$. SrO and $TiO_2$ terminated surfaces are composed by three slabs. To prevent interactions between periodic slabs, a 16 Å vacuum in the z direction and the dipole moment correction was employed. The isolate isopropanol previously optimized, was positioned at about 3 Å over the surface in different positions. Then, all atomic positions were relaxed during optimization including surfaces and adsorbate atoms. The convergence criteria for both energies and forces are $1.0x10^{-6}$ Ry and $1.0x10^{-3}$ Ry/a.u. The adsorption energies were calculated using the following equation:

$$E_{ads}=E_{(surface+adsorbate)}-E_{surface}-E_{adsorbate}$$

All energy barriers and transition states were obtained with the CI-NEB method, considering a convergence criterion of 0.05 eV/Å for the forces and using the Broyden optimization scheme.

**Results and discussion.**

The results show that the dehydrogenation occurs through a mechanism involving the dissociative adsorption of the alcohol on the SrO terminated surface, followed the nucleophilic attack of a hydride species on the previously adsorbed hydrogen atom to form molecular hydrogen and the corresponding carbonyl compound, with an energy barrier of 2.32 eV. The dehydration instead occurs by the molecular adsorption of the alcohol on the $TiO_2$ terminated surface, followed by various possible E1 elimination pathways leading to the formation of the corresponding alkene and a water molecule, with an energy barrier of 1.43 eV. The calculated energy barriers are in good agreement with experimental values[1].

# Investigation of metal molybdate catalysts for the hydrodeoxygenation of anisole

S. Löbner[1], S. Haida[1], C. Kubis[1], A. Brückner[1], A. Abdel-Mageed[1,*]

[1]*Leibniz-Institute for Catalysis, Rostock, Germany*
[*]*Ali.Abdelmageed@catalysis.de*

**Introduction.** Crude oil and its follow-up products are currently used as feedstock for a large portion of industrial, carbon-containing products contributing greatly to greenhouse gas emissions, carbon dioxide in particular [1]. Therefore, it is desirable to replace these oil-based resources with renewable ones. One option is the use of biomass extracts e. g. from pulp industry. Cellulose, hemicellulose, and lignin are polymers forming the cell wall of plants. In paper production cellulose is separated from the other components and the lignin is mostly treated as waste and burned. Depolymerization of lignin can be achieved with flash pyrolysis [2]. This produces a so-called bio-oil, a complex mixture containing highly oxygenated products, such as phenolics. The compounds are limited in their further use which make hydrodeoxygenation (HDO) of the bio-oil a necessary step in its valorization to useful chemicals. Compared to noble metals, Mo-based catalysts are cheaper alternative and described as efficient catalysts for HDO but without aromatic ring hydrogenation [3]. In this study metal molybdates were used for the HDO of anisole in the gas phase.

**Experimental/methodology.** The catalysts were prepared from stoichiometric mixing of ammonium heptamolybdate and metal nitrates in water followed by drying at 60°C and calcination at 450°C for 6 h. HDO was performed in a fixed bed reactor. The catalysts were used diluted with quartz. Anisole was introduced into the gas stream (a mixture of hydrogen and nitrogen) with a saturator. Before the reaction the catalysts were reduced in-situ for 2 h in pure hydrogen at 325°C. The reaction products were analyzed on-line with an Agilent 7890A gas chromatograph equipped with a Quadrex 007-624 column. All catalysts were characterized before and after the reaction using X-ray diffraction and other methods.

**Results and discussion.** In this work we studied $CuMoO_4$, $NiMoO_4$ and $CoMoO_4$. As a reference point we also investigated pure $MoO_3$. $NiMoO_4$ and $CoMoO_4$ catalysts reach almost full conversion at the start of the reaction and conversion decreases with time-on-stream (TOS). $MoO_3$ and $CoMoO_4$ start out with a low conversion which increases with TOS and decreases after reaching a maximum after 6 rsp. 8 h TOS. During the reaction the main products formed were benzene and phenol. However, $CuMoO_4$ and $NiMoO_4$ have a higher selectivity towards the deoxygenated products compared to $MoO_3$ and $CoMoO_4$. Interestingly, $CuMoO_4$ showed an increased selectivity towards toluene whereas $NiMoO_4$ shows an increased methane selectivity. For all catalysts selectivity towards deoxygenates decreases with higher TOS, whereas oxygenate selectivity increases. These findings will be discussed considering structural characterizations obtained from surface and bulk sensitive methods.

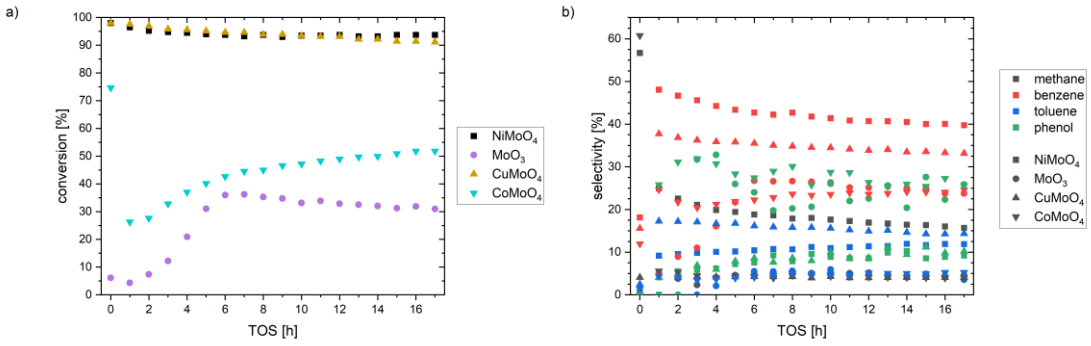

**Figure 1: Changes in a) conversion and b) selectivity with time-on-stream (TOS) for metal molybdate catalysts. Conditions: 325°C; WHSV=0.31 $g_{Anisole} \cdot g_{MxMoO3+x}^{-1} \cdot h^{-1}$; GHSV=1650 $mL_{gas} \cdot mL_{cat}^{-1} \cdot h^{-1}$; atmospheric pressure**

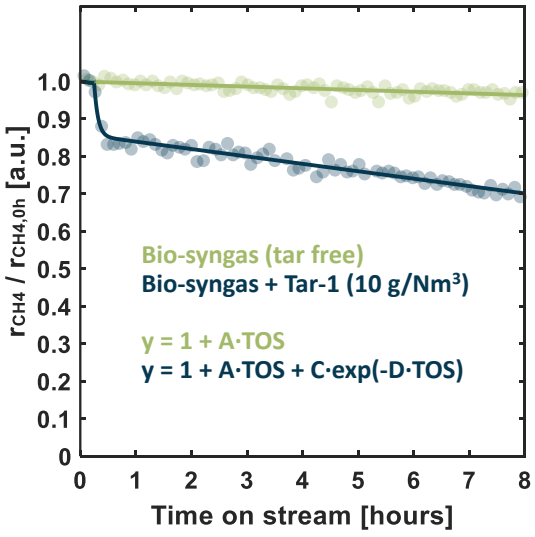
# Steam Reforming of Bio-Syngas Hydrocarbon Impurities with Ni-Co/Mg(Al)O Catalysts – Operating Parameter Effects

A. Lysne[1], I. Saxrud[1], K. Ø. Madsen[1], E. A. Blekkan[1*]



[1]*Department of Chemical Engineering, NTNU, Trondheim, Norway*
[*]*edd.a.blekkan@ntnu.no*

**Keywords:** Bio-syngas conditioning, tar steam reforming, Ni-Co catalysts

**Introduction.** Biomass gasification can provide low $CO_2$ emission bio-syngas for application in renewable chemical and fuel production. The gasification product typically contains hydrocarbon impurities, including condensable aromatic hydrocarbons (tars), causing downstream condensation and coking issues [1]. Such impurities can be removed by catalytic steam reforming, avoiding cost-intensive high temperature cracking and absorption strategies. Recent reviews call upon further development of bi-metallic Ni-Co systems for such applications, targeting high-stability, low-coking reforming catalysts [2].

**Experimental/methodology.** The Ni-Co/Mg(Al)O catalyst series was synthesized *via* calcination of hydrotalcite-like precursors, following the protocol reported by He *et al.* [3]. Fresh samples were characterized by XRD, XRF, ICP-MS, TPR, $N_2$-physisorption and $H_2$-chemisorption. Activity and deactivation experiments were performed in a model bio-syngas ($CH_4/H_2/CO/CO_2$ ratio = 10/35/25/25, molar) with and without model tar addition. The performance of a 20-20 wt% Ni-Co/Mg(Al)O catalyst was tested (8 hours on stream) at different operating temperatures (650-800 °C), steam-to-carbon ratios (S/C, 2-5, molar hydrocarbon basis), tar loading (10-30 g/Nm$^3$, toluene, dry syngas basis) and model tar compositions (Tar-1 = 100/0/0, Tar-2 = 75/25/0, Tar-3 = 70/25/5 wt% toluene/1-methylenaphthalene/phenol). Coke formation and sintering effects were evaluated by characterization of spent catalyst samples with TGA-TPO, Raman spectroscopy and STEM/EDS.

**Results and discussion.** The fresh catalyst characterization results and effects of Ni-Co ratio have been reported elsewhere [4]. Complete model tar removal at the expense of catalyst deactivation by coke formation was found at all tested conditions. The added tar carbon was well accounted for as $CH_4/CO/CO_2$ in the effluent flow. The activity and deactivation were evaluated in terms of the $CH_4$ reaction rate. The samples were compared considering the initial rapid activity loss and further linear deactivation function terms (see figure). The results show optimum temperature and S/C ratio conditions, minimizing overall coke formation and sintering effects. Simultaneous adjustment of the bio-syngas $H_2/CO/CO_2$ composition by WGS reaction equilibration (preparing for downstream Fischer-Tropsch applications) was demonstrated throughout the range of tested temperature and S/C ratio conditions.

**Typical activity curves in tar free and model tar bio-syngas environment [4]**

# Catalytic Hydrodeoxygenation of Lignin Oil for Biofuel Production

Hongfei Ma*, Wei Zhang, De Chen

Department of Chemical Engineering, Norwegian University of Science and Technology, Trondheim, (Norway)
*Presenting author, hongfei.ma@ntnu.no

**Introduction.** Hydrodeoxygenation (HDO) has been widely used for upgrading the bio-oil [1,2]. Oxygen can be removed under $H_2$ pressured hydrothermal conditions in the form of $H_2O$. With removing of oxygen, hydrocarbons such as aromatic and aliphatic hydrocarbon compounds are produced. These hydrocarbons are the main components of liquid fuels, such as gasoline, jet fuel, and diesel. Therefore, HDO is recognized as one of the most promising routes to produce hydrocarbon fuels from lignin-derived bio-oils.

Although HDO of the lignin-derived phenolic compounds has been studied quite a lot, and among which, very active and selective catalysts were developed and reported. It is still imperative to continuously devote to the study of HDO reaction over different phenolic compounds with very high activity and deoxygenation performance. Besides, more fundamental knowledge is highly desired to have a better understanding of the reaction pathway, including the kinetic behavior of the intermediates.
**Experimental/methodology.** The phosphide compound MoFeP was prepared via a two-step reduction method [3]. The ruthenium (Ru) promoted catalyst was prepared by impregnating $RuCl_3$ on the above obtained MoFeP/$Al_2O_3$ catalyst with the corresponding amount (1 wt% Ru). Then the samples were calcinated at 500 °C for 2 h with a ramping rate of 1 °C/min. Then the obtained samples were reduced in $H_2$ at 400 °C for 3 h with the ramping rate of 5 °C/min. The finally obtained sample was denoted as Ru-MoFeP/$Al_2O_3$.
**Results and discussion.** Figure 1 represents the product distribution for the catalytic HDO of guaiacol over Ru-MoFeP/Al2O3 catalyst at 250 °C and 5 MPa $H_2$. It shows a very high activity in converting guaiacol, with cyclohexane produced as the main product, and other products are benzene, methylcyclohexane, and toluene, without any oxygen left on the products. It behaves with very good hydrodeoxygenation ability on the Ru-MoFeP/$Al_2O_3$ catalyst toward conversion of guaiacol. The conversion can be reached as high as 90% at the first-hour reaction. With the reaction undergoing, almost full conversion can be obtained after two hours of reaction. Still with cyclohexane and benzene as the main products. Compared with the first hour, the selectivity of cyclohexane increases a little bit, since the other hydrocarbons with unsaturated C=C bonds can be further hydrogenated. However, with the reaction going on, there are almost no changes in the selectivity of methylcyclohexane and toluene, and benzene slightly decreases a little bit. The Ru-MoFeP/$Al_2O_3$ catalyst shows a quite good HDO ability over guaiacol, all the oxygen can be removed, with only hydrocarbons produced.

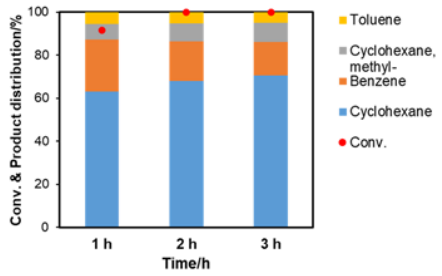

Figure 1. Results of the catalytic HDO of guaiacol. Reaction condition: 1 mL guaiacol, 50 mL Dodecane, $H_2$ 5 MPa (at 250 °C), 0.5 g Ru-MoFeP/$Al_2O_3$.

# Synthesis of nickel-hierarchical zeolite nanosheet composites derived from layered double hydroxides for furfural hydrogenation

Narasiri Maineawklang, Saros Salakhum, Peerapol Pornsetmetakul, Anittha Prasertsab, Supakorn Tantisriyanurak, Chadatip Roadum, Chularat Wattanakit*

*Department of Chemical and Biomolecular Engineering, School of Energy Science and Engineering, Vidyasirimedhi Institute of Science and Technology, Rayong 21210, Thailand*
**Corresponding Author's Chularat.w@vistec.ac.th*

**Keywords:** Hierarchical zeolite, Layered double hydroxides (LDHs), Composites, Furfural hydrogenation

**Introduction.** Furfural hydrogenation of biomass-derived compounds to high-value added chemicals plays an essential role in the development of sustainable resources. Nowadays, it is still challenging to design catalysts with highly dispersed metal nanoparticles (NPs) on solid support providing a high catalytic activity. Therefore, the fabrication of the hierarchical zeolite ZSM-5 nanosheets@NiAl-LDHs is presented by the growth of LDHs precursor on the hierarchical zeolite surfaces. As-synthesized material shows the high dispersion of Ni metallic nanoparticles as catalytic active sites, which can be applied in furfural hydrogenation.

**Experimental/methodology.** A hierarchical zeolite nanosheet (ZSM-5 NS) was prepared via a static hydrothermal method. The ZSM-5 NS@NiAl-LDHs composite was synthesized via the precipitation method at room temperature by the deposition of LDHs on the external surface of ZSM-5 NS. The composites were denoted as ZSM-5 NS@NiAl-LDHs(x) where x represents the amount of NiO (%wt). The catalytic performance of the furfural hydrogenation was investigated using a pressurized batch reactor with 0.25 MPa of $H_2$ at 100 $^oC$ for 90 min. All catalysts were reduced under 50%$H_2$/$N_2$ flow at 650 $^oC$ for 3 h before reaction testing. The reaction result was analyzed using gas chromatography (GC) equipped with a Porabond Q column.

**Results and discussion.** The XRD patterns of ZSM-5 NS@NiAl-LDHs(49) composites demonstrate the combined characteristic patterns of MFI zeolite and LDHs structures. The morphologies of the prepared ZSM5-NS@NiAl-LDHs(49) composites were investigated by STEM and EDS elemental mapping. These materials exhibit the homogeneous dispersion of nickel/nickel oxide nanoparticles on a zeolite support, confirming the uniform growth of LDHs on the ZSM-5 NS surfaces. The benefit of high metal dispersion on the zeolite surface of the ZSM-5 NS@NiAl-LDHs(49) demonstrates the high catalytic performance of furfural conversion and yield of furfuryl alcohol. For the comparison, the ones prepared by the traditional wet impregnation method and the physical mixture show only a small corresponding conversion and yield.

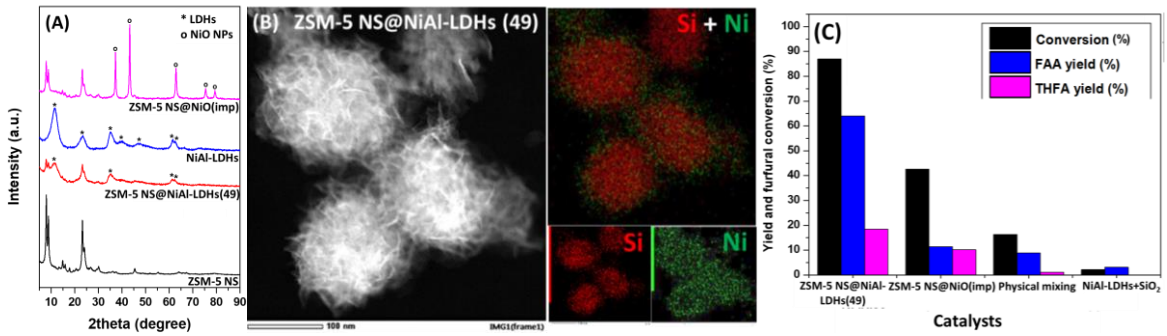

**Figure 1. (A) XRD patterns, (B) STEM and EDS mapping of ZSM-5 NS@NiAl-LDHs(49), and (C) Catalytic performance in furfural hydrogenation over Ni-based catalysts with different oxide supports**

# Gas phase hydroconversion of furfural catalyzed by nanostructured Pt/carbon/metal oxide xerogels

J.R. Rensch, S. Morales-Torres, L. M. Pastrana-Martínez, F.J. Maldonado-Hódar

*NanoTech – Nanomaterials and Sustainable Chemicals Technologies, Department of Inorganic Chemistry, Faculty of Science, University of Granada, Avda. Fuente Nueva, s/n, ES18071 Granada, Spain*
**Corresponding Author's E-mail address (fjmaldon@ugr.es)*

**Introduction.** Furfural (FUR) obtained from biomasss is considered as one of the most important platform molecule for the synthesis of high added-value derivatives such as furfuryl alcohol (FOL), tetrahydrofurfuryl alcohol (THFOL), 2-methylfuran, tetrahydrofuran, furan (FU), pentane, etc, which are widely used in the production of plastics, medicines, fertilizers and fuels [1]. The objective of this work is the development of sustainable FUR hydroconversion processes. Active, selective and stable catalysts working in continuous phase and mild conditions were prepared, avoiding toxicity of clasical chromite catalysts, the deactivation by coke deposition and the drastic experimental conditions ($P_{H2}$, T) typically used in liquid phase.

**Experimental/methodology.** A pure resorcinol (R)-formaldehyde (F), RF organic gels structured in microspheres were obtained in stirred reactors by inverse emulsion and always used as primary support. These microspheres were thereafter coated with $SiO_2$, $Al_2O_3$, $TiO_2$ and $CeO_2$ using the corresponding alkoxides, as precursors. The synthesis procedure was optimized for the complete gelation and curing, the solid recovered by filtering and exchanged with acetone before drying in an oven at 100 °C and finally, carbonized at 850 °C in innert atmosphere. Pt-catalysts (1% wt) were obtained by incipient impregnation of the carbon-MOx composites, dried and activated under He at 400 °C for 2h before characterization (gas adsorption, XRD, XPS and HRTEM/EDX) or reaction. The hydroconversion reactions of FUR were carried out in the gas phase using continuous fixed bed reactors under mild reaction conditions (atmospheric pressure and temperature below 200 °C). The concentrations of reactant and products were determined by GC.

**Results and discussion.** The heat treament provokes simultaneously the carbonization of the organic phase and the formation of the corresponding metal oxides. $TiO_2$ is present as anatase (JCPDS 21-1272), $Al_2O_3$ as $\delta$-$Al_2O_3$ (JCPDS 13-0373) and $CeO_2$ shows the cubic fluorite structure (JCPDS 4-593). Only silica remains amorphous, together the carbon support. The coating of the carbon spheres with the metal oxide layer leads to a decrease of the overall microporosity of the supports, and consequently, the BET surface area values. The mesoporosity however is preserved or even, enhanced in the case of carbon-$Al_2O_3$ composite.

The formation of Pt-nanocrystals by XRD was detected only when supported on the pure carbon xerogel and carbon-$SiO_2$ composites. However, a very good dispersion of Pt-nanoparticles was detected in all cases by HRTEM (Figure 1). Hydrogenation and decarbonylation processes were observed, the catalytic performance being strongly influenced by the support characteristics.

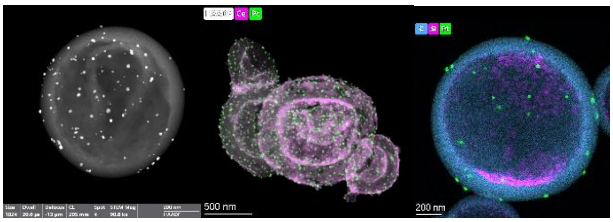

**Figure 1.** HRTEM images of Pt-particles on the "XC" carbon xerogel (la), XC/$CeO_2$-composite (b) and XC/$SiO_2$-composite (c).

In all cases, the MOx coatings increased the activity of the Pt-nanoparticles. At 160 °C the conversion values increased in the order XC-Pt < XC/$SiO_2$-Pt < XC/$TiO_2$-Pt < XC/$Al_2O_3$-Pt < XC/$CeO_2$-Pt. FUR is transformed into FU by decarbonylation, while FOL and THFOL were obtained by hydrogenation. At low temperature (120-130 °C) FUR hydrogenation is the main process (80% selectivity) but with increasing reaction temperature decarbonylation is favoured, reaching at around 200 °C selectivities around 70%. The most active catalysts also favour hydrogenation versus decarbonylation. No deactivation detected after several hours on stream.

[3]*IIQ, Instituto de Investigaciones Químicas (CSIC-US), Dpto. de Química Inorgánica, 41092 Seville, Spain*

**Introduction.** Magnetic induction heating is an emerging subject in the field of catalysis that represents a promising alternative to conventional heating.[1] It is based on the use of hysteresis losses produced in ferromagnetic materials by the presence of an alternating magnetic field. Indeed, the possibility to perform catalytic processes in solution by transforming electromagnetic energy into heat is of great advantage, since it is possible to carry out reactions which normally requires high temperatures and pressures under milder conditions.[2] In this context, the aqueous transformation of biomass-derived oxygenated compounds via magnetically induced catalysis is an attractive way to obtain fine-chemicals and fuels.[3]

**Experimental/methodology.** Non-coated and carbon-coated core-shell **FeCo@Ni** magnetic nanoparticles were used as heating agent and catalyst simultaneously (**Figure 1a**). The FeCo core (heating source) produces heat in close proximity to the Ni shell (catalytically active metal). In addition, the encapsulation of **FeCo@Ni** in carbon (**FeCo@Ni@C**) strongly improved the stability of this magnetic catalyst in solution, making possible its reuse.

**Results and discussion.** In this work, we observed for the first time a magnetic-field-controlled selectivity of hydrogenation and HDO in the reduction of biomass-derived molecules. At low field amplitudes the main product was the hydrogenation product, while at higher field the major product was the HDO product (**Figure 1b**). However, **FeCo@Ni** showed a low activity in water, mostly due to their poor stability in aqueous medium. The encapsulation in carbon circumvented this limitation and led to a stable catalyst suitable for magnetically-induced catalysis in water. In fact, **FeCo@Ni@C** efficiently hydrogenated a series of biomass-derived oxygenated compounds in aqueous medium, showing an excellent stability.

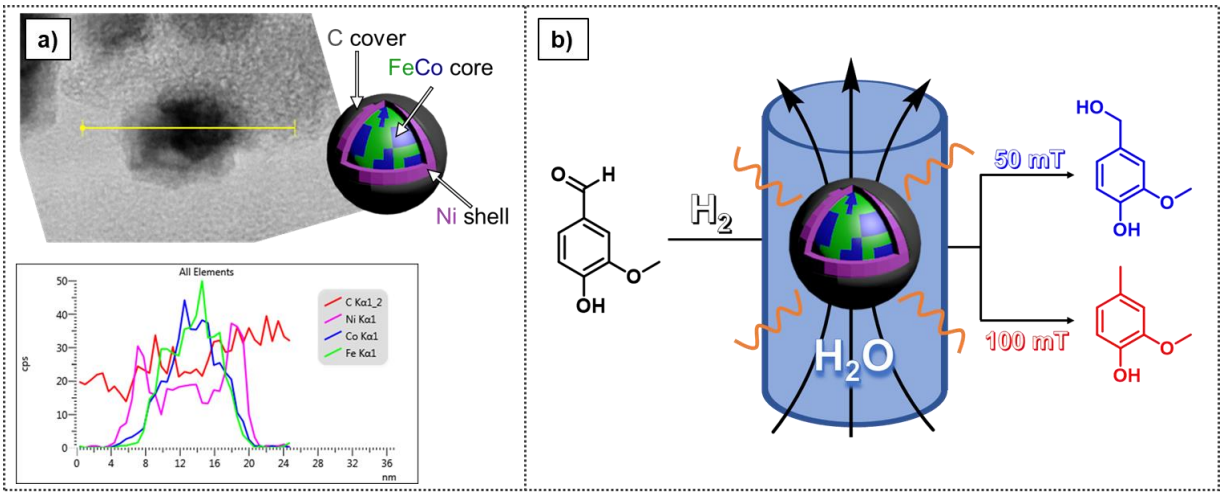

**Figure 1.** (a) STEM-BF image and EDX line scan profile of **FeCo@Ni@C**. (b) Magnetic-field-controlled selectivity of hydrogenation and HDO in the reduction of vanillin.

**Keywords:** biomass, 1,5-pentanediol, heterogeneous catalysis, dihydropyran

**Introduction.** α,ω- diols are commodity chemicals with several applications in producing acrylates, polyurethanes, plasticizers, etc. Nowadays, they are manufactured by petroleum based routes which involve several separations and high costs[1]. Obtaining these α,ω- diols from biomass constitutes an alternative attractive greener route[2]. Among the paths to produce 1,5-pentanediol (1,5-PDO) from furfural (FUR), one of the most relevant is the multistep route:1) hydrogenation of furfural to tetrahydrofurfuryl alcohol (THFA); 2) dehydration of THFA to dihydropyran (DHP); 3) hydration of DHP to 2-hydroxy-tetrahydropyran (2-HY-THP); and 4) hydrogenation of 2-HY-THP to 1,5-PDO[3].
In this study, the last two steps are integrated into one-pot reaction. However, this combination entails side reactions, such as the hydrogenation of the double bond in DHP to give tetrahydropyran (THP). To overcome this drawback, the evolution of the THP and 1,5-PDO yields with bimetallic catalysts have been assessed.
**Experimental/methodology.** A series of bimetallic catalysts of $RuSn_x/C$ have been synthesized by incipient wetness impregnation of Ru/C. The dried and reduced catalysts have been tested in a batch reactor at 125ºC.
**Results and discussion.** Differences have been spotted when comparing the catalytic activity of the reduced and dried catalysts in the synthesis of 1,5-PDO from DHP. All the catalyst achieved 100% conversion of DHP. Yet, the reduced catalysts gave higher yields towards the side product THP. Furthermore, as the Sn content in the catalyst increased, the hydrogenation ability decreased. On the other hand, the Ru/C dried catalyst gave higher yields towards the side product, THP, just as the reduced catalysts. However, when the amount of Sn increased, the yield towards 1,5-PDO followed the same trend, achieving an 81% yield of 1,5-PDO and only an 11% yield of THP with RuSn/C (figure 1). The catalysts have been characterized by XRD, TPR, XPS and $N_2$ adsorption isothermal to explain their catalytic activity.

Both the $N_2$ adsorption isotherms and the XRD do not suggest significant differences in the catalysts of the series. The XRD does not show any crystalline phase indicating that the metals are highly dispersed in the support. However, in the TPR experiments, the maximum reduction peak shifts towards higher temperatures with the Sn content. This shows that there is an interaction between the two metals, which can also be verified by XPS, since there is a shift in the binding energy. In conclussion, Sn decreases the Ru reduction ability throughout the whole $RuSn_x/C$ catalysts series. This affects mainly to the production of THP, whereas the 1,5-PDO yields keep increasing at lower Sn content. When the amount of Sn is suffitienly high, the lower reduction ability of Ru is shown in both reactions, giving lower yields of THP and 1,5-PDO.

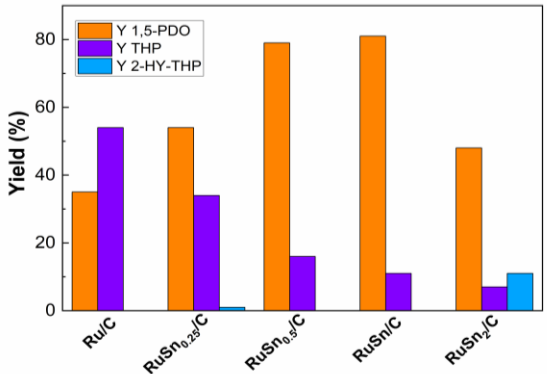

**Figure 1:** DHP conversion into 1,5-PDO on $RuSn_x/C$

**Keywords:** hydrodeoxygenation, bifunctional, renewable, jet-fuel, binder

**Introduction.** The transition towards greener energy sources due to harmful emissions and respective regulations has promoted development of sustainable fuels obtained from renewable souces [1]. An attractive renewable source for fuels as well as basic, fine chemicals and various materials is lignocellulosic biomass. While lignin is considered as a waste product in certain industries, its depolymerization products can be converted through hydrodeoxygenation into hydrocarbons suitable for use as jet-fuel in existing infrastructure and technologies [2]. This is of great importance as the alternative for hydrocarbon-based jet fuel is to apply batteries, which currently is not viewed as feasible because of their excessive weight. Jet fuel consists of $C_8$-$C_{16}$ hydrocarbons. In this work hydrodeoxygenation of isoeugenol, a model compound for lignin depolymerization products, was carried out in a batch reactor using bifunctional catalysts containing platinum, zeolite beta, and a binder, reflecting components of industrial catalysts, to understand their effect on the reaction.

**Experimental/methodology.**

A series of catalysts comprising platinum, zeolite beta and an inorganic binder were tested in the hydrodeoxygenation of isoeugenol, the main product propylcyclohexane, which is within the hydrocarbon range utilized in jet fuel. Platinum was deposited using the evaporation-impregnation method, however, the metal location was varied to change the metal-acid site proximity. Beta zeolites with two different Si:Al ratios, namely Beta-25 and Beta-300, were employed to determine the effect of acid strength. As a binder Bindzil, a type of colloidal silica, was applied. Thus, three types of catalysts for both zeolites were prepared denoted as PtB25Z*X* or PtB300Z*X*, depending on the zeolite, while *X* corresponds to the platinum location: **A** – platinum on both zeolite and Bindzil, **B** – platinum only on zeolite, **C** – platinum only on Bindzil.

Catalysts were characterized by SEM, TEM, pyridine FTIR, $N_2$ physisorption and ICP-AES.

Hydrodeoxygenation (HDO) reactions were carried out at 200 ºC and 30 bar of $H_2$ in a stainless-steel batch reactor using dodecane as solvent. The samples were taken periodically and analyzed by gas chromatography coupled with mass spectrometry.

**Results and discussion.**

A comparison of the catalytic results for both series of catalysts is presented in Table 1.

**Table 1. Catalytic activity of PtB300ZX and PtB25ZX catalysts in hydrodeoxygenation of isoeugenol, performed in a batch reactor at 200 ºC and 30 bar of $H_2$.**

| Catalyst | Dihydroeugenol conversion (%) | TOF ($s^{-1}$) | Liquid-phase mass balance (%) | Propylcyclohexane yield (%) | Propylcyclohexane selectivity (%) |
|---|---|---|---|---|---|
| PtB25Z**A** | 78 | 0.08 | 68 | 56 | 76 |
| PtB25Z**B** | 82 | 0.13 | 62 | 53 | 75 |
| PtB25Z**C** | 53 | 0.09 | 66 | 21 | 66 |
| PtB300Z**A** | 61 | 0.12 | 78 | 45 | 77 |
| PtB300Z**B** | 46 | 0.06 | 85 | 37 | 90 |
| PtB300Z**C** | 25 | 0.06 | 83 | 6 | 88 |

Catalysts where Pt was located closer to the acid sites (types A and B) displayed higher dihydroeugenol conversion and propylcyclohexane yield, while deposition of platinum on the binder (type C) gave the lowest activity. Additionally, catalysts containing Beta-25 displayed higher activity than the catalysts containing H-Beta-300.

**Keywords:** Biodiesel, ABPs, biofuel, Superbiodiesel.

**Introduction.**

The valorization of animal by-products (ABPs) as is the case of animal fats from tanning industry has become of interest since the regulations limit its use in the food chain. The main objective is to demonstrate at pilot plant scale the production of biofuels from animal fat residues. These biofuels will be achieved by transesterification with methanol using supercritical conditions with the use of catalyst, incorporating glycerol derivatives as biodiesel component thus producing technical, environmental, and economic advantages on regard the traditional process.

**Experimental/methodology.**

Animal fats will be separated from proteins and processed continuously with methanol in a CSTR reactor at supercritical conditions (400ºC, 200ºC) using pelletized catalyst. After reaction methanol is separated from the biodiesel as shown in the figure. The throughput of the pilot plant is around 20 kg biodiesel/day.

**Results and discussion.**

The supercritical method takes advantage of the homogeneous phase, which improves phase solubility, increasing the reaction rate of the triglycerides and esterification of free fatty acids (FFA). Consequently, this method can process practically any kind of raw materials, such animal fats and waste vegetable oil, which are difficult to process through conventional transesterification reaction. Glycerol is incorporated into the homogeneous liquid product increasing the final yield and decreasing 80% of the carbon footprint of conventional diesel and 35% of that of first-generation biodiesel.

**Keywords:** *nickel-cobalt*, *magnetic nanoparticles*, *magnetic catalysis*, *lignin valorisation*

**Introduction.** Global climate change and fossil feedstock shortage have drawn considerable attention to lignocellulosic biomass. Particularly, lignin can be depolymerized into the so-called bio-oils; smaller aromatics needing oxygen removal to be profitable.[1] Thus, a catalytic system for one-pot lignin hydrogenolysis and hydrodeoxygenation is an imperative challenge. Excitingly, our latest works on magnetic catalysis on metal nanoparticles (NPs), where a catalyst combines heating and catalytic functions, accomplished reactions at reduced bulk temperatures and $H_2$ pressures.[2,3] Then, NiCo-NPs with various Ni:Co ratios were prepared, achieving the right balance between heating and catalytic properties, and tested in the magnetically induced hydroprocessing of lignin bio-oil and lignin models in mild conditions.

**Experimental/methodology.** The $Ni_xCo_y$ NPs were prepared decomposing Ni[*i*PrNC($CH_3$)NiPr]$_2$ and Co[N($SiMe_3$)$_2$](THF) complexes in the presence of palmitic acid in mesitylene at 3 $H_2$ bar and 120 °C. Physicochemical properties were studied by ICP, TGA, XRD, WAXS, HR-TEM and XAFS, while magnetic by VSM and SAR. Catalytic tests were carried out in liquid phase with 1.0 mmol substrate, 0.7 mmol dodecane (IS), 3 $H_2$ bar, and 5 mL solvent in a 100 mL glass batch reactor at the center of a 300 kHz coil.

**Results and discussion.** Interestingly, HR-TEM indicates primary particles being polycrystalline, surrounded by smaller particles. EDX and XAS studies show larger Ni particles, and smaller Co particles around them.

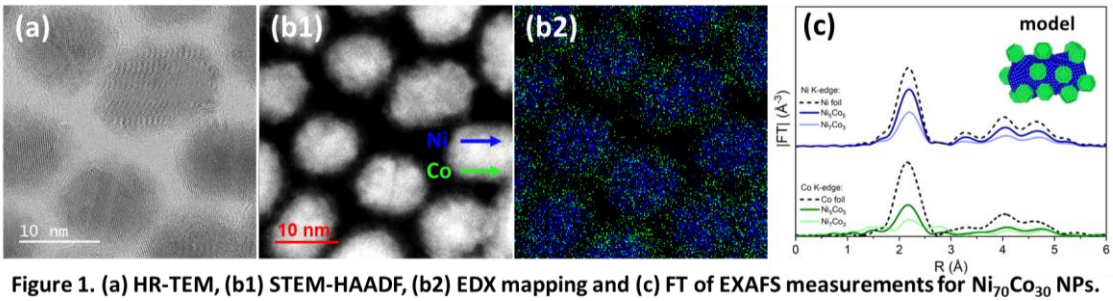

**Figure 1. (a) HR-TEM, (b1) STEM-HAADF, (b2) EDX mapping and (c) FT of EXAFS measurements for $Ni_{70}Co_{30}$ NPs.**

After catalyst optimization, anisole, guaiacol, and eugenol probed lignin oil upgrading. Additionally, diphenyl ether (DPE), 4-phenoxyphenol (DPE-ol) and monobenzone evaluated C–O cleavage in lignin 4-O-5, α-O-4 and β-O-4 linkages. High conversions and cyclohexanol yields were obtained. Kinetics and application to a realistic lignin model will be disclosed in the conference.

**Table 1. Magnetic catalytic performance of $Ni_{70}CO_{30}$ NPs for the hydrogenation of five typical model compounds.**

| Substrate | Reaction time (h) | Solvent | Conversion | Main products (yield, mol% on carbon basis) |
|---|---|---|---|---|
| *Anisole* | 8 | Decane | *100* | *Cyclohexane (70)* |
| *Eugenol* | 48 | Decane | *100* | *Propylcyclohexanol (83)* |

# Preparation and Stability of Catalysts for Hydrodeoxygenation of Black Liquor HTL-oil

Luděk Meca[1*], Alexey Kurlov[2], Pavel Kukula[1], David Baudouin[2]

[1]*Ranido s.r.o., Praha, Czech Republic*

**Keywords:** catalyst stability, hydroprocessing, hydrodeoxygenation, black liquor, supercritical water

**Introduction.** Working on decarbonization of transportation fuels is important for strengthening energy security and sustainable growth. The Black Liquor to Fuel project (BL2F) contributes to that by searching a path from residual biomass – black liquor – to the production of greener fuels. One of the project aims is to develop "Integrated Hydrothermal Liquefaction" process (HTL) converting the black liquor into an intermediate "HTL-oil". Subsequent step to develop – hydrodeoxygenation (HDO) – will allow conversion into a desired fuel intermediate. Herein, we present a study of catalyst stability under a planned operational conditions - supercritical water (SCW) conditions in continuous flow system.

**Experimental/methodology.** The HDO catalysts compositions containing nickel and molybdenum oxides were impregnated on various supports (Table 1). The supports have been previously tested under SCW conditions [1]. These oxidic catalysts were first sulfided in a batch reactor and their stability under SCW conditions was studied in a continuous flow reactor at 400 °C and 300 bar with a 10 g.min$^{-1}$ flow of $H_2O$ or 1000 ppm dimethyl disulfide (DMDS) in $H_2O$. The elemental composition of fresh and tested catalysts was determined by SEM-EDX analysis.

**Table 1. Properties of the prepared catalysts in oxidic form**

| Material | Support used for impregnation | BET surface ($m^2$/g) | XRF composition | | | | | |
|---|---|---|---|---|---|---|---|---|
| | | | $Al_2O_3$ (%) | $TiO_2$ (%) | $ZrO_2 + HfO_2$ (%) | $P_2O_5$ (%) | NiO (%) | $MoO_3$ (%) |
| BLF-01 | $\alpha$-$Al_2O_3$ | 3.5 | 71 | 0 | 0 | 2.0 | 3.8 | 23 |
| BLF-02 | rutile ($TiO_2$) | 6.4 | 0 | 63 | 0 | 2.7 | 5.9 | 28 |
| BLF-03 | monoclinic $ZrO_2$ | 26 | 0.1 | 0 | 66 | 2.4 | 5.3 | 26 |
| BLF-07 | activated carbon | 759 | 0 | 0 | 0 | 1.4 | 4.1 | 19 |
| BLF-07a | activated carbon | 908 | 0 | 0 | 0 | 0.6 | 1.3 | 6.3 |

**Results and discussion.** The catalysts in oxidic form have been characterized using XRF, XRD, BET and TEM. The stability of sulfided catalysts was evaluated in a continuous SCW flow and the remaining Mo and Ni content was determined after 2 h on stream. XRD analysis of the tested catalysts showed that in pure SCW flow, Mo is oxidized to $MoO_2$ and no traces of NiS were observed. The SEM-EDX analysis revealed that more than half of the Mo and Ni was leached out. An additional test of sulfided BLF-07a in a continuous SCW flow containing 1000 ppm DMDS resulted mainly in $MoS_2$ phase with only traces of $MoO_2$. That indicated inhibition of $MoS_2$ oxidation in the presence of sulfur-rich feed. However, the SEM-EDX analysis showed that, similarly to the sulfur-free test, more than 50 % of Mo and Ni was lost during the test. Comparisons of XRD before and after SCW treatment will be presented. Obtained results indicated that NiMo based catalysts were not suitable for applications under SCW conditions.

**Keywords:** Ansiole, Biomass to fuels, Continuous flow reactor, Hydrodeoxygenation

**Introduction.** Fast hydropyrolysis (FHP) of biomass is a promising renewable alternative to produce liquid fuels for the transportation industry [1]. However, FHP bio-oil contains a high percentage of oxygenated compounds; thus, chemical upgrading is necessary. An initial stabilization step is performed to stabilize organic acids and other short-chain highly reactive oxygenates present in the bio-oil [2]. Nonetheless, after this initial stage, the bio-oil still has a high oxygen content. Therefore a hydrodeoxygenation (HDO) step, a second upgrading, is carried out. For this step, hydrogen and the bio-oil are pressurized to favor the adsorption of the oxygenates and hydrogen over traditional hydrotreating catalysts to cleave the C-O bond and produce $H_2O$ and hydrocarbons as the desired product [3]. The required high pressure during HDO is the root cause of the main challenges of this process (i.e., high hydrogen consumption in unwanted side reactions, undesired DECOx reactions, and catalyst deactivation). For this reason, catalysts that are capable of selectively deoxygenating phenolic-derivated compounds to aromatics at relatively lower pressures are of great interest. Palladium on titania is reported to exhibit high activity for HDO and selectivity to aromatics [4]. The present work focus on the pressure-dependent reaction pathways in the bifunctional catalyst. The role of both metallic and acid sites and the metal–support interface in pressure-dependent hydrogenation/dehydrogenation reactions and dehydroxylation reactions will be addressed.

**Experimental/methodology.** The Pd/$TiO_2$ catalyst was prepared by means of incipient wetness impregnation, and the loading of Palladium was 2% of the total weight of the material. The $TiO_2$ support was calcined at 400°C for three hours before impregnation. Catalytic testing was performed in a tubular fixed-bed reactor (15 mm inner diameter) at 350°C with a pressure range from 1 to 20 bar. Before the experiment, the catalyst was pretreated under reaction conditions at 400°C. Product analysis was performed by means of GC-MS, for identification, and GC-FID, for quantification of the compounds.

**Results and discussion.** The product distribution of the different experiments was studied in relevance to the reaction mechanism to understand which was the prevalent main reaction pathway in each scenario. At lower pressures, DECOx reactions gain more dominance over the process, reducing the carbon efficiency (less carbon yield in the liquid product in favor of higher yield of CO and $CO_2$ in the gas phase). Moreover, some oxygenated saturated species, which are intermediates of side reactions (demethylation + hydrogenation), are not able to be fully deoxygenated, hence retaining the oxygen in the liquid product. On the other hand, at higher pressures, the HDO remains the prevalent reaction pathway. However, excessive hydrogenation to saturated species occurs, and the coke formation increases significantly, both reducing the carbon efficiency and poisoning the catalyst. The pressure is optimized based on a detailed understanding of the pressure-dependent reaction network as a function of the catalyst properties.

**Keywords:** cobalt aluminate, 1,4-butanediol, dehydrogenation

**Introduction.**

Lactones and their derivatives are widespread in nature and very used in industry as extraction agents, solvents, intermediates in pharmaceuticals, petroleum industry and agriculture. γ -Butyrolactone (GBL) is extensively used as solvent and for herbicides, N-methyl-2-pyrrolidone, 2-pyrrolidone, N-vinyl-2-pyrrolidone, polyvinylpyrrolidone production[1]. It can be synthesized by 1,4-butanediol lactonization over cobalt aluminate catalysts[2]. In this study we prepared a series of $CoAl_2O_4$ samples by the sol-gel method, in the presence of water, ethanol, methanol and butanol as solvents, following to establish the relationships between the catalyst properties and the catalytic performances in the lactonization of 1,4-butanediol coupled with acetophenone and benzaldehyde hydrogenation.

**Experimental/methodology.**

For the catalysts synthesis, sol-gel method has been used using as precursors aluminum isopropoxide $Al[OCH(CH_3)_2]_3$ and cobalt nitrate hexahydrate $Co(NO_3)_2{\cdot}6H_2O$. Water, ethanol, methanol and 1-butanol were used as solvents, while $HNO_3$ (1M) as hydrolysis rate controller. The obtained gel was dried at 100 $^oC$ and calcined at 500 $^oC$. The microstructure and optical properties were characterized by XRD, SEM, BET, FTIR and UV-VIS techniques.

**Results and discussion.**

The catalysts prepared in the presence of methanol and butanol as solvents have $CoAl_2O_4$ as the predominant phase, while for the samples prepared in the presence of water and ethanol the predominant phase is $Co_3O_4$. Ethanol was the effective solvent in sol-gel method, it's using leads to synthesis of the sample with the lower lattice strain, the highest surface $Co^{3+}/Co^{2+}$ ratio and with the highest Co/Al ratio (Table 1). Otherwise, a good correlation of the lactone yield with these parameters was observed for all the studied samples.

**Table 1.** Structural parameters and specific surface properties of CoAl samples

| Sample | D (nm) | BET surface area ($m^2/g$) | Microstrain (ε) $10^{-3}$ | $Co^{3+}/Co^{2+}$ | Co/Al |
|---|---|---|---|---|---|
| $CoAl_W$ | 9.8 | 126 | 1.70 | 0.49 | 1.85 |
| $CoAl_E$ | 9.9 | 94 | 1.62 | 0.65 | 1.86 |
| $CoAl_M$ | 7.9 | 114 | 1.98 | 0.50 | 1.68 |
| $CoAl_B$ | 6.6 | 108 | 2.39 | 0.14 | 1.14 |

**Keywords:** Hydrodeoxygenation (HDO), Zeolite Beta (ZB), Lanthana Promoter, Bimetallic, Ball Milling.

**Introduction.** Biofuels are promising fossil fuel alternative with a sustainable circular carbon economy [1]. Among the deoxygenation reaction pathways, hydrodeoxygenation (HDO) offers the best prospects for upgrading bio-oil to biofuel without generating pollutants like CO and $CO_2$ [2]. This study aims to design catalytic systems by investigating the promoter's and mechanochemical treatment's effects on the production of biodiesel through palm oil hydrodeoxygenation reaction.

**Experimental/methodology.** Catalyst design involved the following approaches: 1) Using a metal oxide promoter to counteract the acidity of the zeolite beta (ZB) support, 2) Synthesizing a bimetallic system (NiCu) to improve metal reducibility and limit coke formation, and 3) Tuning two interfaces using mechanochemical treatment. First, the support is ball milled to decrease the particle size and increase the exterior surface area (***interf-1***). Second, the promoter and support simultaneously ball milled with expected improvement in dispersion and better metal anchoring due to produced defects in the promoter (***interf-2***). *Catalyst synthesis:* Wet impregnation was used to prepare the monometallic (Ni/La-ZB) and bimetallic (NiCu/La-ZB) catalysts. The ZB support used is commercial, from ZEOLYST INTERNATIONAL ($SiO_2/Al_2O_3$=25). *Post-synthesis treatment:* Interface tuning was achieved using planetary ball milling with water as solvent.

**Results and discussion.** Various characterization techniques were utilized to study the catalysts' structural and textural properties, surface species, reducibility, and acid/base properties. After investigating the support structure, (XRD) showed that ZB remained crystalline following wet impregnation and post-mechanochemical treatment. An increase in ZB crystal size was seen with the milled *interf-1* catalyst. It increased from 12.08 nm (pristine ZB) to 13.13 nm, attesting to the recrystallization as expected. Additionally, results showed excellent promoter dispersion on the support for all studied catalysts which were apparent in the (XRD) profiles and (HAADF-STEM) images. Moreover, after mechanochemical treatment of *interf-1*, the metal dispersion was further improved and resulted in smaller particles as evidenced by the average crystal size calculated from (XRD) analysis and (HAADF-STEM) images. On the contrary, for *interf-2*, the particles were rather agglomerated. Calculated Ni crystal sizes were 14.49 and 15.36 nm for *interf-1* and *interf-2* (XRD), respectively, and the average metal particle sizes were 33.4 and 44.6 nm (HRTEM), respectively. ($H_2$-TPR) profiles showed that the addition of Cu greatly influenced the reducibility of NiO, evident in the peaks shifting to lower temperatures. Furthermore, the mechanochemical treatment results showed further peaks shift to lower temperatures attributed to the enhanced metal dispersion and electronic interaction. Incorporating the La promoter increased the basic sites of all the catalysts, as deduced from the ($CO_2$-TPD) studies performed. (XPS) results showed that the surface Si/Al ratio increased with the addition of the promoter to the monometallic catalyst, indicating changes in the zeolite framework that led to a less acidic surface. (XPS) results also revealed that Cu prefers residing on the surface in all bimetallic catalysts. The next steps of this work involve the continuation of advanced catalyst characterization ($NH_3$/CO-DRIFTS and Synchrotron XAFS) alongside catalytic evaluation to study the catalyst pathway selectivity and product yield.

**Keywords:** biogas, self-reforming, reforming, sulfur

**Introduction.**

Biogas is an attractive feedstock with financial and environmental benefits as a partial replacement of fossil fuels [1]. An interesting alternative is the conversion of methane by the two simultaneous oxidants naturally present in biogas, $CO_2$ and $H_2O$ implying a decrease in carbon emissions. If an additional content of steam is introduced by obtaining a $CH_4/H_2O/CO_2$ ratio close to 3/2/1 then, a $H_2/CO$ ratio 2/1 is obtained, which is suitable for most of industrial applications such as methanol production and Fischer Tropchs reaction [2]. However, the main involved is the common presence of sulfur that hinders the raw biogas employment requiring a cleaning treatment and thus increasing the costs of the obtained syngas. A different and cost-effective approach is using a sulfur tolerant catalyst.

**Experimental/methodology.**

A multi-metallic sample of NiCe with Sn and Rh and supported over high surface alumina was tested in presence of dimethyl sulfide (DMS) at 700 ºC and GHSV: 3200 $h^{-1}$ as it was it was reported elsewhere [3].

**Results and discussion.**

A long-term run was carried out in presence of two different sulphur contents, Figure 1. The change of poison concentration allowed us to determine if a previously used sample was capable of tolerating this higher concentration. Methane conversion was slightly higher than the corresponding of $CO_2$ in agreement with the carbon deposition observed and the higher $H_2/CO$ ratio than theoretical expected, 2/1. Additionally, the coke formation and the sulphur content did not conduct a clear deactivation of the tested solid for the firsts 35 hours of run. However, after the switch to a higher poison content, the activity started to decline, taking as much as 25 hours to achieve almost 15% in methane or carbon dioxide conversions. This slow deactivation process might be due to some active sites were firstly passivated by coke deposition after getting contact with more sulphur, preventing a quicker deactivation by previously noticed [3], whilst the closer values of both conversions found imply that another path for $CO_2$ conversion was simultaneously taken place during the reforming study, probably the reverse Water Gas Shift and the coke gasification by carbon dioxide (reverse of Boudouard reaction) contributing to the noticed decrease of $H_2/CO$ ratio and the increase in carbon balance respectively. The trend found suggests that sulphur deactivation may depend on the previous state of the sample in agreement with some alternatives reported in literature for extending the lifespan of the catalyst like passivation. However, this approach may modify the catalyst performance (activity and selectivity) as it was found in a previous work with the multi-metallic catalyst ex-situ poisoned with DMS [3].

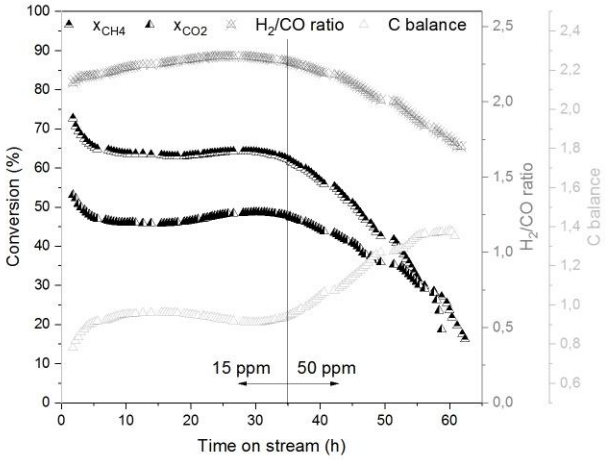

Figure 1. Results of activity test with two different subsequent sulphur contents, 15 ppm followed by 50 ppm.

# Reductive catalytic fractionation of agricultural residues: the case study of Ecuadorian biomass as an attractive source of phenolic monomers

Diego Montesdeoca[1,2*], Damien P. Debecker[1]

[1]*Université catholique de Louvain, Louvain-la-Neuve, Belgium*

[*]*d.montesdeoca@uclouvain.be*

**Introduction.**

Current world politics, seeking to reduce the generation of pollutants and solid waste, together with a society less dependant on fossil resources, is driving the search for alternative and sustainable feedstocks for the supply of energy, chemicals and materials.

Lignocellulosic biomass is emerging as a promising alternative to fossil carbon, with streams being especially important in the case of agricultural residues (over 3.3 billion tons per year are generated worldwide[1]), since substantial parts of the crops become waste as straws, husks, cobs, bagasse, and others. This abundant, available and cheap resource could be exploited to produce valuable compounds with potential use as fuels or platform molecules through biorefinery schemes.

Ecuador has an impressive variety of crops and plantations, generating large amounts of biomass which are hardly exploited, so the relevance of treating them whit a lignin-centered biorefinery approach is explored.

At present, reductive catalytic fractionation (RCF), a lignin-first biorefinery approach, is widely studied as a way to depolymerize lignocellulosic biomass into phenolic monomers, leaving the cellulosic fraction almost intact. While woody biomass as feedstock has been prioritized, only scarce information is available concerning less conventional (yet abundant) lignocellulosic biomass sources.

**Experimental/methodology.**

In this work, the adoption of RCF for the valorization of abundant Ecuadorian agricultural residues is investigated: sugarcane bagasse (SC), banana rachis (BR), rice husks (RH), cocoa pod (CP), guadua cane (GC), hemp stems (HS), and african palm rachis (AP). Typical RCF conditions were applied: 3 g of biomass and 0.3 g of a commercial catalyst (Ru/C, 5 wt%) in 120 mL of solvent (methanol), at 200°C under 30 bar of $H_2$ (loaded at ambient temperature) for 3 hours. The main process streams (feedstock, lignin oil, and residual pulp) were characterized in depth to gain insights into cellulose and hemicellulose retention in the residual pulp, and especially the fractionation level of lignin into its monomers in the lignin oil.

**Results and discussion.**

Reductive catalytic fractionation of Ecuadorian biomass derived in residual pulps having delignification degrees in the order of 50% with hemicellulose removals close to 25% and C6 polysaccharides recoveries of about 90%. Also, lignin oils were obtained, whose characterizations revealed the presence of a wide array of lignin monomers, comprising units of propyl-, propanol-, and ethyl-substituted guaiacol/syringol (usual when used woody feedstocks), along with units of methyl-hydrocoumarate/hydroferulate (mirroring the herbaceous nature of the explored biomasses). Also, the unsaturated forms of these monomers were identified. Overall, the phenolic monomer yields followed the order: 26.9% (SC), 15.8% (GC), 15.0% (AP), 13.5% (HS), 9.2% (RH), 6.9% (BR), 1.6% (CP), with more than 67% selectivity for saturated monomers. Notably, hemp stems presented interesting results, since monomers with propanol side chain were obtained with a selectivity ~50% compared to 10-25% shown by the other biomasses. By using another commercial catalyst, Pd/C (5 wt%), used to preserve the OH content of the lignin monomers[2], the selectivity increased to 85% with a total yield of 27%.

On the other hand, agricultural residues showed high contents of ash (4-20%) and extractives (6-36%), when woody feedstocks have less than 1% for ash and below 5% for extractives[3]; we show that high ash contents correlates with low phenolic monomer yields.

**Keywords:** propylene glycol, selective oxidation, non-precious

**Introduction.**

An increasing demand for energy, chemical products, food production and the rise in anthropogenic $CO_2$ emissions worldwide is driving the investigation and development of catalytic processes which replace fossil resources, reduce energy consumption and environmental waste and eliminate the use of toxic and/or hazardous samples [1]. Biomass resources have become widely researched as sustainable and renewable raw materials for producing industrial and fine chemicals, which are in high demand. Upon catalytic transformation of biomass feedstocks (such as glycols, sugars and cellulose), propylene glycol is produced in medium to high yields [2-4]. Thus, due to the presence and functionality of two hydroxyl groups, it presents itself as a candidate starting material for various catalytic transformations, including selective oxidation. Propylene glycol oxidation products such as pyruvic acid, pyruvaldehyde, lactaldehyde and lactic acid have integral roles in the pharmaceutical and agrochemical industries.

Additionally, they have further essential roles in producing fine/speciality chemicals. The C3 acids and aldehydes are currently obtained from routes considered homogeneous (enzymatic), from compounds that are petrochemically derived (for example, propylene) or employ supported precious metal catalysts in batch systems. These routes are considered inefficient, costly and environmentally harmful, which motivates the need for a greener biomass-derived process. This study currently aims to prepare non-precious heterogeneous metal oxide catalysts to be tested in the selective oxidation of propylene glycol.

**Experimental/methodology.**

CuO and MnOx were supported on MgO, $CeO_2$ and $SiO_2$ by wet impregnation. The supports were chosen due to their surface properties, i.e. basic, redox and acidic sites. The catalysts were characterised using surface and bulk techniques such as $N_2$-physisorption, TGA-DSC, electron microscopy (SEM and TEM), PXRD, and temperature-programmed probing. Catalytic testing was conducted in a continuous flow–fixed bed reactor. The products obtained were analysed using gas and liquid chromatography.

**Results and discussion.**

$CO_2$-TPD revealed that the ceria-based catalysts mainly had strong basicity, whereas the MgO-based catalysts ranged in basicity (weak to strong). This difference in basicity is attributed to the presence of basic hydroxyl groups on the surface of MgO compared to $CeO_2$. These basic sites may play a role in forming acetol which can then be converted to one of the desired products. $H_2$-TPR was used to assess the extent of reducibility of the prepared catalysts. Reducibility is important as the supported metal oxide has to be reduced in the proposed reaction mechanism to form the desired product. From the results, the copper-based catalysts showed the highest ease of reducibility as they had low temperature (±150 °C) reduction peaks in comparison to the manganese-based catalysts that had multiple higher temperature (>250 °C) reduction peaks. The catalytic testing of the prepared catalysts resulted in various products being formed, including acetol, propanols and lower alcohols. The formation of acetol is promising as it is an intermediate in the production of pyruvaldehyde and pyruvic acid.

# The effect of synthesis method on supported Ni-W catalysts for the hydrogenolysis of erythritol

W. M. Mthiyane[1*], A. Govender[2], M. Shozi[3]

[1,3]*Walter Sisulu University, Mthatha, South Africa*

**Keywords:** synthesis, nickel, erythritol, hydrogenolysis

**Introduction.** The global community is tasked with coordinating and co-operating to find innovative solutions for clean energy from renewable energy sources. This urgency stems from the detrimental effects traditional ways of harnessing energy from fossil deposits, such as coal, have on the environment and climate. Sugar alcohols, such as erythritol, are profusely oxygenated compounds that present an excellent opportunity for tailored and selective deoxygenation to useful platform chemicals, such as butanediols, through the scission of C-C and C-O bond hydrogenolysis reactions.[1] Catalysts for hydrogenolysis reactions must have the ability to activate hydrogen, one of the key reactants, which is activated over a metal surface. Hydrogenolysis catalysts consisting of a base metal (Ni, Co, Cu *etc.*) promoted by or mixed with a noble metal (Pt, Pd, Rh, Ru, *etc.*) anchored on support materials (alumina, ceria, *etc.*) are critical for the hydrogenolysis of erythritol to useful chemicals.

**Experimental/methodology.** NiO-$WO_x$/$Al_2O_3$ catalysts were synthesized *via* wet impregnation, co-precipitation, and sol-gel methods.[2] Catalysts were calcined and characterized by ICP-OES, PXRD, $N_2$ physisorption, TPR, SEM and HRTEM, and XPS. The catalysts, reduced only at optimum temperature for NiO → Ni, were tested in a high-pressure autoclave for the hydrogenolysis of erythritol.

**Results and discussion.** The Ni/$Al_2O_3$ system facilitates the scission of C-C bonds of sugar alcohol substrates, which is unwanted for our application. The introduction of W not only suppresses the undesired C-C bond breakage through the action of W-oxo species but does this by increasing the active metallic Ni dispersion which gives the Ni-W system potential for selective hydrogenolysis of erythritol to desired products.[3]

**Keywords:** α,β-unsaturated aldehyde, formic acid, copper, rhenium, heterogeneous catalysis.

**Introduction.** Formic acid (FA) is a renewable biomass material that can be used as a source of hydrogen. FA is a fairly stable molecule, liquid at room temperature, with low toxicity and non-flammable in concentrations below 85% vol. This makes FA decomposition a promising strategy for hydrogen storage abd use. The selectivity is crucial for the production of ultrapure $H_2$, since the contamination by carbon monoxide produced by the dehydration pathway may reduce the activity of the catalysts [1]. We have previously demonstrated the suitability of FA as hydrogen source for the hydrogenation of gas molecules, butadiene, in the same catalytic bed [2]. In this work we aim at studying the selective hydrogenation of unsaturated aldehydes to unsaturated alcohols using crotonaldehyde (CRO) as a model molecule. This is a challenging reaction since hydrogenation of C=C bonds is easier than C=O bonds thermodynamically and kinetically. With that objective, we have studied Cu and Re as active phase supported on carbon, since they are both active in the FA decomposition and hydrogenation reactions.

**Scheme 1. Reaction scheme.**

**Experimental/methodology.** The catalysts were prepared over a commercial high surface area graphite (G, Timcal, $S_{BET}$: 400 $m^2/g$) by incipient wetness impregnation using aqueous solutions of $NH_4ReO_4$ and $Cu(NO_3)_2 3H_2O$ to obtain the same molar loading in monometallic and bimetallic catalysts, eg. 10 wt.% Re for monometallic Re/G. Prior to the reaction, the catalysts were reduced *in situ* at 300 (Cu/G, CuRe/G) or 350°C (Re/G) for 1 h. The gas phase hydrogenation was done in a fixed-bed quartz reactor at atmospheric pressure and 140 °C or 180 °C using fresh catalyst a total flow of CRO 0.42 ml/min and 1.3 ml/min of FA.

**Results and discussion.** Fig. 1 shows the selectivity and conversion in the hydrogenation of CRO for the evaluated catalysts. At the tested temperatures, FA conversion (not shown) was between 30-90% and selectivity to $H_2$ 98-100%, i.e. the $H_2$/crotonaldehyde molar ratio was 1-2.8. The results show that it is possible to hydrogenate CRO using FA in the same catalytic bed. The most active catalyst on CRO hydrogenation is that based on Cu metal. However, it is the Re catalyst that achieves highly selective to the target product at both reaction temperatures, i.e. crotyl alcohol, reaching values above those reported by noble metals such as iridium [3]. The effect of temperature was analysed for Re and Cu. As expected, conversion increased with temperature, while the selectivity to propane and butanol increased at the expenses of crotyl alcohol. In contrast, athough Cu is also quite active, it favoured the formation of butanol and butanal. In this tandem catalytic system, selectivity followed a similar trend to that of Cu/G. Further tests are being performed to analyse the effect of using exogenous-$H_2$ vs FA.

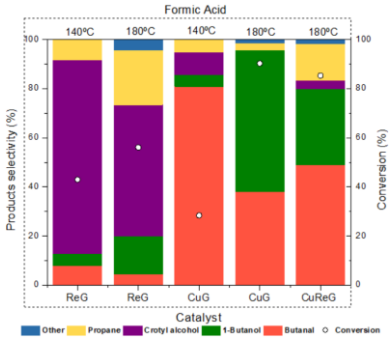

**Figure 1. Selectivity (bars) and conversion (circles) using (FA) .**

**Keywords:** nickel, supported catalysts, xylitol, hydrogenolysis, diols

---

## Introduction

Hydrogenolysis of xylitol produces value-added chemicals such as ethylene glycol (EG), 1,2-propanediol (1,2-PDO), and mono-alcohols such as methanol, ethanol, etc. EG and 1,2-PDO are used in many industrial processes as raw materials in heat-transfer fluid industries, as monomers in the manufacture of polyester resins, and in pharmaceutical, cosmetics, and packaging industries. Generally, the hydrogenolysis of xylitol requires the use of supported metal catalysts (i.e Pt, Ru, Ni, Cu) and the addition of a homogeneous base. Nickel catalysts have been shown to have high activity in the conversion of sorbitol to glycols under high hydrogen pressure and temperature [1, 2]. In this work, we report the performance of Ni and bimetallic Pt-Ni catalysts supported on mixed oxide supports.

## Experimental

Metal oxide supports were prepared by the co-precipitation method, using ammonium hydroxide as the base. Calculated quantities of precursor salt solutions were mixed at 60 $^{O}$C, pH 10 was maintained, and the temperature of the solution was 80 $^{O}$C. The supported catalysts were prepared by the wet impregnation method. Powder x-ray diffraction (XRD) was used to determine the phases in the material. $H_2$-Temperature programmed reduction (TPR) was used to understand catalyst reducibility. $CO_2$-Temperature programmed desorption (TPD) was used to quantify the basic sites of the support and catalysts. Xylitol hydrogenolysis reactions were carried out in a high-pressure stainless-steel autoclave.

## Results and discussion

$N_2$ physisorption data showed that all the prepared materials were mesoporous and have a high BET surface area. In all the prepared catalysts Ni was reducible at temperatures below 500 $^{O}$C, which meant that the risk of sintering was minimized. Incorporating the base in the alumina structure improved the catalytic activity and selectivity towards glycol at mild reaction conditions.

**Keywords:** Biomass Upgrading, Heterogeneous Catalysis, Hydrogenation

**Introduction.** Recently, our group demonstrated the direct valorization of hemicellulose into a tricyclic plastic precursor DMGX (Figure 1a), which upon polymerization yielded a new class of degradable, high-performance polyesters.[1] Conversion of DMGX into its corresponding diol, denoted XGDO, could yield a novel rigid structure with promising potential as a bisphenol-A replacement (Figure 1b). However, the selective hydrogenation of esters is challenging due to the low reactivity of the carbonyl group in esters. For this reason, stoichiometric agents such as $LiAlH_4$ are often used. Catalytic hydrogenation using $H_2$ is an attractive and cleaner alternative, however this generally requires harsh reaction conditions (in industry: 200-300 °C, 100-300 bar $H_2$), in which the DMGX molecule is not stable. Recent works have demonstrated catalytic systems with milder conditions for hydrogenation of several highly oxygenated, bio-based molecules, but generally utilize specific metal-acid site synergies,[2] which leads to decomposition of the acid-sensitive acetal in DMGX. In addition, another difficulty arises from the DMGX's inherent chemical structure, containing multiple C-O bonds that are prone to metal-catalyzed hydrogenolysis. Here we develop a selective catalytic system for heterogeneous hydrogenation of highly oxygenated, acid-sensitive substrates with low thermal stability, in a green solvent under mild conditions.

**Experimental/methodology.** DMGX (>99 %) was synthesized as previously reported.[1] Hydrogenations of 0.05-0.1 M solutions of DMGX (in various solvents) were performed in hastelloy Parr reactors (25-50 mL) with metal loadings of 2-8 mol %, 30-50 bar $H_2$ pressure, reaction temperatures of 150-190 °C, magnetic stirring and reaction times of 12-24 h. The reaction mixtures were analyzed by GC-FID (after silylation) with iso-propylphenol as external standard, and by NMR. Catalysts were prepared via a wet impregnation procedure or commercially obtained. Catalyst supports were self-prepared or obtained commercially.

**Results and discussion.** Initially, several noble metal catalysts on traditional carbon and oxide supports were screened. These supports led to very complex reaction mixtures with little or no XGDO formation (at high DMGX conversion), indicating the degradation of the cyclic acetal structure in the presence of Brønsted acid sites at elevated temperatures. In order to avoid these sites in the system, weakly-acidic/basic supports such as hydroxy apatite and Mg-spinel were used. Impregnated with ruthenium, these catalysts led to clean reaction mixtures with XGDO yields of up to 47 % (conversion: 98 %, mole balance: 58 %), together with half reduced intermediates, under relatively mild conditions (50 bar $H_2$ , 190 °C) in cyclopentylmethyl ether (CPME). NMR and GC of the crude reaction mixtures reveal no significant evidence of by-product formation, which when combined with the low mole balance, indicates adsorption of reaction species to the catalyst surface. This is being verified by simple adsorption studies, TGA and catalyst recycling/pre-saturation tests. Finally this system will be evaluated on a larger substrate scope. These results indicate that this system may enable clean hydrogenation of acid-sensitive, thermally unstable oxygenated esters under relatively mild conditions.

**Keywords** Chemocatalytic, integrated system, ethanol, propane-2-ol, nanowires, tungsten based catalysts

**Introduction**

The conversion of lignocellulosic biomass into high-value chemicals and fuels, which are currently research hotspots, is a promising technique for reducing energy depletion[1]. The nanowires (NWs) appeared to be very stable, influencing the growing industry and potentially lowering the cost of the process [2]. This work is primarily concerned with the elucidation of reaction mechanisms and the understanding of bond functionality in which the presence of Bronsted acid from tungsten-based catalysts and Bronsted base from hot compressed water (HCW) collectively participate in combination with NWs supported metal catalysts for the conversion of cellulose to $C_2$ and $C_3$ alcohols.

**Experimental/methodology**

Metal oxide nanowires (MNWs) were synthesised using a plasma-assisted method and metal nanoparticles (mP) were impregnated on the as-synthesised NWs. In a high pressure slurry batch reactor, reactions were carried out to obtain the optimal conditions for the desired products, namely $C_2$ and $C_3$ alcohols. After performing the series of reactions, the catalysts were characterised to reveal the catalysts-activity relationship. Various analytical techniques were used to quantify the liquid and gaseous products collected after the reactions.

**Results and discussion**

The as-synthesised MNWs have a tetragonal crystal phase, and the peak at 39.67° corresponds to mP in the PXRD plot shown in Fig. 1. (a). The wire like morphology of mP/MNWs catalysts can be seen in Fig. 1(b) using TEM and SEM at 100nm and 4µm, respectively. The activity performance shown in Fig 1(c) reveals the optimum condition for $C_2$ and $C_3$ alcohols. Maximum yields of 32.33% and 51.52% of ethanol and propane-2-ol at optimum condition of R2 and R4, were obtained.

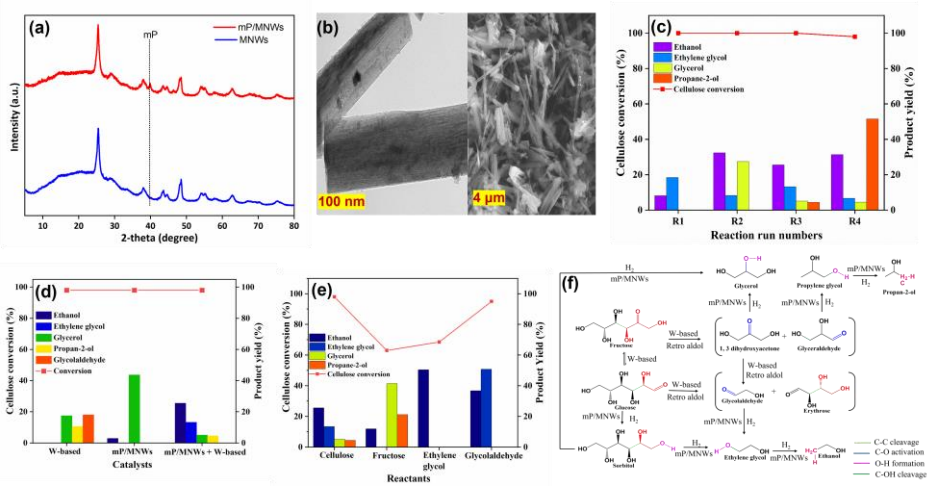

**Fig 1. (a) PXRD pattern and (b) morpholoy of pristine catalysts, catalytic activity under various (a) reaction conditions, (d) catalysts (e) reactant (f) bond functionality based on activation and cleavage of bonds**

To investigate bond functionality, the reactions were carried out with various catalysts (Fig. 1(d)) and reactants (Fig. 1(e)). These findings suggest that metal sites provide the hydrogenolysis/hydrogenation reaction by forming O-H and cleaving C-OH to form alcoholic products, and tungsten-based catalysts aid in C-C cleavage, allowing the retro aldol reaction to occur, as illustrated in Fig. 1(f).

**Keywords:** Autothermal reforming, Methanol, Lower alcohols, Copper-based bimetallic catalyst.

**Introduction.** Autothermal reforming (ATR) of methanol is one of the key reactions for on-site hydrogen supply to fuel cells due to its high H/C ratio, low reaction temperature (< 200 °C), and fast start-up operation[1]. Recently, biomass-derived methanol (bio-methanol) has been attracting attention as an alternative to fossil fuel methanol for the realization of a $CO_2$ recycling system. Generally, bio-methanol contains lower alcohols (0-2%) as impurities[2], which are separated from methanol by energy-intensive purification. In previous work, traces of lower alcohols reduced the catalytic activity and durability of Cu/ZnO/$Al_2O_3$ (CZA) by depositing carbonaceous species[3]. The inability of the Cu-based catalyst to cleave the C-C bond in lower alcohols was responsible for the inhibitory effect of lower alcohols. In this study, in order to reduce the inhibitory effect of lower alcohols, a series of metal-doped CZA catalysts were prepared and tested for the ATR of methanol with lower alcohols as a model bio-methanol. The effect of metal doping on the catalytic performance was investigated.

**Experimental/methodology.** CZA was prepared by co-precipitation methods (Cu loading 40 wt%). Metal-doped CZA catalysts (M-CZA: M loading 1 wt%) were prepared by impregnation methods by using CZA as the support. Catalytic tests were carried out in a fixed-bed flow reactor at atmospheric pressure. X-ray absorption spectroscopy (XAS) was performed using the BL01B1 beamline at the SPring-8 (Hyogo, Japan).

**Results and discussion.** Fig. 1 shows the methanol conversion in ATR of methanol with 1 mol% ethanol at 140 °C. The methanol conversion and hydrogen production rate decreased monotonically with the reaction time for CZA, while they were stable even in the presence of ethanol for Ru-CZA and Rh-CZA. CZA converted ethanol into various C1, C2 and C3 compounds, including methane, acetaldehyde and methyl acetate. On the other hand, the amount of C2 and C3 compounds was significantly reduced, and methane and CO were formed on Ru-CZA and Rh-CZA. Based on the temperature programmed oxidation (TPO) profiles, the carbonaceous species derived from lower alcohols were deposited on CZA, while they were not deposited on Ru-CZA and Rh-CZA. In addition, CZA with ZnO/$Al_2O_3$(ZA) supported Ru or Rh catalyst (physical mixture) exhibited lower methanol conversion and methane yield than Ru-CZA and Rh-CZA. Structural analysis by XAFS indicated that Cu-Rh and Cu-Ru alloy or Ru oxide were formed. These results suggest that Ru and Rh adjacent to Cu can act as active sites for the decomposition of ethanol and acetaldehyde, resulting in the suppression of carbonaceous species deposition on the Cu surface.

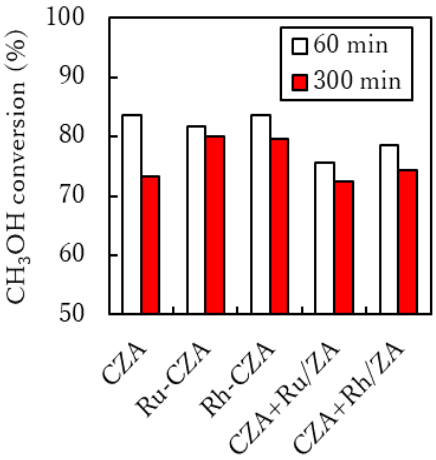

**Fig. 1 Time course of methanol conversion with ethanol in ATR at 140 °C. Conditions: Catalyst 100(single), 200(physical mixture) mg, $CH_3OH$:$H_2O$:$C_2H_5OH$:$O_2$:$N_2$ =30:36:0.3:10:30 ml $min^{-1}$.**

**Keywords:** guaiacol, phenol, hydrodeoxygenation, Ni/alumina

**Introduction.** Lignocellulosic biomass is a promising feedstock for the production of renewable chemicals and fuels. Lignin is polymeric component of lignocellulose, comprising of methoxylated phenylpropane monomers. In thermochemical and/or chemical processes, lignin can be converted into liquid products (bio-oils) with a high oxygen content, which mainly consist of aromatic compounds. The oxygen content of bio-oxygenates can be significantly reduced by catalytic hydrodeoxygenation (HDO) reaction [1]. Guaiacol (GUA), a representative component of bio-oil, is commonly used as a model compound in the HDO processes. Products obtained form GUA like cyclohexane (CHN), cyclohexanol (CHL), phenol (PHE), catechol (CAT), benzene (BEN), and toluene (TOL) can be used as fuel, solvent or precursors of nylons, chemicals, polymers, drugs, herbicides, cosmetics, and plastics [2]. The main objective of the present study is the understand the HDO reaction of GUA and PHE model compounds into value-added products. The effect of surface modification and the reaction conditions such as space time, temperature, and pressure as well as time-on-stream on the catalyst activity and selectivity was studied.

**Experimental/methodology.** Ni catalysts were prepared by wet impregnation using γ-alumina ($Al_2O_3$, Alfa Aesar) and phosphorous-modified γ-alumina ($Al_2O_3$(P)) supports. Modification was done with $H_3PO_4$ solution. The Ni content was 5 and 20 wt%. The catalysts were characterized by XRD, $H_2$-TPR and FT-IR spectra of adsorbed pyridine and phenol. Catalytic experiments were carried out using a flow-through, tubular, fixed-bed microreactor at 10 bar total pressure in the 200-300 °C temperature range, whereas the space time was varied between 0.1 and 1.0 $g_{cat}\ g_{GUA/PHE}^{-1}$ h.

**Results and discussion.** Demethylation and transalkylation are the main reactions of GUA over Lewis acid $Al_2O_3$ and $Al_2O_3$(P) supports giving CAT derivatives as main products. On 5Ni/$Al_2O_3$ and 20Ni/$Al_2O_3$ catalysts, O-free compounds like cycloalkanes and BEN derivatives were mainly formed at 300 °C and 10 bar. At higher temperatures, the thermodynamic equilibrium shifts toward dehydrogenation reaction resulting in mainly BEN derivatives. At lower temperature (225 °C) and/or space time CHL derivatives were also formed in larger quantities. However, $Al_2O_3$(P) supported Ni catalysts were stable and selective in the formation of PHE derivatives. They catalyze demethylation and demethoxylation but do not initiate ring saturation. In order to clarify the different catalytic behavior, the adsorption complexes formed from PHE chemisorption was investigated by FT-IR spectroscopy. Results show that adsorbed phenolates species are formed on the neat γ-$Al_2O_3$ support, which is neccessery for further deoxygenation. However, a weak interaction was observed on the $Al_2O_3$(P) support. Phosphatization was shown to result in partial elimination of Lewis type acid-base pair sites and thereby lowering the surface concentration of phenol intermediates on these sites, which in turn hindered the hydrogenation of the aromatic ring. It was concluded that by using non-noble metal, supported on pure γ-alumina and phosphatized γ-alumina, and adjusting the reaction conditions, the GUA hydroconversion could be directed towards selective formation of required target compound.

# Exploring the dehydrogenation behavior of biomass-derived organo-oxygen molecules over MOF and alumina supported platinum catalysts

I. Prieto, J. Gancedo, D. Ursueguía, S. Ordóñez*

[1]*Department of Chemical and Environmental Engineering, University of Oviedo, Oviedo, Spain*

**Keywords:** hydrogen chemical storage, bioplatform molecules upgrading, MOF-supported catalyst, LOHCs

**Introduction.**

Hydrogen transport and storage is still a bottleneck in the decarbonization of the industrial processes. Chemical storage in unsaturated liquid organics (LOHCs) is a promising alternative for doing these steps in a more safe and economical way. However, these technologies present important challenges to be solved, as the required high selectivities in the hydrogenation and dehydrogenation steps, or the selection of LOHCs of sustainable origin, since most of the LOHCs nowadays proposed are petrochemical derivatives.

In order to propose new LOHCs formulations of renewable origin, the dehydrogenation of the fully hydrogenated forms of biomass-derived molecules has been studied in this work: tetrahydrofuran, representing the hydrogenated form of the furanic derivatives obtained in the hydrolysis of (hemi)cellulosic materials; methyl-cyclohexylketone (MCK) and methyl-cyclohexylether (MCE), representing hydrogenated derivatives of chemicals obtained in the lignin upgrading. Methylcyclohexane (MCH) was used as reference, since toluene/MCH is a typical LOHC nowadays used in industrial practice (Chiyoda Process). As Pt is considered as the most active active phase for these reactions, two Pt catalysts were considered for this purpose, using a common support as alumina and a MOF (MIL-101(Cr)).

**Experimental/methodology.**

MIL-101 (Cr) was prepared according to literature reported processes[1], Pt being added by incipient wetness[2]. Alumina-supported catalyst was a commercial sample (0.5wt% Pt, Engelhard). Catalysts were tested in a fixed bed reactor (70 mg, 250-350ºC, 0.2 MPa) using a flow of 15 Nml/min with 10 % (mol/mol) of reactant in He. Fresh and used catalysts were characterized for checking the evolution of metal dispersion (HRTEM), morphological changes upon reaction ($N_2$ physisorption and XRD), and the coke content (TPO).

**Results and discussion.**

Methylcyclohexane (MCH) present total conversion and selectivity to toluene at T=350ºC for Pt/Al2O3 catalyst. Although selectivity and reactivity trends for MOFs are similar (activation energy of about 84kJ/mol for both catalysts), thermal stability of MOF-supported catalyst is lower. THF dehydrogenation is a more complex reaction, with conversions lower than 27% at 300ºC, and low selectivities to furan, being C3-C4 alkenes the main reaction products. In that case, MOFs-supported catalyst present lower activity. In both cases (MCH and THF) catalyst stability of the MOF-based material is higher, and formation of coke deposits is negligible.

In the case of MCK and MCE, the dehydrogenated products are obtained with higher selectivities (up to 20 % to benzophenone and anisole, respectively), but deactivation effects are also more important with significant formation of carbonaceous deposits. In such cases, the lower acidity of the MOF-based catalysts leads to slighter catalyst deactivation.

Our results suggest that the support can tune the activity of the active phase, as well as the deactivation behavior of the catalyst. Concerning to the molecules, cyclohexylated derivatives are more promising as LOCHs than saturated oxygen heterocycles.

**Keywords:** photocatalyst, saccharide, hydrogenation, nitrobenzene

**Introduction.** The hydrogenation of nitro aromatics to amino aromatics is a very important reaction because amino aromatics are key intermediates for valuable compounds[1]. Generally, the hydrogenation of nitro aromatics is achieved using high-pressure hydrogen gas ($H_2$) at a high temperature. In addition, industrial $H_2$ production is steam reforming of natural gas, an exhaustible resource[2]. Therefore, the development of a method with mild conditions for the production of amino aromatics with green $H_2$ is desired. Since photocatalytic reaction is a redox process caused by photoirradiation under ambient condition, photocatalytic hydrogenation with biomass, renewable resource, has been studied[3]. In this study, photocatalytic hydrogenation of nitrobenzene over $TiO_2$ using various types of saccharides as an $H_2$ source was investigated[4].

**Experimental/methodology.** Bare $TiO_2$ was suspended in distilled water containing nitrobenzene and glucose in a test tube. The tube was sealed with a rubber septum under Ar and then photoirradiated by a high-pressure mercury arc with magnetic stirring at 298 K. After the reaction, $TiO_2$ was removed by filtration, and then the amounts of nitrobenzene and aniline were determined by high-performance liquid chromatography with a ODS column.

**Results and discussion.** Bare $TiO_2$ photocatalyst almost quantitatively converted nitrobenzene to aniline with various saccharides without the use of hydrogen gas. Although aniline was formed when any saccharide was used, the use of disaccharides (lactose, maltose, and sucrose) decreased the reaction rate. The rate of photocatalytic hydrogenation of nitrobenzene using saccharides is determined by the degradation rate of saccharides at positive holes.

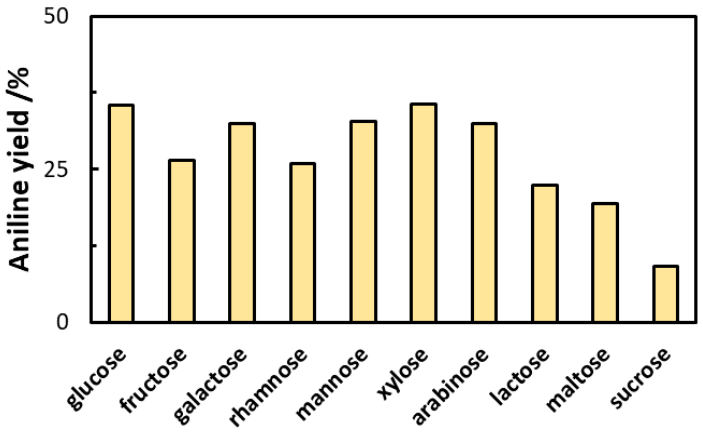

**Figure Aniline yield after 60-min photoirradiation in the photocatalytic hydrogenation of nitrobenzene using various saccharides instead of hydrogen.**

**Keywords:** Glycerol, Carbon dioxide, Dry reforming, Synthesis gas, Ruthenium

**Introduction.** Problems caused by both of production and consumption of fossil fuels have driven scientists to focus on researching renewable fuel production and effective energy conversion processes. Among these processes, the synthesis of biodiesel from transesterification yields 1 mole of glycerol for every 3 moles of fuel produced. Scientists have proposed different approaches to valorize this excess glycerol. One of these ways is utilizing glycerol as a feedstock for hydrogen and synthesis gas (syngas) production. Until recently steam reforming of glycerol was thoroughly investigated. Another method, which is $CO_2$ reforming (dry reforming) of glycerol is interesting due to combining two excess compounds into a desirable product. Dry reforming of glycerol is the combination of glycerol decomposition and reverse water gas shift reactions. Due to the endothermic nature of the reforming reactions, if the heating could be done renewably, the dry reforming process can be carbon negative.

**Experimental.** In this work, dry reforming of glycerol has investigated on $Ru/La_2O_3$, $Ru/ZrO_2$, and $Ru/La_2O_3$-$ZrO_2$ (support 9 wt.% $La_2O_3$, all catalysts are loaded with 1 wt.% Ru). Activity experiments were done for 5 hours at 750 °C and a $CO_2$/glycerol ratio of 1 to 4. Product composition was quantified *via* two on-line gas chromatographs. The effects of the support on catalysts' morphological, electronic, and surface chemistry were investigated thoroughly *via* TEM, *in-situ* DRIFTS, XPS, ATR-IR, and XRD techniques.

**Results and discussion.** When the activity experiments carried on, $Ru/La_2O_3$-$ZrO_2$ have shown the highest $CO_2$ conversion, which was followed by $Ru/ZrO_2$ and $Ru/La_2O_3$. After activity experiments, the stability of the catalysts has been tested in stability experiments at 750 °C and $CO_2$/glycerol = 3 for 72 hours. In these experiments, $Ru/ZrO_2$ catalyst was deactivated by 33% due to the sintering of Ru particles, structural deformation of monoclinic zirconia support, and strong metal-support interaction between Ru and zirconia. Under identical conditions, $Ru/La_2O_3$ catalyst was deactivated by 27% due to severe coking and dehydroxylation/carbonylation of the lanthana support. Lastly, lanthana stabilized tetragonal zirconia support improved fine dispersion of the Ru nanoparticles. Thus, the $Ru/La_2O_3$-$ZrO_2$ catalyst deactivated only 15% in the stability experiments, which was on par with more expensive Rh catalysts [2].

# Aqueous-phase reforming of black liquor HTL water

J. Palo[1*], M. Reinikainen[1], S. Rautiainen[1], J. Lehtonen[1]

[1]*Technical Research Centre of Finland VTT, Espoo, Finland*
[*]*jasmiina.palo@vtt.fi*

BL2F is a Horizon 2020 project that aims to use pulp mill side-product, black liquor (BL), to produce clean, high-quality fuels for marine and aviation [1]. In the BL2F project, an integrated hydrothermal liquefaction (HTL) process is developed, which includes hydrogen production from black liquor HTL waters via aqueous-phase reforming.

Aqueous-phase reforming (APR) is a catalytic process where oxygenated compounds are converted to hydrogen and light hydrocarbons, typically over a nickel or platinum catalyst [2]. The reaction takes place in aqueous liquid phase at mild temperatures (180 – 250 °C) and elevated pressures (15 – 50 bar) to maintain the feed properties near bubble point. Keeping reactants in the liquid phase also avoids the use of an energetically demanding vaporization step compared to e.g. the steam reforming process. Moreover, hydrogen production is thermodynamically favored at low temperatures with a low carbon monoxide yield. Aforesaid features make APR a promising technology to utilize and upgrade industrial wastewaters.

A limited amount of literature exists on the APR of real process waters, especially in continuous fixed-bed reactors. Therefore, this work focused on testing the APR of HTL process water in continuous operation along with extensive catalyst testing and characterization. Before experiments with real aqueous streams, catalyst screening was carried out with single compounds characterized to be present in the actual feed. MeOH, phenol, and 4-methylcatechol were chosen to represent the main chemical groups to be studied for their characteristic features. Fe- and Ni-based catalysts were synthesized for the experiments and their activities were compared with a commercial Pt catalyst. The hydrogen yield from methanol at the beginning of the reaction was high, up to 40 %, but the catalyst deactivated rapidly in the course of the reaction, Fig 1. The fast deactivation was even more pronounced with the other model compounds. The best catalyst was chosen for long-term operation with real water fraction from the black liquor HTL process. To study the mechanism leading to the fast deactivation, fresh and spent catalysts were characterized with XRD, TOC, ICP, and $N_2$ physisorption.

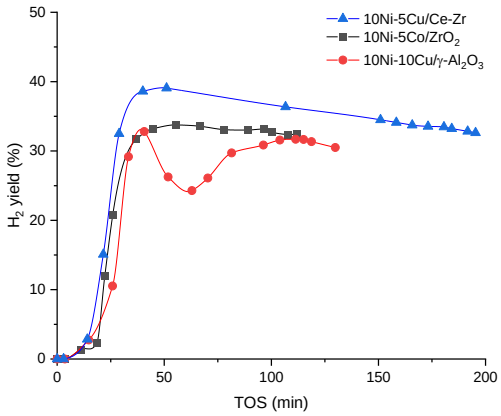

**Figure 1. $H_2$ yield over nickel-based catalysts during APR of methanol. Reaction conditions: T=230 °C, p=32 MPa, $Q_{MeOH}$= 2 cm$^3$/min (5 wt-% MeOH in water), and WHSV=4 h$^{-1}$.**

# Alkaline Thermal Treatment of Lignin for Sustainable Production of Hydrogen with in-situ Carbon Capture

Jieun Park[1] , Woo-Jae Kim[1*]

[1]*Ewha Womans University, Seoul 03760 (Korea)*
[*]*wjkim1974@ewha.ac.kr*

**Keywords:** Biomass, Lignin, Alkaline Thermal Treatment(ATT), Hydrogen, $CO_2$ Capture

**Introduction.** Biomass is a carbon-neutral energy source that absorbs $CO_2$ from the atmosphere through photosynthesis and can even be carbon negative when combined with carbon capture technology. Lignin is a natural amorphous three-dimensional polymer that comprises about 30% of lignocellulose biomass and can carry the highest proportion of energy among biomass fractions [1]. In terms of $H_2$ production from lignin using steam gasification, it produces very low levels of $H_2$ and high levels of $CO_2$ and many $C_2$ hydrocarbon gases. On the other hand, the use of alkaline catalysts can enhance $H_2$ production from lignin, as we domonstrated with other biomass, such as seaweed. In this presentation, we showed the ATT reaction dramatically increases $H_2$ production from lignin [2]. NaOH is involved in the production of $H_2$ and $CO_2$ capture. It also produces a small amount of $CH_4$ while inhibiting the evolution of $C_2$ hydrocarbons and $CO_2$ [3]. Lignin, a by-product of the waste wood or craft process, has been wided used as a fuel by simple combustion. However, this waste lignin can be made into high value-added energy through the ATT process as we showed in this study.

**Experimental/methodology.** The reactor consists of a furnace having three temperature zones and a quartz tube. A stoichiometric amount of biomass (lignin) and alkaline catalyst are added to the alumina boat and placed in the middle temperature zone of the furnace. NaOH was used as an alkaline catalyst. $N_2$ gas was supplied to the Quartz tube as a carrier gas using a mass flow controller. The Agilent 490 Micro GC is used to analyze the product gas collected in the gas tedlar bag and the product gas in real-time.

**Results and discussion.** The alkaline thermal treatment reaction, in which NaOH is added as a catalyst, introduces a new and simple reaction pathway compared to the existing biomass gasification/pyrolysis, and to convert lignin biomass into hydrogen even at a low temperature. In addition, during the alkaline thermal treatment reaction, carbon from biomass is captured as solid carbonate, and greenhouse gases such as carbon dioxide, which are generated as by-products, are not generated. We produced 83.85 mmol $H_2$ from 1g of lignin, which is 2 times higher amount of $H_2$ compared to other biomass ATT.

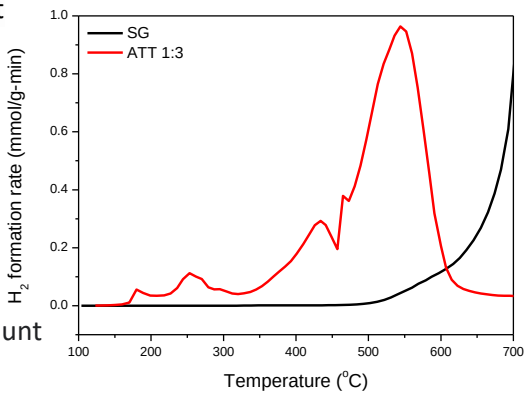

**Fig. 1 $H_2$ production from SG and ATT**

**Keywords:** Polypropylene, Additive Manufacturing, Honeycomb, Warpage

**Introduction.**

Additive Manufacturing(AM) is an open-access technology which allows printing three-dimensional product using various materials with minimal equipment. Fused Deposition Modeling(FDM) type has a high utility and accessibility but has a limit at printing material[1]. Polypropylene(PP) is a industrial material with low cost of production compared to its mechanical strength and chemical resistance, but has a limit to be applied at FDM technique due to its high crystallinity causing warpage and low shape stability[2,3]. In this study PP was composited with beeswax and printed by FDM for the purpose of honeycomb fabrication of beekeeping industry in a streamlined process. PP composites were printed with various printing options to evaluate the warpage and optimize the 3D printer suitability.

**Experimental/methodology.**

Homo PP was compounded with beeswax, talc, woodflour, compatibilizer and extruded with 1.75mm thickness using a mini filament extruder. Filament PP compounds were printed into 60X60X2mm sized sample using FDM type 3D printer. Printed samples were evaluated its warpage by measuring their length, thickness and distance between sample and surface. Samples were printed with different nozzle temperatures, bed temperatures, and nozzle speeds. The mechanical and thermal properties of PP composites were measured by universal testing machine(UTM), differential scanning calorimetry(DSC), thermogravimetric analysis(TGA). Crystallinity of PP compounds were measured using X-ray differaction(XRD). Also scanning electron microscope(SEM) were used to assess the morphology of printed composites.

**Results and discussion.**

Warpage data of the PP compound showed that a beeswax contained PP compound has a relatively low shrinking behavior, since the proportion of crystalline region decreased. Containment of beeswax reduced PP composites' warpage behavior but also lowered mechanical strength of compound. Table 1 shows that the absent of compatibilizer cause a least warpage, but slightly reduced the mechanical properties of PP compounds.

Table 1. Mechanical properties of PP compounds

| Characterization | ASTM Standard | PP compound | PP/wax | PP/wax/com | Unit |
|---|---|---|---|---|---|
| Tensile strength | D638 | 39.6 | 31.6 | 29.0 | MPa |
| Elongation | | 20 | 21.2 | 14.9 | % |
| Flexural modulus | D790 | 2503 | 1856 | 1914 | MPa |
| Flexural Strength | | 57.3 | 38.6 | 36.1 | MPa |

**Keywords:** electrochemical conversion, $PbO_2$ anode, furfural, maleic acid, bio-based feedstock

**Introduction.** Furfural (FF) is a promising renewable platform molecule derived from hemi-cellulose, which can be further converted to various compounds and chemicals, alternatives to the fossil fuel derived ones, thanks to its molecular structure and functional groups. [1,2] Recent advances in the conversion of furfural to maleic acid (MA), and the progress obtained in the development of a $PbO_2$ based electrode used for setting up a new electrochemical route at industrial scale to produce maleic acid from biobased feedstocks are reported. In particular, the fabrication and characterization of some $PbO_2$ electrodes, and their electrolysis results obtained conducting the target reaction in a 10 $cm^2$ lab scale flow cell are presented and discussed.

**Experimental/methodology.** The electrodes have been prepared starting from different metallic titanium substrates (gauze, mesh). A $SnO_2$-$Sb_2O_3$ interlayer was applied, then $PbO_2$ was deposited by electroplating from aqueous solutions containing $Pb^{2+}$ and $Cu^{2+}$ cations under different conditions. The morphology, crystalline structure, and porosimetry data were collected and investigated whereas oxidation states and surface chemical composition of the electrodes were acquired by X-ray photoelectron spectroscopy (XPS). The samples were tested as anode for the reaction of FF → MA in a microflow divided cell (ElectroCell) using 0.5 M $H_2SO_4$ and 75 mM furfural (100 mL) as catholyte. A Pt gauze was the cathode whereas Nafion 324 CEM served as cell membrane. 3-hour experiments were carried out sampling every 30 minutes and analyzing the obtained products. The results were expressed as combined Faraday yield (FY maleic acid + HFO) where HFO denotes the 6-electron reduction intermediate of the reaction.

**Results and discussion.** Stringent control of electroplating conditions of parameters such as temperature and current density is necessary to obtain the β-$PbO_2$ active in the reaction. An inner $SnO_2$-$Sb_2O_3$ layer prepared by dip-coating and thermal decomposition method ensures a good adhesion of the $PbO_2$ electrodeposited coating with a cheap and affordable procedure that allow to obtain a stable DSA having the requirements for industrial application. Improved performances were obtained using PVA to modify the $PbO_2$ electrode deposition, as shown from the electrochemical testing results reported in figure below. The chemical-physical characterization of the anodic materials prepared and tested together with the electrochemical investigations were useful to identify the key parameters that determine the performance of the electrode and helped to direct the choices for its optimization in view of the subsequent scaling up.

**Keywords:** ketonization, aldol condensation, $TiO_2$, bio-oxygenates, bio-fuels

**Introduction.** The development of a catalytic system for the conversion of light oxygenates (i.e. $C_2$-$C_4$ carboxylic acids, ketones, aldehydes, alcohols) via chain-growth reactions represents an attracting strategy to enrich pyrolysis bio-oil with valuable compounds for fuel and chemical applications [1]. In this respect, C-C coupling reactions like ketonization and aldol condensation can transform light bio-oxygenates into species with longer C-chain and lower O-content, thus enhancing their stability and heating value. Unveiling reaction pathways and kinetics is of the utmost importance for mechanism comprehension and catalysts screening, as well as to tune process selectivities and foster catalyst stability. In this work, the reactivity of two model oxygenates (acetic acid and acetone) on $TiO_2$-based catalysts was investigated.

**Experimental/methodology.** Ketonization and aldol condensation tests were carried out in an isothermal micro fixed-bed reactor, feeding acetic acid or acetone, respectively. A commercial anatase $TiO_2$ powder (Tronox, DT-51D) was used (140-200 mesh), after calcination in air at 400°C and pre-treatment in $H_2$ at 400°C. Experiments were performed at varying temperature (150-400°C), GHSV (2-6·$10^4$ NL/h/kg) and inlet concentration of the reacting oxygenate (1.5–3.5 % in $He/N_2$). Online measurements in a GC-TCD (Agilent 6890) were used to analyze the composition at the inlet and the outlet of the reactor, and were coupled to offline GC-MS analyses (Agilent 6890, 5973 MSD) for species identification.

**Results and discussion.** Tests with acetic acid limited to temperatures below 300°C allowed to selectively activate ketonization reaction to acetone ($2CH_3COOH \rightarrow CH_3COCH_3 + CO_2 + H_2O$), revealing a wide coverage of catalyst active sites and a zeroth order dependence [2]. At higher temperatures, the appearance of several heavier compounds ($C_{6\text{-}10}$) showed an increased complexity of reaction network with the ignition of secondary reactions starting from acetone. Experiments feeding acetone as reactant were performed to observe the impact of changing operating conditions on products distribution. As an example, the effect of reaction temperature is shown in Figure 1, where the main products are seen: $C_6$ oxygenates (MO mesityl oxide, MIBK methyl isobutyl ketone), isophorone (cyclical oxygenated $C_9$), mesitylene (deoxygenated aromatic $C_{9_deoxy}$) as well as $C_4$-$C_7$-$C_{10}$ olefins. The complex variety of products composition reflects the existence of multiple reaction routes, among which emerge consecutive acetone condensations ($C_3 \rightarrow C_6 \rightarrow C_{9_deoxy}$ or $C_3 \rightarrow C_6 \rightarrow C_9 \rightarrow C_{9_deoxy}$) and competitive cracking to olefins. Experimental data are now exploited to define a reaction scheme and to quantify kinetics. Moreover, broad catalyst characterization (BET, XRD, TPR, $CO_2/NH_3/CH_3COOH$-TPD) allowed to associate activity values to catalyst morphology and features, while analyses on spent catalytic samples (BET, TPO) revealed a decreased pore volume due to the build-up of C-deposits.

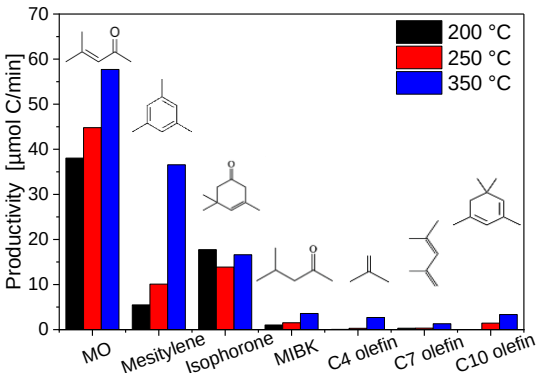

**Figure 1. Productivity of main C-products during acetone condensation at varying temperature. GHSV=4·$10^4$ NL/h/$kg_{cat}$ (total 4600 µmol/min). Feed: 3% acetone in $He/N_2$.**

Guided by the ongoing kinetic analysis, strategies to control process selectivity and to hinder the production of undesired products with C-coking tendency (e.g. olefins) are under investigation.

**Introduction.** Carbohydrates such as glucose, fructose or xylose can be transformed to obtain valuable products, such as furanic compounds and organic acids. Nevertheless, the catalytic processes involve a complex reaction scheme, and the selectivity strongly depends on the substrate and on the catalyst. Zeolites with transition metals in the structure, especially Sn-BETA, have shown good activity for glucose isomerization. However, while the specific case of glucose isomerization on Sn-BETA is mechanistically understood[1], the other reaction pathways such as retro-aldolization, dehydration to organic acids have been less well elucidated. Likewise, the influence of different Lewis acidic sites (metals) or of the substrate (sugar) has been scarcely examined so far. Herein, we study the selectivity of the reactions of transformation of biomass-based carbohydrates over different Lewis acidic zeolites.

**Experimental/methodology.** A commercial beta zeolite was dealuminated by a strong acid ($HNO_3$ 69%). Once dealuminated, Sn, W, Zr or Hf were incorporated (precursors: $SnCl_4{\cdot}5H_2O$; $ZrOCl_2{\cdot}8H_2O$, $W(C_{12}H_{30}O_6)$; $HfCl_4$) targeting a content of 1% wt. Solid State Ion Exchange (SSIE) and Equilibrium Adsorption in a solvent (water or isopropanol, EAW or EAI, respectively) were compared. Pyridine adsorption monitored by in situ FTIR allowed probing Lewis acid sites. The reactivity of glucose, fructose and xylose was studied and compared at two different temperatures (95 °C and 150 °C) in aqueous medium (40 bar $N_2$).

**Results and discussion.** The dealumination treatment decreased the aluminum content in the parent material from Si/Al =13 to about 200 with no structural or textural modification. In the case of Sn and Hf, we found incorporation methods allowing the deposition of the targeted amount of metal in the zeolite, without forming metal oxide clusters. For these two metals, the Lewis acidity measured by pyridine was perfectly correlated to the amount of deposited metal. In the case of Zr and W, however, the formation of metal oxide clusters could, for the moment, not be avoided. Further work needs to be done on the preparation protocol for these two metals. In the catalytic tests, Sn-BETA selectively converts glucose into fructose. Little-to-no selectivity towards retro-aldolization of glucose was observed. On the opposite, the conversion of fructose and xylose led to significant rates of formation of retro-aldolization products with Sn-BETA. The formation of lactic acid is also observed with these substrates. A correlation between catalyst activity and Lewis acid site concentration is noticed with Sn-BETA. However, Hf-BETA and Zr-BETA are almost inactive, in spite of the presence of Lewis acid sites. Thus, not only the amount of Lewis acid sites matters, their quality is important. The W-incorporated materials yield mannose in the conversion of glucose (epimerization product), but we observed a near total leaching of the metal in solution during the reaction. This study reveals that the metal could drive the reaction selectivity.

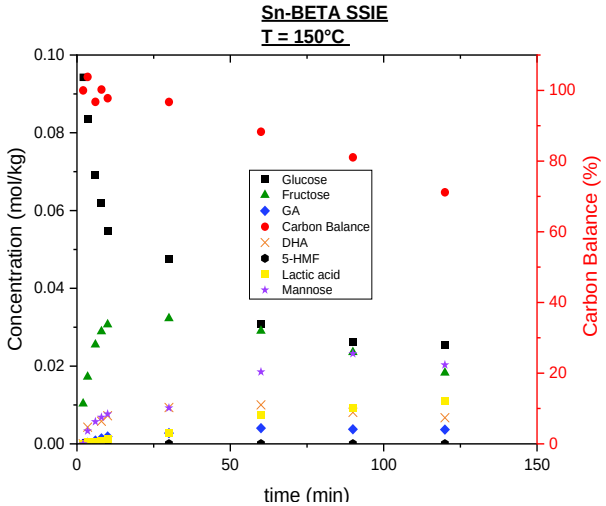

**Figure 1: Glucose conversion versus time over Sn-BETA SSIE. Reaction conditions: T= 150 °C, P= 40 bar $N_2$, initial concentration of glucose 0.1 mol/kg and $n_{metal}/n_{substrate}$= 1/100**

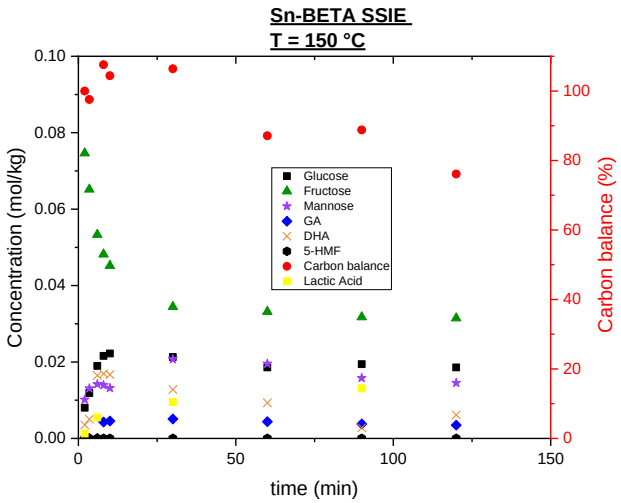

**Figure 2: Fructose conversion versus time over Sn-BETA SSIE. Reaction conditions: T= 150 °C, P= 40 bar $N_2$, initial concentration of fructose 0.1 mol/kg and $n_{metal}/n_{substrate}$= 1/100**

**Keywords:** Ethanol, Copper nanoparticles, Acetaldehyde, Sol-gel method, Impregnation method

**Introduction.** Copper in the form of nanoparticles (NPs) is a well-known redox catalyst active in numerous catalytic reactions, including ethanol dehydrogenation to acetaldehyde. This reaction is critical for the future due to the ongoing changes in the oil industry: ethanol dehydrogenation is the first step of possible sustainable production of butadiene from bioethanol. Cu NPs deposited on silica used for this purpose suffer from low stability during time-on-stream due to the nanoparticles' sintering and coking.[1] Therefore, we have studied particle size and doping effects of $Cu/SiO_2$ catalysts to improve their stability.[2]

**Experimental/methodology.** This work is focused on the preparation of $SiO_2$-supported nanoparticles ($Cu/SiO_2$; 2.5 wt%; commercial Aerosil-300 used as catalyst support) by several methods to control the nanoparticles size: dry impregnation, strong electrostatic adsorption[3], sol-gel method[4], and deposition of pre-prepared NPs by solvothermal hot-injection synthesis.[5] Catalysts with leading performance were doped with Ni and Zn (Cu:M ratio: 10:1 and 100:1 wt%) by dry impregnation. The catalysts were characterised by STEM-EDS, $N_2$ porosimetry, TGA, TPR, ICP-OES, and XPS. The catalytic activity of prepared $Cu/SiO_2$ was tested in a gas-flow fixed-bed reactor connected to gas chromatograph. Sintering of nanoparticles was evaluated by STEM-EDS and coking by XPS and TGA after the catalytic tests.

**Results and discussion.** The largest particles were prepared by solvothermal synthesis (14.7 nm). Dry impregnation caused a broad distribution of particle sizes (3.9 nm) compared to the narrow distribution by strong electrostatic adsorption (2.6 nm). The smallest NPs were prepared by hydrolytic and non-nonhydrolytic sol-gel (mostly atomic clusters). All $Cu/SiO_2$ catalysts were highly selective to acetaldehyde (>90 %). The catalysts prepared by hydrolytic sol-gel and dry impregnation exhibited outstanding performance at 255 °C (65 % ethanol conversion and 2.79 g $g^{-1}$ $h^{-1}$ acetaldehyde productivity and 57 % of ethanol conversion and 2.42 g $g^{-1}$ $h^{-1}$ acetaldehyde productivity, respectively). All catalysts suffered from the sintering (**Fig. 1**) and coking above 255 °C causing a severe deactivation. The most stable catalyst (dry impregnation) stabilized at 50 % ethanol conversion after 14 hours time-on-stream. Doping the most active (hydrolytic sol-gel) and the most stable (dry impregnation) catalysts with Ni and Zn led to the following results: (i) Nickel enhanced the catalytic activity at 220 °C but caused a strong deactivation at higher temperatures; (ii) Zn-doped catalysts exhibited better stability up to 290 °C without losing both activity and selectivity.

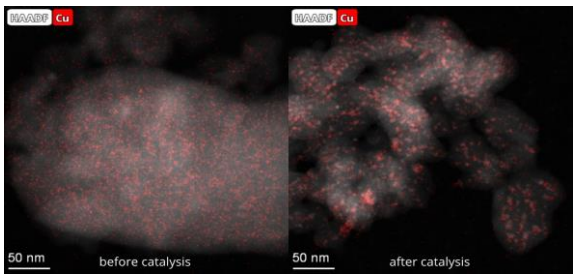

**Figure 1: Sintering of Cu nanoparticles (red color) followed by STEM-EDS.**

**Introduction.** Ethanol conversion is one of the promising alternative routes for the production of versatile chemicals, for example, acetic acid, ethylene, acetaldehyde, and diethyl ether. Among them, acetaldehyde is one of the vital chemicals to produce several industrial substrates, such as drugs, perfumes, and disinfectants. However, acetaldehyde production via the oxidative dehydrogenation still suffers because it requires the addition of oxygen under high temperatures, high production cost, and unfriendly environmental conditions. Therefore, non-oxidative dehydrogenation of ethanol to acetaldehyde is considered to be an alternative route. Indeed, several catalysts including metal oxides, zeolite, and mesoporous silica combined with noble metal active sites have been applied as promising catalysts. Although they performed high ethanol conversion, low acetaldehyde yield was obtained. In this contribution, we fabricated nanosized Cu-based mordenite (MOR) zeolites with their pore-opened structures for ethanol conversion to acetaldehyde. The generation of secondary pores of zeolite was obtained using the ammonium fluoride ($NH_4F$) etching approach, which could significantly enhance the accessibility to active sites. In addition, the effect of different types of mesoporous structures on the catalytic activity was systematically investigated.

**Experimental/methodology.** The nanosized MOR zeolite was synthesized via a simple hydrothermal method using nano-silica as a silica precursor. Subsequently, the pore-opened MOR was prepared by etching the obtained nanosized MOR with $NH_4F$ solution. Afterwards, the Cu-MOR was prepared via the ion-exchange method using Cu aqueous solution at the optimized conditions. The catalytic performance of dehydrogenation of ethanol to acetaldehyde was investigated using a fixed-bed reactor at 300-450°C. The reaction mixtures were analyzed using gas chromatography (GC) equipped with an FID detector and PoraBOND Q column.

**Results and discussion.** We reported here the catalytic performance of ethanol dehydrogenation to acetaldehyde over Cu-based nanosized MOR as displayed in Figure 1. It was found that the unmodified Cu-MOR with 4.5 wt% of Cu (4.5wt%Cu-MOR) provides 67% of ethanol conversion and 50% acetaldehyde yield. Surprisingly, the pore-opened nanosized Cu-MOR (4.5wt%Cu-$NH_4F$-MOR) can greatly improve the catalytic performance, eventually achieving high ethanol conversion (85%) and acetaldehyde yield of 57%. This work highlights new possibilities for acetaldehyde production from ethanol using the modified nanosized MOR catalyst.

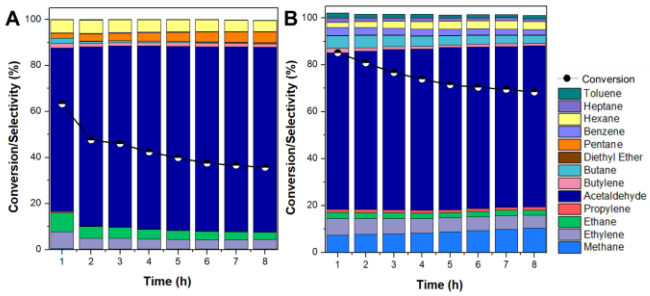

**Figure 1.** Catalytic performances of (A) 4.5wt%Cu-MOR and (B) 4.5wt%Cu-$NH_4F$-MOR in the dehydrogenation of ethanol to acetaldehyde under the optimized conditions.

# Properties and performance in transesterification of potassium catalysts on zeolite X prepared by impregnation and physical mixing

P. Tayraukham[1], K. Deekamwong[1,2], C. Keawkumay[1,2], J. Wittayakun[1], S. Prayoonpokarach[1*]

**Keywords:** potassium catalyst, zeolite NaX, impregnation, physical mixing, transesterification

**Introduction.** Potassium supported on zeolite NaX (K/NaX) has been used as a catalyst for transesterification to produce biodiesel [1,2]. The catalyst is prepared by the impregnation (IM) method [1,2] by adding $CH_3COOK$ in buffer solution on zeolite NaX. $K_2CO_3$ is generated after calcination and is believed to be the active catalytic site [1,2] . However, the IM method is time-consuming and involves several steps. This work investigates an approach to reduce the catalyst preparation time by using the physical mixing (PM) method. The properties and performance of IM and PM catalysts are compared.

**Experimental/methodology.** K/NaX from the IM method was prepared by impregnation with a method from the literature[3]. Potassium acetate buffer was a precursor and the potassium loading was 12 wt%. The sample is named IM. K/NaX from the PM method was prepared by grinding NaX powder and $CH_3COOK$ for 20 min. The sample is named PM. The IM and PM sample after calcination at 500 °C for 3 h are named IMC and PMC. The samples were characterized by TGA, XRD and FTIR and tested in transesterification of palm oil with the method from the literature [3]. The products were analyzed by thin-layer chromatography and gas chromatography.

**Results and discussion.** TGA thermograms of NaX, IM and PM show weight loss below 350 °C from the adsorbed water (Figure (a). The amount of weight loss was in the order NaX > PM > IM. IM and PM show weight loss in the range of 400 – 460 °C, corresponding to the decomposition of $CH_3COOK$ to generate $K_2CO_3$ [6,7]. Therefore, calcination at 500 °C is suitable for generating $K_2CO_3$ as active species. XRD patterns of all samples show characteristics of zeolite NaX and the intensity decreased after calcination. FTIR confirmed the presence of carbonate species on NaX. Figure (b) shows gas chromatograms of the biodiesel products. The biodiesel yield of NaX was null, whereas those from IMC and PMC were 55.3% and 45.5%, respectively. It can be concluded that the dispersion of potassium species on zeolite NaX by IM method enhances the catalytic activity compared to the PM method.

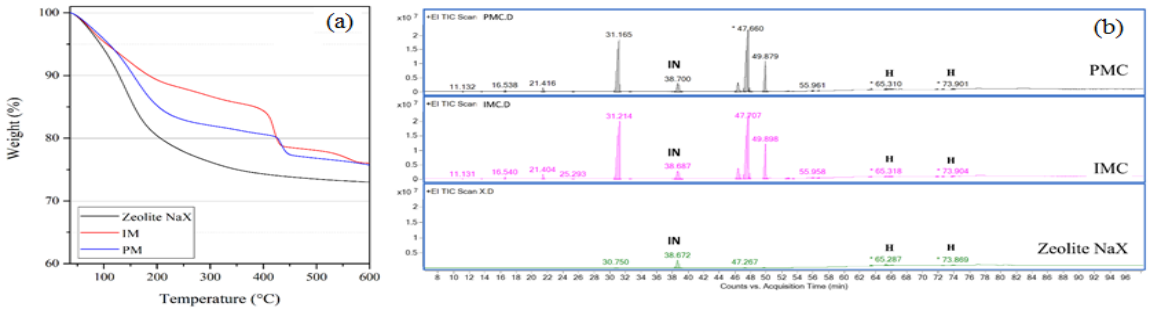

Figure (a) TGA (b) GC results from transesterification products from zeolite NaX, IMC and PMC.

**Introduction.** 1,5-pentanediol (1,5-PDO) is a high-value product due to its multiple applications [1]. The production of 1,5-PDO from petroleum derivatives is costly because it involves complex steps and $C_5$ feedstocks are not available on a large scale. In contrast, there are $C_5$ feedstocks obtained from biomass, such as furfural (FUR), which is produced on an industrial scale. Among the green routes to produce 1,5-PDO from FUR, the most competitive is the Dehydration-Hydration-Hydrogenation (DHH) multistep route because it employs cheap catalysts resulting in high yields [2]. An essential step is the gas-phase dehydration of tetrahydrofurfuryl alcohol (THFA) to give rise to dihydropyran (DHP). To date, the ideal conditions for such reaction have been reported by [2], who obtained DHP yields of 86% employing γ-$Al_2O_3$ as catalyst at 375°C in a continuous flow reactor. This work aims to lower the temperature of this reaction by using acid catalysts based on $Al_2O_3$-$TiO_2$ mixed oxides to obtain 1,5-PDO from biomass more competitively.

**Experimental/methodology.** Five acid catalysts were studied; pure oxides ($Al_2O_3$ and $TiO_2$) were purchased, whereas three $Al_2O_3$-$TiO_2$ mixes oxides have been synthesized by sol-gel method [3] and labeled as SG_2($Al_2O_3$)($TiO_2$), SG_($Al_2O_3$)($TiO_2$), and SG_($Al_2O_3$)2($TiO_2$). The dehydration reaction of THFA into DHP has been followed by in situ monitoring infrared spectroscopy at 200°C and 400°C.

**Results and discussion.** Figure 1 shows the spectra obtained for five catalysts just before cutting the THFA feed (19,5 min). The infrared bands observed at 2973 and 2875 $cm^{-1}$ are associated with the presence of THFA on the catalyst surface, while the peaks at 1597 and 1463 $cm^{-1}$ can be associated with the formation of DHP. Therefore, the main inference is that the mixed sol-gel catalysts, unlike the commercial catalysts, show activity at 200°C. Specifically based on DRIFT spectra, the SG_($Al_2O_3$)($TiO_2$) catalyst presents the best behavior on the THFA conversion and DHP yield. When these experiments were conducted at 400°C, all the samples were active in the THFA dehydration reaction. This behavior is due to the different surface acidity of the catalysts, determined by DRIFT after adsorption of pyridine and deuterated acetonitrile as probe molecules.

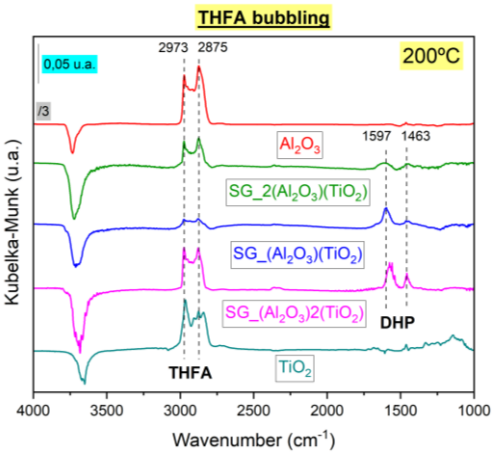

**Figure 1.** DRIFT *in-situ* spectra monitoring for the $Al_2O_3$-$TiO_2$ acid catalysts.

In conclusion, *in situ* monitoring of the reaction may allow us to detect intermediates and deactivation species on the surface, in addition to reactants and products. The previous results are promising regarding the use of $Al_2O_3$-$TiO_2$ mixed catalysts to lower the dehydration temperature of THFA to obtain DHP.

# Two-step configuration of carbon-carbon coupling and hydrodeoxygenation catalyst for the upgradation of biomass derived oxygenates

**Kishore Rajendran[1], Albert Miró i Rovira, Petter Tingelstad, Kumar R. Rout[1], De Chen[1*]**

[1]Dep. of Chemical Engineering, Norwegian University of Science and Technology (NTNU), NO-7491 Trondheim, Norway
Email: de.chen@ntnu.no

**Introduction.** Biomass valorization in the transportation sector is highly anticipated due to the increasing demand for green fuels. Predominant literature in Hydrodeoxygenation (HDO) is directed toward the reduction of oxygen species. The carbon yield of liquid fuels is critical for energy efficiency and the cost of biomass conversion [1]. However, only limited focus is given to the simultaneous retention of carbon together with the removal of oxygen species in the final upgraded bio-fuel to increase the carbon yield. The C1-C5 short-chain oxygenates (ketones, aldehydes, acids) represent 15-20% of the conventional bio-oil obtained via fast-pyrolysis. The unstabilized bio-oil poses challenges such as its acidic nature, low H/C, high O/C ratio etc., which are not compatible with current gasoline/diesel range fuel specifications [2]. Therefore, a two-step configuration of carbon-carbon (C-C) coupling and HDO catalyst could potentially convert under-utilized short-chain oxygenates into long-chain oxygenated hydrocarbon, which could be further deoxygenated by the HDO catalyst.

In this work, hydrogenation metals such as Au, Cu, Ni, Ru, Pt, and Pd were supported on reducible oxides such as $TiO_2$, $ZrO_2$, $CeO_2$ for C-C coupling upgradation. Coupling the assessed C-C coupling reaction using real biomass feedstock (beech wood) was later combined with HDO catalysts such as Mo, Nb, Re, W supported on $TiO_2$ support.

**Experimental/methodology.** Two fixed-bed stainless-steel reactors were used in series to perform pyrolysis at 600 °C and followed by ex-situ catalytic upgradation at 300-400 °C, 1 bar. The C-C coupling catalyst was placed prior to the HDO catalyst in the 2$^{nd}$ reactor. The gaseous products were analyzed by GC-TCD/FID, whereas liquid products were analyzed by GC-MS/FID. The water content of the bio-oil was analyzed by Karl Fischer titrator.

**Results and discussion.** We observe Cu and Au to outperform other strong hydrogenation metals during C-C coupling reaction. On the other hand, the combination of Mo-Nb, Re-Mo over $TiO_2$ support showed superior activity compared to other candidates for HDO catalysts. Overall, the dual-bed configuration was successfully implemented to retain higher carbon in the upgraded bio-oil with decreased oxygen content compared to conventional HDO treatement. Additionally, all the synthesized and spent catalysts were characterized by chemisorption, H2-TPR, TGA, XPS, SEM, XRD, BET, and Raman.

**Keywords:** Beta zeolite, Platinum, Catalytic pyrolysis, Activation energy

**Introduction.** The growing demand for clean energy and environmental protection has pushed the government agencies to incentivate the development of new technologies for minimizing the impact of fossil sources. Among them, catalytic pyrolysis emerges as an efficient route for producing energy and chemicals from biomass, thanks to its flexibility, low cost, and simplicity. However, the process still needs active catalysts which can be tailored for each application. With this goal in mind, beta zeolites-supported platinum were evaluated in the catalytic pyrolisis of medium density fiber (MDF) residues, in this work. Thermokinetic parameters were also determined by Flynn-Wall-Ozawa (FWO), Kissinger-Ahakira-Sunose (KAS) and Friedman isoconversional methods.

**Experimental/methodology.** Samples of beta zeolite with different SAR (29, 42 and 75) were prepared as described elsewhere [1], but using silica extracted from coal ash from a thermoelectric power plant. Platinum (1%) was impregnated using hexachloroplatinic acid. The catalysts were characterized by Fourier transform infrared spectroscopy, X-ray diffraction (XRD), porosity measurements, nuclear magnetic ressonance, temperature programmed reduction (TPR) and acidity measurements by temperature programmed desorption of ammonia. MDF residues, previous treated [1] were mixed with the catalyst in the 1/0.2 (biomass/catalyst) ratio. Pyrolysis was performed on a TGA Q50 equipment (V6.7 Build 203, Universal) using around 7.0 mg of sample. The oven was heated from 25 °C to 900 °C at heating rates (β) of 5, 10, 15 and 20 °C $min^{-1}$ under nitrogen flow (60 mL $min^{-1}$). The thermokinetic parameters were determined by Flynn-Wall-Ozawa (FWO), Kissinger-Akahira-Sunose (KAS) and Friedman methods.

**Results and discussion.** The XRD patterns of the catalysts showed typical profiles of beta zeolite, regardless platinum and the value of Si/Al ratio. As expected, the acidity decreased with increasing SAR for zeolites. Platinum decreased the amount and the strenght of acidic sites, the platinum-based sample with the lowest SAR (31) being the most acidic solid. Zeolites showed strong, moderate and weak acidic sites but for platinum-based samples only for the most acidic catalyst (SAR=31), weak sites were found. The TPR profiles were similar among the platinum-containing samples, indicating that the different values of SAR do not affect the interaction of platinum with beta zeolite. The curves show low and high temperature peaks, related to the reduction of platinum in weak and strong interaction with the support, respectively. Thermogravimetry results showed that platinum-based catalysts accelerate biomass decomposition mainly in the second stage, the main step of lignocellulosic biomass degradation, reaching the third stage at a lower temperature as compared to beta zeolites. Friedman method produced the highest correlation index ($R^2$=0.9757), indicating better adjustment to the pyrolysis data. The activation energy ($E_a$) average obtained by the Friedman method for the non-catalytic pyrolysis was 118.04 kJ $mol^{-1}$, which decreases over all catalysts ($E_a$=102.89 kJ $mol^{-1}$) indicating that the average activation energy for the decomposition of lignocellulosic componentes was decreased by beta zeolite. However, platinum increased the activation energy ($E_a$=112.95 kJ $mol^{-1}$). This finding can be associated with other reactions, catalyzed by platinum during MDF degradation. It was also noted that platinum increased the production of volatiles, during the second decomposition stage. Platinum can thus be useful to control the selectivity of beta zeolites, tailoring the catalysts for different applications.

**Keywords:** Perovskite, iridium, hydrogen, ethanol steam reforming

**Introduction.** Scientific, technological, and industrial development has enabled the gradual replacement of fossil fuels by renewable sources. Among them, bioethanol is a viable and promising alternative for producing hydrogen from steam reforming (ERS). However, its efficiency depends on the properties of the catalyst and then there is a constant investigation for active and selective catalysts which can also be resistant to coke formation. With this goal in mind, this work describes the synthesis and characterization of iridium supported on mixed oxides derived from nickel, cobalt, magnesium, and lanthanum perovskites for hydrogen production by ERS.

**Experimental/methodology.** Nickel and/or cobalt and/or magnesium and lanthanum perovskites ($La_{1-x}Mg_xNi_{1-y}Co_yO_3$; x = 0 and 0.5 and y = 0 and 0.5) were prepared by the decomposition of amorphous citrate method, followed by heating at 800 °C [1]. The perovskites were characterized and heated (10 °C $min^{-1}$) under gas flow (10% $H_2/N_2$) up to 700 °C, giving rise to nickel and/or cobalt supported on lantana with (or not) magnesium. The catalysts were passivated, impregnated with a solution of chloroiridic acid (1% w/w) and then heated (10 °C $min^{-1}$) under gas flow (10% $H_2/N_2$) up to 700 °C, giving rise to the iridium catalysts. The samples were passivated and named according to the metals: L (lanthanum), N (nickel), C (cobalt), M (magnesium) and I (iridium). They were characterized by thermogravimetry, Fourier transform infrared spectroscopy, X-ray diffraction, specific surface area (Sg) measurements, temperature programmed reduction and temperature programmed desorption of ammonia. The catalysts were evaluated in ESR at 1 atm and 500 °C, for 8 h. The reaction products ($H_2$, CO, $CO_2$, $CH_4$, ethane and ethene) were analysed by gas chromatography. After reaction, all catalysts were characterized by X-ray diffraction and Sg measurements .

**Results and discussion.** XRD patterns confirmed the formation of perovskites for all cases. Small amounts of other phases (NiO, $La_2NiO_4$, $CoMgO_2$, $La_2NiO_4$ and MgO) were also found depending on the composition of the catalyst. After reduction, all solids showed metal oxides, as well as metallic nickel and/or cobalt. Small amounts of other phases (NiO, CoO, $La_3Co_3O_8$ and $NiMgO_2$) were also detected indicating that nickel and/or cobalt were not completely reduced. The Sg ranged from 14 (LMNCI) to 26 $m^2\ g^{-1}$ (LMCI) for fresh catalysts and from 14 (LMNCI) to 39 $m^2\ g^{-1}$ (LMNI) for the spent ones. During ERS, the Sg increased for LMNI and LMCI while the others did not change. The main products of ERS were $H_2$ and $CO_2$, but other products (CO, $CH_4$ and $C_2H_4$) were also formed by parallel and consecutive reactions. All catalysts produced high amounts of $H_2$, a fact that was related to the high activity of the metals in ethanol dehydrogenation and in methane steam reforming (MSR). LMNCI catalyst produced the highest value, demonstrating the cooperative action among the metals. For the cobalt (LCI) and nickel (LNI) samples, magnesium decreased $H_2$ production and increased $CH_4$ and CO amount, indicating that MSR and the water gas shift reaction (WGSR) were inhibited by magnesium. A different behaviour was noted for the other samples, magnesium increasing $H_2$ and CO production while $CH_4$ amount was decreased. This means that the MSR was favoured by magnesium. Except for LCI, LMCI and LMNCI samples, the catalysts did not produce ethylene, the main coke precursor. Therefore, the catalysts are able to inhibit deactivation and increase their stability throughout the reaction. The LMNCI sample is the most promising catalyst producing the highest $H_2$ amount, the least amount of $CH_4$ and less than 1% of ethylene.

**Keywords:** Biofuel, black liquor, hydrodeoxygenation

**Introduction.** Black liquor (BL), a side stream from chemical pulping industry, is a promising feedstock for biofuels as it contains circa half of the energy of the lignocellulose. EU project Black Liquor to Fuel (BL2F) aims to develop a feasible route from black liquor to drop-in biofuels for aviation and shipping. In the first step, black liquor is treated under hydrothermal conditions to separate the cooking chemicals and produce hydrothermal liquefaction (HTL) oil from the organics [1]. The HTL oil is then further upgraded using catalytic hydrotreating using an integrated hydrothermal hydrodeoxygenation process. The aim of the hydrothermal hydrodeoxygenation (HDO) is to remove most of the oxygen and sulfur present in the feed and to stabilise the oil for easier transport and further upgrading at oil refineries. In this work, we study the hydrodeoxygenation of both model compounds and HTL oil in supercritical aqueous media.

**Experimental/methodology.** The HDO experiments were carried out in a batch reactor using sulfided NiMo catalysts and hydrogen gas. The catalyst supports were selected based on the stability tests in supercritical water conditions. Model compound studies were carried out using isoeugenol and 4-methylcatechol to represent the different functionalities present in the HTL oil. The products were analysed by GC-MS to assess the effect of the catalyst and reaction conditions on the product distribution. Similarly, experiments with HTL product were carried out in sub- and supercritical water conditions, and the effect on the degree of deoxygenation was studied.

**Results and discussion.** The HDO of the model compounds in aqueous media gave cresols as main products (Figure 1). The reaction conditions and catalyst had a clear effect on the conversion and the extent of cracking and hydrogenation of the aromatic ring. With the real HTL oil as a feedstock, the main parameter to be montored was degree of deoxygenation (DOD). The effect of the catalysts and reaction conditions on DOD will be presented.

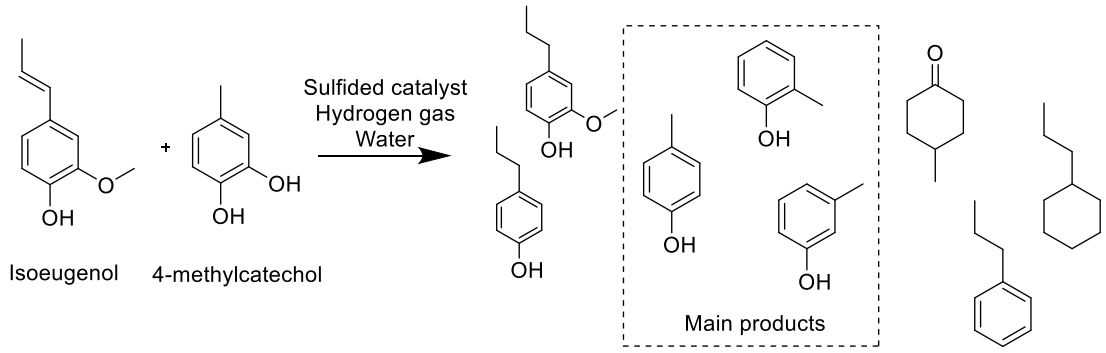

**Figure 1. Hydrodeoxygenation of black liquor HTL oil model compounds in supercritical water.**

**Keywords:** hydrogenation/hydrogenolysis, sugar alcohols, diols, bio-based chemicals, biochar

**Introduction**

An important valorization route of biomass derived sugars, such as glucose and xylose, is their hydrogenation/hydrogenolysis to sugar alcohols (e.g. sorbitol, xylitol) and smaller diols/glycols (e.g. ethylene glycol, propylene glycol and glycerol), which can be utilized in the production of food ingredients, pharmaceuticals, polyesters, surfactants and functional fluids. Additionally, biomass can be converted to biochar via pyrolysis, which after appropriate physical/chemical activation can serve as micro/mesoporous metal support for the above said hydrogenation reactions [1-3].

**Experimental/methodology**

Model glucose aqueous solutions of relatively high concentration, ca. 5-20% were used as feedstock to study/optimize the reaction conditions (temperature, time, $H_2$ pressure) towards either increased sorbitol yield via hydrogenation or enhanced production of smaller diols/glycols via combined hydrogenation/hydrogenolysis. The metals tested as catalysts were Ru, Pt and Ni, each one exhibiting varying hydrogenation reactivity/selectivity towards the above targeted products. Commercial micro/mesoporous activated carbons as well as activated biochars, derived from miscanthus straw pyrolysis at 700$^o$C, were used as metal supports. Optimization tests were conducted on small-size high pressure stirred batch reactors (50-100 mL). The hydrogenation of glucose was performed at 120-180$^o$C, for 3-5h, at 30 bars $H_2$, while hydrogenolysis required more intense conditions, i.e. 200-220$^o$C, 1-3h, 30-50 bars $H_2$. The optimized parameters and catalysts were then tested on a 5 Lit micro-pilot reactor working under batch/fed-batch and continuous flow conditions. The real biomass derived glucose feedstocks were obtained via a high-gravity enzymatic hydrolysis/saccharification of cellulose pulps obtained from organosolv fractionation of hardwood biomass. The products were analyzed by HPLC/RID, LC-MS, NMR, Karl-Fischer titrator, while the catalysts were characterized by XRD, BET, XPS, TEM.

**Results and discussion**

Glucose hydrogenation was optimized to over 90% sorbitol yield (at ~99% glucose conversion), mainly over Ru catalysts, with minor co-production of ethylene glycol (EG) and 1,2-propanediol (1,2-PDO). The biochar-based catalysts exhibited similar performance to that of the commercial activated carbons, via mainly affecting/promoting the dispersion of the active hydrogenation metal. Higher temperatures with noble metals, and mainly with Ni catalysts, favored the cascade hydrogenation-hydrogenolysis reaction pathways, leading to enhanced production of EG and 1,2-PDO, over sorbitol. The real cellulose hydrolysates feedstocks afforded similar reactivity and yields towards the targeted products, while upscale production was effectively verified in the micro-pilot reactor. Catalysts were also proven stable and reusable.

**Keywords:** Biomass, Biofuels, Cobalt-based catalysts, Hydrogen.

**Introduction.** Sorbitol is a promising building block for the production of chemical that can be produced from renewable biomass, such as corn starch–based glucose and corn steep liquor. Transformation of sorbitol in aqueous phase can be tailored to selectively produce hydrogen (APR process) or heavier alkanes that can be used in the gasoline pool and other less oxygenated compounds (HDO) [1]. Hence, sorbitol is a pivotal platform molecule for the decarbonization of the economy.

$CoAl_2O_4$-derived catalysts and bimetallic Pt/$CoAl_2O_4$ have been successfully used for hydrogen production by glycerol APR [2]. In this work, a comparative approach for value-added chemical production from aqueous-phase sorbitol transformation under inert atmosphere and $H_2$ pressure has been carried out.

**Experimental/methodology.** Cobalt aluminate was synthesized by coprecipitation (xCoAl, x = 0.25-0.625 Co/Al molar ratio) and Pt-modified catalyst (Pt = 0.3 and 1.0 wt.%) was prepared by wet impregnation (xPt/CoAl). The physico-chemical properties of the freshly reduced and spent catalysts were evaluated by a sort of techniques. A 300-mL stainless steel batch reactor (Autoclave Engineers) fitted with systems for liquid and gas sampling was used for the catalytic transformation of 6.25 wt.% sorbitol aqueous solution. The tests were carried out at 240 °C/60 bar, under $H_2$ and $N_2$ atmosphere, for 8 h.

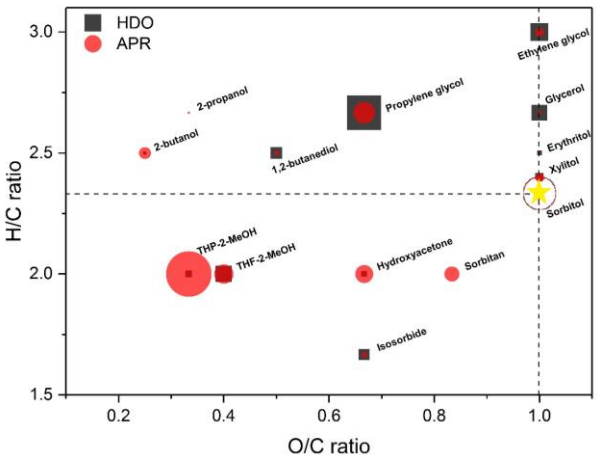

**Figure 10. Van Krevelen representation (H/C vs. O/C atomic ratio) of liquid products obtained during sorbitol transformation (HDO vs APR) over 0.3Pt/CoAl.**

**Results and discussion.** All the catalysts were very active for the transformation of sorbitol under $H_2$ pressure (HDO), achieving complete conversion after 6 h reaction. Pt containing bimetallic catalysts were the most active among all. Propylene glycol and ethylene glycol were the main liquid products obtained for all catalysts. In short, due to the predominance of surface basic sites, our Co-containing catalysts promoted the retro-aldol condensation route for sorbitol HDO. Under $N_2$ atmosphere (APR), on contrary, none of the studied catalyst reached the complete sorbitol conversion in 8 h of reaction (maximum conversion of 93.5% for 1Pt/CoAl and 92.6% for 0.3Pt/CoAl). In sorbitol APR, the most relevant products were tetrahydropyran-2-methanol (THP-2-MeOH) and hydroxyacetone. Sorbitol HDO over 0.3Pt/CoAl catalyst yielded more hydrogenated liquids (higher H/C ratio) than sorbitol APR, which resulted in a higher yield towards liquids with low H/C and O/C ratio (Fig. 1).

**Keywords:** formic acid, funtionalized CNTs, glucose, vanadyl

**Introduction.** Starch is a lignocellulosic derivatives that can be valorized in an aqueous medium using heterogeneous catalysts to added-value chemicals such as formic acid (AF), which is an $H_2$ storage molecule [**1**]. As catalytic systems, one of the advantages of carbon nanotubes (CNT) as supports is the possibility of modifying their acid-base properties through a surface functionalization (CNT-f) [**2**], and in the active phase, the vanadyl cation ($VO^{2+}$) exhibits redox characteristics [**3**], which are essential for the starch conversion reaction. In this work, the catalytic conversion of glucose to formic acid in aqueous medium was used as a representative starch molecule on VO (10 wt%) supported on CNT and CNT-f (f= COOH and $NH_2$) catalysts denoted as VO/CNT, VO/CNTCOOH and VO/CNT$NH_2$

**Experimental/methodology.** The catalysts were syntetized by wetness impregnation of 10 wt% of VO on the CNT and CNT-f supports. The materials were characterized by X-Ray diffraction (XRD), physisorption of $N_2$ (BET)at 77 K and XPS measurements. The conversion of glucose (15 g*$L^{-1}$) was carried out in a batch reactor at 700 RPM, 30 bar of $O_2$, 140 °C and 50 mg of catalysts in aqueous medium.

**Results and discussion.** XRD of the VO-impregnated CNTs are very similar to the CNTs used as supports; the BET area of the supports decreases 38% due to the incorporation of VO. XPS analysis suggests that the CNTs are functionalized at a lower percentage than nominal. The VO leaches from the CNTs and CNT-f, in the first reation cycle. The solids are active in the catalytic conversion of glucose to FA, all exceeding 85% conversion of glucose at 140 °C and 180 min of reaction. At 20% isoconversion the selectivity to FA has the following order VO/CNT>VO/CNTCOOH>VO/CNT$NH_2$ with 57%, 54% and 45% respectively. The presence of vanadium leads to the catalysts being efficient in the production of formic acid as the major product.

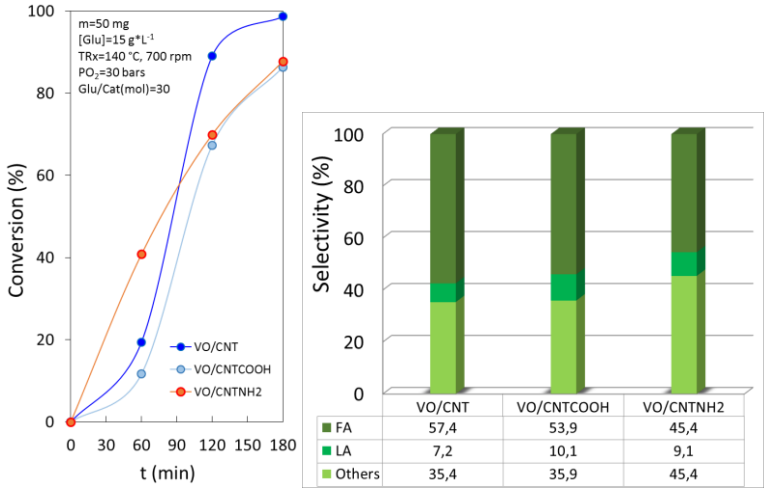

**Figure 1. Glucose conversion curves and selectivity to FA on VO/CNT-f catalysts.**

**Keywords:** Cellulose, Photoreforming, $TiO_2$, Carbon, Copper, Hydrogen.

**Introduction.**

The growing concentration of $CO_2$ in the atmosphere, mainly due to the high energy demand and the current model based on fossil fuels, is becoming a serious problem. Among the several approaches to address this problem, finding a suitable way to produce green hydrogen as an alternative fuel is a central one, for which the use renewable resources is mandatory. In this context, the present work deals with the photoreforming of biomass or biomass components or derivatives, like cellulose, using $TiO_2$-based photocatalysts [1]. In order to improve the efficiency of bare titania, photocatalyts have been prepared by means of doping it with carbon and/or by the incorporation of metal species.

**Experimental/methodology.**

A series of carbon-doped titania photocatalysts were prepared by hydrothermal synthesis of $TiO_2$ (12 h, 180 °C) using titanium tetraisopropoxide, and adding either sucrose [2] or graphene oxide as dopant sources. Bare $TiO_2$ was prepared, as well, by the same method and conditions. Copper was added to the composition of the resulting $TiO_2$ and $TiO_2$-C samples by impregnation with an aqueous solution of copper nitrate [3]. The following characterization tecniques were used: ICP-OES, XRD, XPS, and TEM. The photocatalytic activity tests were performed in a Heraeus UV-RS-2 glass reactor with a 150 W mercury lamp (365 nm), using 1 g cellulose, 20 mg photocatalyst and 500 mL distilled water. The generated gas was swept by He flow (60 mL/min) and continuously analysed by mass spectrometry. The resulting solution was analysed by ionic chromatography and by the determination of total organic carbon (TOC).

**Results and discussion.**

XRD data show that anatase is the crystalline phase of the synthesize photocatalysts. XPS results reveal that copper is mainly present as Cu(I) and/or Cu(0). The tested photocatalysts show, in general, a high hydrogen production (1500-1900 $\mu mol \cdot h^{-1} \cdot g \cdot cat^{-1}$), being the catalyst that contains carbon from succrose and copper the most active. The activity of these catalysts is noticeably higher than the previously determined for the commercial titania P25 (hydrogen production = 595 $\mu mol \cdot h^{-1} \cdot g \cdot cat^{-1}$) [3]. The obtained results show an important effect of both, carbon doping and metal incorporation, in the photocatalytic performance of $TiO_2$.

**Introduction**

In recent years, aqueous phase reforming (APR) of polyols and sugars is envisaged as a possible replacement of the current hydrogen production methods such as steam reforming and auto thermal reforming, given its low operating temperature, moderate pressures and not least, the ecological advantage of converting and utilizing biomass instead of fossil fuels [1]. Nickel catalysts in this reaction are known to have very good biomass conversions but also a strong selectivity for methane at the expense of the hydrogen final yield. Shabaker et al. [2] demonstrated how the addition of tin to Ni-Raney catalysts (Ni concentration >60%wt.) decreased the selectivity to the methanation reaction. In this study, we aim to substantially decrease the nickel concentration in the catalyst and by varying the reaction parameters, to preserve more than encouraging results on the APR process under batch conditions.

**Experimental/methodology**

Different compositions of $Sn_xNi_y/Ce(Zr)O_2$ were prepared by micellar-assisted synthesis and following reduction and sintering process. The catalysts were characterized by X-ray Powder Diffraction, $^{119}$Sn-Moessbauer spectroscopy, High Resolution-Trasmission Electron Microscopy, $H_2$-Temperature Programmed Reduction, $H_2$-Chemisorption and *ex-situ* X-ray Adsorption Spectroscopy. The APR reaction was carried out in a batch "Parr" reactor, processing an aqueous solution of ethylene glycol 6 % wt. at a screening temperature of 270 °C, an initial pressure of 20 bar and changing the initial pH.

**Results and discussion**

The combination of the information obtained from the X-Ray Powder diffraction and High Resolution-Trasmission Electron Microscopy analysis of the mixed metal oxides shows a fine dispersion and co-existence of the tin and nickel oxides within the $Ce(Zr)O_2$ catalytic support. The reduction process leads to the formation of two different combinations of $Sn_xNi_y$ alloys clearly differentiated and quantified by $^{119}$Sn-Moessbauer spectroscopy. The two different combinations of active metallic alloys make significant differences both in terms of conversion and hydrogen yield and in terms of selectivity in the methanation reaction in comparison with the monometallic nickel catalyst. It is also shown how a change in operating conditions, such as a change in the initial pH, influences the development of the reaction decisively.

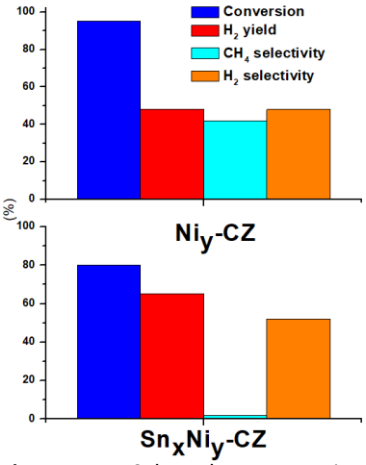

**Figure 1:** Selected comparative collection of conversion values, selectivity and hydrogen yield of a bimetallic $Sn_xNi_y$ catalyst and its monometallic counterpart ($Ni_y$).

**Introduction.** Biomass is considered a highly relevant sustainable source of energy and organic carbon for today's technological society, so that it is pivotal to industrial renewal for covering the future needs of chemicals, energy and fuels. Highly valuable chemicals that can be obtained from biomass are called platform molecules. Typically, they would find application in more than one industrial sector, and they would be crucial in future biorefinery schemes. Among them, 5-hydroxymethylfurfural (HMF) and levulinic acid (LA) show a great potential as they can be converted to newly recognized attractive chemicals, including 2,5-bishydroxymethylfuran (BHMF), gamma-valerolactone (GVL), dimethylfurfural (DMF) to name a few. The main challenge associated with the use of these intermediates is their rich chemistry and, hence, difficulties in getting high selectivity to the final targeted products. Therefore, we designed the methodology allowing the synthesis of metal nanoparticles of controlled size and location using a versatile photon-assisted method allowing for the tuning of the particle size to optimal value [1]

**Methodology**. The strategy of solar photon-driven assisted synthesis method uses the redox photoactivity developed by the surface of the host semi-conductor used as support when activated upon suited irradiation. It relies on the promotion of electrons from the valence to the conduction band of the semi-conductor, further able to reduce pre-adsorbed metal ions at the semi-conductor support surface [1]. 1%Ru/$TiO_2$ catalysts prepared according to this methodology were compared to their counterparts prepared by a span of standard methods. Their catalytic efficiency was tested in several reactions like: (1) hydrogenation of LA with formic acid as hydrogen source to GVL (biofuel additive) and (2) HMF hydrodeoxygenation towards DMF (biofuel additive) or BHMTHF (bio-plastic precursor).

**Results and discussion.** This versatile methodology allows for the synthesis of well-defined metal nano-particles on the support and additionally permits a fine control over both the size and the narrow distribution of the supported nanoparticles. Thanks to the control of synthesis parameters like irradiation time or photonic flux, we were able to elaborate catalysts with average Ru size of in the range 0.6- 4.9 nm. We demonstrated that the size of the Ru nanoparticles is one of the key parameter strongly influencing both activity and selectivity in the studied reactions. For example, an optimum nanoparticle size of 1.5 nm was observed for 1%Ru/$TiO_2$ in the case of LA hydrogenation with FA used as hydrogen source. Smallest Ru particles (0.6 nm) were very susceptible to sintering and carbon deposit formation, whereas too large particles influence the adsorption strength and did not provide enough active sites. Besides the dominant effect of the particle size, other parameters like metal-support interaction, Ru oxidation state, catalyst acidity and presence of residual chlorine from the $RuCl_3$ precursor in the upper monolayer were also thrully discussed.

a) HRTEM of a 1% Ru/$TiO_2$ catalyst with a Ru nanoparticle size centered on 0.6 nm. b) Influence of the Ru nanoparticle size on GVL yield [1]

**Introduction**

Levulinic acid (LA) is a well-known product of hexose sugar hydrolysis/dehydration and is inexpensively obtained by the decomposition of cellulosic feedstocks. Levulinic acid is an attractive platform material for the production of s range of chemical products, including methyltetrahydrofuran, γ-valerolactone, 1,4-propanediol, angelicalacotone, diphenolic acid and levuilinate esters (Fig. 1.). Among the various levulinic acid derivatives, γ-valerolactone (GVL), in particular, is of significant commercial importance, owing to its usefulness as a solvent, food additive, fuel component, and as a precursor for high-value chemicals (linear α-olefins, esters) and fuel range synthetic hydrocarbons. Although easily produced by hydrogenation of LA over Ru, the commercial usefulness of Ru-based catalysts for GVL production has been limited by deactivation issues resulting from (a) the leaching of Ru species through the formation of Ru–carboxylate complexes with levulinic acid (pKa ~4.59) in liquid phase (especially in water), (b) deposition of carbonaceous impurities (particularly in non-aqueous solvents) and (c) sintering and coking of Ru-nanoparticles in vapor phase reactions. The aim of the present work was to develop an active, selective, and stable catalyst for continuous hydrocyclization of aqueous LA to GVL under low-temperature conditions (≤100 °C).

**Experimental**

Aqueous phase hydrogenation of levulinic acid was performed under batch as well as, continuous flow conditions at 10 bar $H_2$ pressure using custom-made lab-scale reactors. In all experiments free flowing catalyst particles sized between 50–150 µm were used. All hydrogenation catalysts were obtained by the incipient wetness impregnation method using $RuCl_3.xH_2O$ as a Ru source.

**Results and discussion**

Herein, for the first time we demonstrate that surface acid-base properties of support have a marked effect upon the performance and stability of supported Ru catalysts upon hydrocyclization of aqueous LA to GVL in liquid phase. Among the tested catalysts, a bi-functional Ru/$NbOPO_4$/SBA-15 catalyst incorporating highly dispersed redox Ru sites and well balanced strong Brønsted acidic sites (optimum B/L and M+S/W ratio) outperformed the benchmark monofuncational (Ru/SBA-15, Ru/MCM-41) and physically blended bi-functional catalysts (Ru catalysts mixed with acid co-catalysts e.g. $NbOPO_4$/Amberlyst-15). Further, the catalyst also demonstrated remarkable stability in a fixed-bed reactor, maintaining high activity and GVL selectivity (72-86%) during ca. 300 h time on stream operating at 10 bar, 90-100 °C under varying $H_2$/levulinic acid flow rates, corroborating its potential for large scale GVL production under continuous flow conditions. The exceptional performance and durability of the bi-functional catalyst was attributed to the presence of well dispersed hydrothermally and chemically stable acid ($NbOPO_4$) and redox (Ru) sites.

# On the promoting effects of cobalt and nitrogen over copper-based catalysts to produce hydrogen *via* methanol steam reforming

J.L. Santos[1,*] and J. Gascon[1].

[1]*1KAUST Catalysis Center (KCC), King Abdullah University of Science and Technology (KAUST)*
[*]*jose.santos@kaust.edu.sa*

**Keywords:** $H_2$ production, MeOH steam reforming, copper-doped catalysts, bimetallic catalysts.

**Introduction.**

In the future energy transition away from fossil fuels for mobile applications, hydrogen appears to become a crucial energy carrier. Methanol Steam Reforming (MSR) is suggested as a possible alternative source to produce hydrogen, primarily because of its high yield and convenience. Although since 1985, $Cu/ZnO/Al_2O_3$ with a copper content of 35–50 wt.% has been the most used catalyst, several noble and non-noble metals, as well as groups 8-10 metals-based catalysts, have already been examined [1]. However, there is still a lack of knowledge about the catalytic performance of bimetallic systems. The promoter roles of cobalt and nitrogen in copper-based catalysts with low copper loading have thus been studied in this work.

**Experimental.**

A series of copper-zinc-based catalysts, supported on alumina and doped with cobalt and nitrogen, have been synthesized by coprecipitation. The co-precipitation of the nitrate salts was conducted for 48 hours at room temperature, with magnetic stirring, at a constant pH of 10 (enabled by $Na_2CO_3$ and NaOH). The solid was recovered by filtration after stirring, dried at 100°C overnight, and then calcined at 350°C for five hours. In a high throughput reactor system with four parallel stainless-steel reactors, feeding a 1/1 water/methanol combination, powdered and unreduced catalysts were tested from 150 to 350 °C. Additionally, a series of tests consisting of five successive cooling-heating cycles and a continuous cycle for more than 50 hours were used to assess the stability of the synthesized catalysts.

**Results and discussion.**

On a copper-zinc catalyst supported on alumina, the promoter effects of cobalt and nitrogen have been studied. The average particle size of metallic copper decreased with the addition of cobalt and nitrogen. At the same time, cobalt enhanced copper's reducibility, lowering its reduction temperature by more than 20°C. Nitrogen addition resulted in an increased aluminum loading, which reduced the quantity of copper leached through the formation of tetraamine copper (II) and did not change the copper's reducibility.

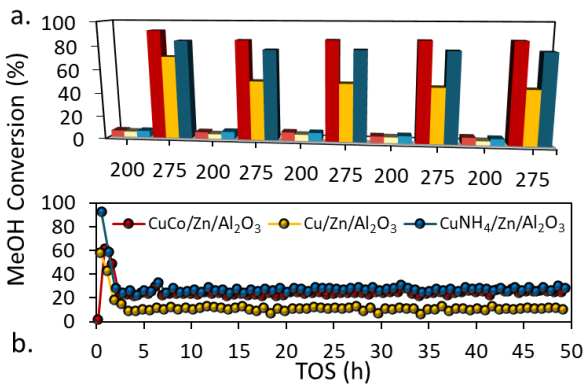

***Figure 1a.*** *Heating-cooling cycles test at 200 and 275°C and* ***b.*** *50 h. stability test.*

Although the catalytic performance of the copper-zinc catalyst was improved by both cobalt and nitrogen doping, the Co-promoted the Reverse Water Gas Shift (RWGS), lowering the hydrogen yield. Nitrogen doping, however, only enhanced the MSR reaction. The stability of the promoted copper catalysts remained unchanged over the time on stream, even after five cooling-heating cycles and more than 50 hours of reaction at 230°C.

**Keywords:** HDO, hydrodeoxygenation, lipids, fuel upgrading, biofuel

**Introduction.** There is a growing need for alternatives to fossil fuels for shipping and aviation [1]. In this research, we worked with lipids from black soldier fly larvae (BSFL) fed with sugars derived from municipal solid waste. Upgrading the fatty substance through hydrodeoxygenation could show to be a promising path for the generation of fuels coming from second-generation feedstocks. Research has been done on HDO of oils with a high oxygen content[2,3], although there is lacking research on BSFL lipid.

**Experimental/methodology.** The experiments were performed in a 500 mL size batch autoclave reactor at temperatures ranging from 250°C to 450°C and with initial hydrogen pressures between 30 barg and 70 barg. Lipid oil in wax form was supplied by Enorm Biofactory in Denmark while the NiMo/alumina catalyst used in the hydrodeoxygenation tests was synthesized using commercially available precursors.

**Results and discussion.** Oil samples were analyzed by elemental analysis for oxygen content. As expected, temperature and pressure had a significant impact on hydrodeoxygenation. An optimal temperature for lower pressures (30 bar abs initial pressure) was found to be at around 375 °C. At lower temperatures, higher oxygen removal was achieved with higher hydrogen pressure. Further work will be done to optimize these parameters.

**Table 1. Table of**

| Sample | Temperature (°C) | Pressure (bar abs) | Oxygen % |
|---|---|---|---|
| A | 350 | 30 | 1,991 |
| B | 350 | 70 | 0,293 |
| C | 450 | 30 | 0,418 |

# Oxidation of furfural to maleic acid on $LaCo_xFe_{1-x}O_3$@C catalysts

D. Díaz[1], C. Herrera[1,2], G. Pecchi[1,2], C. Sepúlveda[1,2*]

[1]*Depto Físico-Química, Fac Cs Químicas, Universidad de Concepción, Chile*
[2] *Millennium Nuclei on Catalytic Process towards Sustainable Chemistry (CSC), Chile*
[*]*cathsepulveda@udec.cl*

**Keywords:** furfural, oxidation, Co effect.

**Introduction**. Green Chemistry is oriented towards the design of chemical processes of renewable raw materials that reduces or eliminates the generation of waste and that allow obtaining products with high added value. Biomass is a renewable source that can be used for a large number of applications, where furfural is a promising platform intermediate molecule from hemicellulose transformation with several green applications, and its low oxygen content makes it a promising raw material in the fine chemical industry[1]. Maleic acid (MA) is one of the top 12 biobased molecules of the Department of Energy of US, and it can be obtained from furfural oxidation through 2(5H)furanone and 2-hydroxyfuran as intermediates[2, 3]. In this work the catalytic evaluation of $LaFeO_3$@C, $LaCoO_3$@C and $LaCo_xFe_{1-x}O_3$@C (x=0.0, 0.1, 0.3. 0.5, 0.7, 0.9, 1.0) perovskites in the oxidation of furfural is reported.

**Experimental/methodology.** The pure and substituted perovskites were synthesized using the citrate method and characterized by $N_2$ physisorption at 77 K, thermal programmed reduction ($H_2$-TPR), X-Ray diffraction (XRD) and thermal programmed desorption of $CO_2$ ($CO_2$-TPD). The catalytic activity was evaluated in a semi-batch reactor in the oxidation of furfural at 150 °C, 30 bar of pure $O_2$ and 50 mg of perovskites as catalysts.

**Results and discussion.**

The Figure 1 shows the selectivity calculated at 25% of furfural conversion over the perovskite@C catalysts, where almost 100% of MA selectivity on $LaFeO_3$@C catalyst is obtained. After Co addition, a drastically decrease of MA selectivity to around 60 % and 40% of 2-hydroxyfuran is detected over all Co-substituted and pure $LaCoO_3$@C. These results suggests that the presence of Co species change the oxidative properties of the $LaFeO_3$@C catalysts by formation of more stable intermediates on the catalytic surface such 2-hydroxyfuran. The physicochemical characterization results of the Co-substituted perovskite@C catalysts shows a modification of reduction temperatures of Co and Fe oxides, several changes in the intensity and temperature of $CO_2$ desorption signals and an important decrease of the specific surface area in comparison to pure $LaFeO_3$@C and $LaCoO_3$@C catalysts. These results suggest that Co addition promotes an interaction between Co and Fe oxides modifyng the electronic and basic properties which change the surface catalytic behavior.

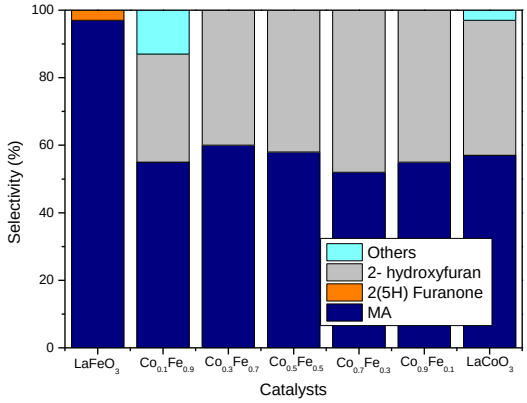

Figure 1: Selectivity at 25 % of furfural conversion.

# Protection strategy for selective oxidative esterification of HMF-dimethylacetal to dimethylfuran-2,5-dicarboxylate

*N. Sheet, N. Arai, J. J. Wiesfeld, R. Osuga, A. Fukuoka, K. Nakajima**
*Institute for Catalysis, Hokkaido University, Sapporo, Japan*
nakajima@cat.hokudai.ac.jp

**Keywords.** Protection strategy, biomass conversion, oxidative esterification, dimethylacetal functionality.

**Introduction.** 5-Hydroxymethylfurfural (HMF), a biomass-derived furan compound, is one of the versatile platform chemicals to produce various value-added building blocks of advanced biobased polymers.[1] However, chemical reactions of HMF accompanies severe and complex side reactions predominantly in concentrated solutions and produces insoluble polymerized species, so-called humins. Protection of the reactive formyl group with 1,3-propanediol (PDO) to form a six-membered acetal ring enabled the use of concentrated solutions (10-20 wt%) in various redox reactions and ensured high productivity of the intended products.[2-4] Herein, we applied dimethylacetal-protected HMF (HMF-acetal) in the oxidative esterification with supported Au catalysts for the stepwise synthesis of dimethylfuran-2,5-dicarboxylate (MFDC).

**Methodology.** HMF-acetal was prepared by the acetalization of HMF with methanol and supported gold catalysts were synthesized by the deposition-precipitation method.[3] Oxidative esterification reactions of HMF, HMF-acetal and MFFC-acetal (the dimethylacetal form of methyl 5-formyl-2-furancarboxylate) in methanol were conducted in pressure-resistant Teflon-lined stainless steel autoclave reactors. The mixture of a methanolic substrate solution (100 mg, 10-20 wt%), Au/$CeO_2$ (100 mg) and $Na_2CO_3$ (1 mol%) was stirred at 373 K for 2 h under pressurized oxygen (0.9 MPa). After reactions, the reaction mixtures were diluted with ethyl acetate (50 mL) to dissolve all products and analyzed with Gas Chromatography (Shimadzu, GC-2014).

**Results and Discussion.** Oxidative esterification of HMF-acetal at 10-20 wt% afforded MFFC-acetal exclusively in high yields (>90%). In contrast, the reactions of non-protected HMF under the same reaction conditions gave the mixtures of 5-hydroxymethylfuran-2-methyl carboxylate (MHFMC), MFDC and humin-type byproducts (Figure 1). Kinetics studies revealed that protecting highly reactive formyl group of HMF with dimethylacetal functionality not only suppresses byproducts formation but also facilitates the rate of first reaction step to convert -$CH_2OH$ in HMF-acetal to -$COOCH_3$ (Figure 2). The dimethyl-acetal group did not undergo oxidative esterification under such mild reaction conditions, while increase in reaction temperature resulted in severe byproduct formation, which prevents the direct synthesis of MFDC from HMF-acetal.

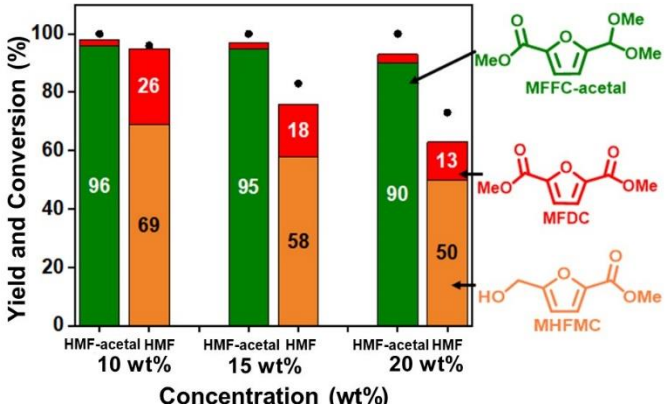

**Figure 1.** Oxidative esterification of HMF-acetal vs HMF.

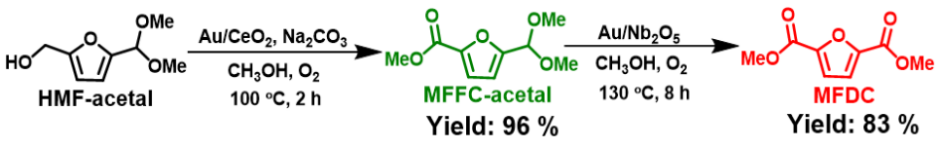

**Figure 2.** A stepwise route to synthesize MFDC from HMF-acetal with two supported Au catalysts.

Therefore, a two-step process was designed to synthesize MFDC selectively from concentrated methanolic solutions of HMF-acetal. The second step, oxidative esterification of MFFC-acetal to MFDC, was conducted with crude MFFC-acetal and Au/$Nb_2O_5$, which produces MFDC in an 83% yield (A 10 wt% MFFC-acetal solution, Au/$Nb_2O_5$, 130 °C, 0.9 MPa $O_2$, 8 h) (Figure 2). Thus, the present approach opens a new stepwise route for MFDC production with an HMF-acetal and two supported Au catalysts.

# Interfacial oxygen vacancy over Ni/CeZrOx catalysts for ethanol steam reforming: Ni-support interaction and resistance to coking

Mingyan Wang, Azam Jamsaz, Ngoc Nhiem Pham, Thi Van Anh Hoang, Eun Woo Shin*
*School of Chemical Engineering, Univerisity of Ulsan, Ulsan, Republic of Korea*
**Corresponding Author's E-mail address: ewshin@ulsan.ac.kr*

**Introduction.** Recently, ethanol steam reforming (ESR) has received great attention as an environmentally friendly and clean $H_2$ production process. Ethanol's advantages include its non-toxicity and ease of handling and transport. Moreover, when bioethanol produced mainly through fermentation of saccharide is used as a feed, carbon neutrality can also be achieved because $CO_2$ generated from reforming can be reabsorbed into biomass as a raw material [1-2]. Ni-based catalysts lead to a high hydrogen yield at high reaction temperatures due to their ability to cleave C–C and C–H bonds. It is well known that $Ce_xZr_{1-x}O_2$ supports have a high OSC with oxygen vacancies, which plays an important role in enhancing catalytic activity under reducing and oxidizing conditions [3]. Therefore, tracking the reaction pathway over oxygen vacancies is essential for not only elucidating the ESR mechanism but also finding a key property to improve the catalytic performance. In this study, two types of Ni/$CeZrO_X$ catalysts were separately synthesized with different Ni contents. The Ni/$CeZrO_X$ catalysts were prepared by impregnating Ni species into the $CeZrO_X$ support or by one pot (OM) method to investigate not only the formation of oxygen vacancies by Ni–support interaction but also the role of those vacancies in the coking behavior of ESR.

**Experimental/methodology.** The ethanol steam reforming tests were performed at atmospheric pressure in a fixed-bed vertical quartz tube reactor (450 mm in length and 10 mm in inner diameter). In all tests, 0.3 g of catalyst was placed on a frit inside the reactor with glass wool. The catalyst was reduced in situ in flowing $H_2$ (6 mL/min) with He (30 mL/min) at 750 °C for 2 h. The reaction tests were conducted for 8 h at 550 °C. The steam-to-carbon mole ratio (S/C) was fixed at S/C = 3 for every reaction test. The Ni/CeZrOx catalysts were characterized by various tools including $N_2$ adsorption-desorption technique, $H_2$-TPR, Raman spectroscopy, XRD, TEM, and XPS.

**Results and discussion.** From diverse characterization results, it was confirmed that the Ni/CZ-OM catalysts had highly dispersed Ni nanoparticle and well devoloped oxygen vacancy in the interfacial region,which was caused by the Ni-support interaction during the preparation process. Figure 1 shows the coke amounts generated during the reaction tests. A lot of coke were generated over the Ni/CZ catalysts while coking barely occurred over the Ni/CZ-OM catalysts. The high Ni dispersion and neighboring oxygen vacancy over the Ni/CZ-OM catalysts suppressed coking behavior during the ESR.

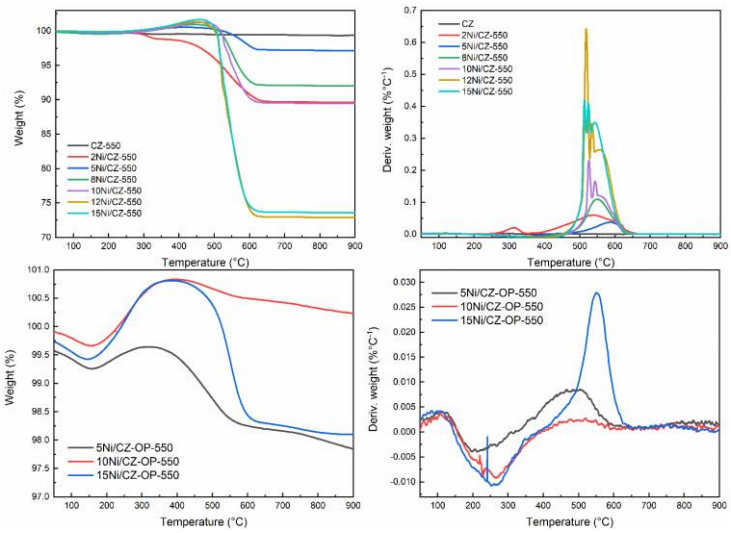

**Figure 1. TGA and DTGA results of the spent Ni/CZ catalysts.**

**Keywords:** nickel, sulfated-zirconia, xylitol, glycols, mono-alcohols

**Introduction.** Replacing fossil-based feedstocks with biomass-derived resources to produce renewable fuels and chemicals addresses chemical industries' challenges.[1] In this context, xylitol is one key intermediate platform to explore. It can be hydrogenated into a variety of important chemicals, such as ethylene and propylene glycol which are used as monomers in the synthesis of polyester fibers, antifreeze and coolants and butanediols used for manufacturing plastics and solvents.[2,3] This process can be achieved using bifunctional catalysts which contain both acid and metal sites.[4] Acid sites come from a solid support such as alumina, silica and sulfated-zirconia, while the metal sites are facilitated by a supported metal, such as Pt, Pd, Cu and Ni.[3,4]

**Experimental/methodology.** Bifunctional catalysts were synthesized using sol-gel method for the sulfated-zirconia support and wet impregnation to load Ni. The prepared catalysts were characterized using different techniques such as x-ray diffraction (XRD), inductively coupled plasma optical emission spectroscopy (ICP-OES), $N_2$ physisorption, scanning electron microscopy (SEM), transmission electron microscopy (TEM), temperature programmed reduction (TPR) and temperature programmed desorption (TPD). Catalytic testing was carried out in an autoclave at 50 bar $H_2$ pressure and 200 °C using 15 wt% xylitol as the feed.

**Results and discussion.** TPR confirmed that metal reduction was complete at 400 °C for all catalysts. TPD showed medium to high acid strength and high Ni dispersion on the support surface for the catalysts. Main products observed were ethylene, propylene and butylene glycol, glycerol, methanol and 1- and 2-propanol. An increase in calcination temperature of the catalyst support led to an increase in glycols selectivity.

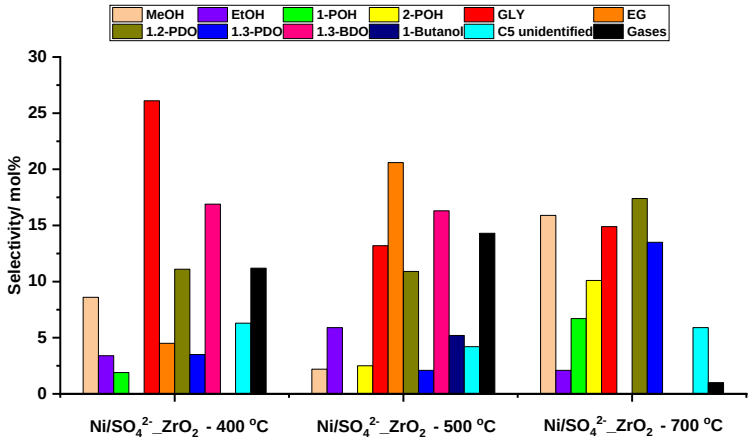

**Figure 1:** Selectivity of 15 wt.% Ni/$SO_4^{2-}$-$ZrO_2$ catalysts at 70% iso-conversion. Reaction conditions: 0.5 g catalyst, 15 wt.% xylitol, 50 bar $H_2$ pressure.

# Effect of iron on the dispersion of copper on alumina supported catalysts

L. Skuhrovcová[1*], J. Kolena[2]

[1]*ORLEN UniCRE a.s., Ústí nad Labem, Czech Republic*
[*]*lenka.skuhrovcova@orlenunicre.cz*

**Keywords:** iron, copper, catalysts, surface, support, alumina, hydrogenolysis, glycerol.

**Introduction.** Selective hydrogenolysis of natural polyols to lower alcohols is a promising way to phase out fossil materials from the petrochemical production system. Copper catalysts are commonly used for the hydrogenolysis of glycerol to 1,2-propanediol, which are a cheaper but less active alternative to noble metal catalysts [1,2]. A new impregnated Cu catalyst, modified with iron was prepared in the frame of this study. Its performance in the selective hydrogenolysis of glycerol to 1,2-propanediol was tested. The effect of iron addition was also studied in detail.

**Experimental/methodology.** The catalysts were prepared by impregnation with the use of the incipient wetness method followed by drying and calcination. Mesoporous y-alumina was used as the catalysts support, bimetallic water solution of Cu and Fe nitrates was used as the impregnation agent. The catalysts prepared were characterized by following methods: ICP analysis, thermal programmed reduction, X-ray diffraction. $N_2$ physisorption and SEM microscopy. Testing of the catalysts in the hydrogenolysis of glycerol was carried out in a tubular reactor at a temperature of 230 °C, pressure of 7 MPa with adjustable feed flow rate of hydrogen.

**Results and discussion.** It was found that a small addition of iron had a considerably positive effect on catalysts activity while the increase of iron amount above Fe/Cu ratio of 0.03 didn't lead to further increase of the activity and even decrease of the activity was observed above Fe/Cu of 0.1. It was disclosed that iron had a positive effect on forming fine dispersion of Cu particles on the catalysts surface and a small amount of iron contributed to the formation of egg-shell Cu profile in the cylindrical catalysts particles at the same time.

**Introduction**

Processing of biomass as a renewable energy source is still a potential alternative solution for the production of energy, fuels and chemicals [1,2]. Out of the three fractions it is composed of, the cellulose fraction is the most energetic [3]. The cellulose fraction is composed of glucose molecules linked by β-1,4-glicosidic bonds [4]. It is possible to decompose it with energy or chemical compounds by grinding, treatment with inorganic acids or with the participation of catalytic materials [5].

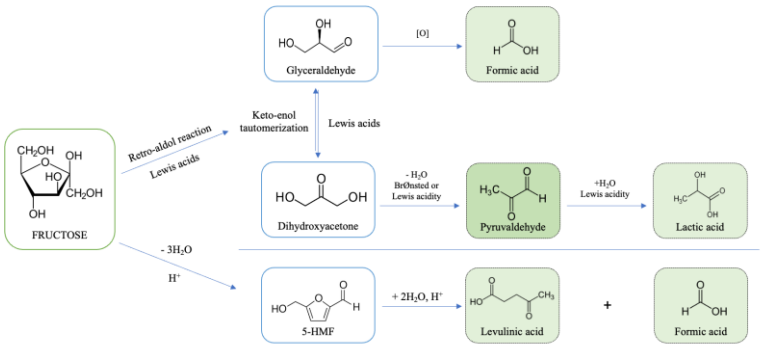

Fig. 1. Valorization of fructose to lactic, formic and levulinic acids.

**Experimental/methodology.**

MFI-based zeolite catalysts were prepared by ammonium exchange followed by ion exchange using $SnCl_4 \cdot 5H_2O$ and $FeCl_3 \cdot 6H_2O$ salts. The one-pot catalytic conversion of fructose was performed at 220 °C for 1-5 h. Identification of products formed in the post-reaction mixture were identified with the participation of GC

**Results and discussion.**

Lactic acid (LAC) was obtained with the yield of 68.7% (after 2 h) and levulinic acid (LA) with the yield of 70.9% (after 5 h) with the participation of MFI. In turn, formic acid with a yield of 28.5% (after 5h) was obtained with the participation of Fe-MFI.

**Keywords:** sustainable fuels, pyrolysis oil upgrading, catalytic hydrodeoxygenation

**Introduction.** The transportation sector is a large contributor to anthropogenic climate change, and the demand for green and sustainable technologies for shipping, air and land mobility has progressively increased over the past decades. Electric cars and hydrogen mobility has seen major technological advances and increased commercial availability in recent years. However, for sectors such as aviation and heavy transport, these technologies face many challenges especially regarding energy density. This deems them impractical and unlikely to be cost-effective alternatives to liquid fossil fuels. [1]

Renewable hydrocarbon fuels derived from biomass have recently drawn much attention as more sustainable alternative fuels. They can be easily blended with fossil fuels as drop-in fuels or fully replace in the aviation and heavy transportation sectors. Fast pyrolysis and catalytic fast pyrolysis are two widely applicable and low-cost processes used to convert solid biomass into a condensed bio-oil. [2,3] However, the produced pyrolysis oils are complex chemical mixtures with high water and oxygen contents, which limits their stability and applicability in internal combustion engines. By further upgrading by catalytic hydrodeoxygenation, the properties of pyrolysis oils can be improved significantly, where oxygen is removed through the formation of water with limited negative effect on the carbon yield. [2,4]

In this contribution, we present possible reactor designs for the catalytic hydrodeoxygenation of pyrolysis oils derived from biomass. Two intrinsically different systems are developed and compared to identify the optimal process design and parameters for an efficient, continuous hydrodeoxygenation of pyrolysis oils, and thus the production of sustainable biofuels.

**Experimental/methodology.** Catalytic HDO experiments have been conducted on two separate reactors: a continuous dual trickle bed reactor setup and continuous slurry type reactor design. The upgraded pyrolysis oils were analysed by high-precision liquid chromatography (HPLC-MS), Karl-Fischer titration for water content and total acid number (TAN) titration. The exhaust gas was analysed by on-line gas chromatography (GC) with a thermal conductivity detector (TCD).

**Results and discussion.** The dual trickle bed reactor design allowed for treating the pyrolysis oil under a temperature gradient. By introducing an initial stabilisation step at moderate temperatures (180-250 °C) before the hydrodeoxygenation at high temperature (350-450 °C) in the trickle bed reactor, catalyst stability was found to be improved significantly as reactor blockages due to coking was suppressed. Initial results from the slurry type reactor also shows great prospects for efficient hydrodeoxygenation. Research is ongoing to establish the most efficient design for the process.

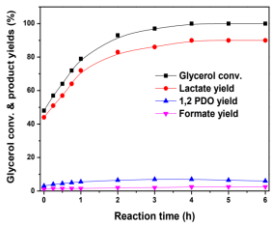
# Development of continuous reaction system for catalytic dehydrogenation of biomass



D. Y. Song, J. W. Min, J. H. Kim, I. H. Song*

*Korea Research Institute of Chemical Technology, Daejeon, Republic of Korea*
**Corresponding Author's E-mail address (*ihsong@krict.re.kr)*

**Keywords:** Dehydrogenation, CSTR, kinetics, Glycerol

**Introduction.**
This study aims to produce ethyl lactate from waste glycerol, and separates high purity ethyl lactate through carbonation and esterification. In this process, glycerol and KOH, raw materials, produce potassium lactate through dehydrogenation, and high-purity ethyl lactate is made through esterification with carbon dioxide and ethanol. In this study, we develop the reaction kinetics of glycerol dehydrogenation in order to design a continuous heterogeneous catalytic reactor.

**Experimental/methodology.**
To develop a reaction kinetics , the mechanism of the catalytic reaction was identified and a high-pressure dehydrogenation reaction was performed to measure the reaction rate of the mechanism. The reaction was conducted in a batch reactor of 1 L with 3%Pt/m-$ZrO_2$ catalyst 2.1 g, water 140 mL, glycerol 138 g (6M), and KOH 126 g (9M) loaded at the beginning of the operation. $N_2$ gas was purged at 1 bar and the vapor pressure was observed during the reaction.

| | k_ref [L²/mol/gcat/h] | E [J/mol] |
|---|---|---|
| $k_1$ | 8.34E-03 | 67329 |
| $k_2$ | 1.34E-04 | 90194 |
| $k_3$ | 6.55E-02 | 40176 |
| | Kad_ref [L/mol] | H [J/mol] |
| $K_G^{ad}$ | 2.90E-02 | -2907 |
| $K_{KOH}^{ad}$ | 6.43E-02 | -2123 |
| $K_{H_2}^{ad}$ | 3.59E-02 | -1735 |

**Results and discussion.**
Lactic acid (LA), formic acid (FA), acetaldehyde (AA), and propylene glycol (1,2-PDO; PG) were the main species observed in the experiment, probably due to very fast reaction rates of intermediates. Therefore, the overall reactions were considered for the conversion of glycerol, and the Langmir-Hinshelwood type rate equations were assumed. In the left figure, at 200 °C, glycerol was completely consumed in 4 h of batch time, while the reaction at 180 °C showed approximately 95% conversion, requiring more operating time for the complete consumption. However, the LA yield reached the maximum value of 90% for both temperatures, indicating that there exists a tradeoff for temperature between the batch time and energy consumption. Kinetic parameters were estimated by the aid of the lsqcurvefit function in MATLAB (MathWorks, Inc.) as summarized in the table. And with the kinetics, CSTR reactor was designed by simulation study. It was confirmed that target performance could be obtained by connecting three reactors in series.

**Keywords:** cellulose, vanadium-based catalysts, oxidation, formic acid

**Introduction.**
In recent years, several efficient catalytic systems have been developed to convert cellulose into value-added products. Carboxylic acids including levulinic acid, lactic acid, gluconic acid, acetic acid, and formic acid (FAc) were obtained by transformation of cellulose, glucose or disacharides [1,2]. FAc is an important raw material widely used in the chemical, textile, pharmaceutical, agricultural, and rubber industries. In recent years FAc has been proposed as a reversible source of hydrogen storage, for example for proton exchange membrane fuel cells as a possible hydrogen generator [3]. Currently, the production of FAc is based mainly on fossil resources. Therefore, the production of FAc from biomass can be considered as a promising alternative route to obtain hydrogen from renewable sources [4,5]. In this work, we report on a heterogeneous catalytic system for the oxidation of microcrystalline cellulose to FAc using different supported vanadium oxides as catalysts and water as the solvent.

**Experimental/methodology.**
Oxidation reactions were carried out in stainless steel autoclaves lined with PTFE at temperature of 200 °C, oxygen pressure of 1.0 MPa for 5 hours. The liquid samples were collected by removing the solid catalyst via centrifugation, and analyzed by HPLC method equipped with UV and RID detectors, using a HPX-87H column and 5 mmol $L^{-1}$ sulfuric acid aqueous solution as the mobile phase with a flow rate 0.5 mL $min^{-1}$. Contents of carbon dioxide in the gaseous mixtures were determined by GC equipped with TCD.

**Results and discussion.**

The results of a preliminary study of the cellulose oxidation showed a significant effect of different types of V-based catalysts on the distribution of oxidation products. The highest yield of FAc (65 %) was achieved using a Mo-V/$SiO_2$ catalyst. These results are similar to those obtained in a reaction system with a difficult to recycle heteropolyacid catalyst (the Keggin-type structure of $H_4PMo_{11}VO_4$). The Mo-V/$SiO_2$ catalyst was easily separated from the reaction mixture by filtration and used in subsequent runs. Three recyclings of the catalysts proved a good stability of the catalyst in the studied oxidation system.

This catalytic oxidation process promises to be a viable route for the syntheses of formic acid from biomass sources.

# Glycerol addition on liquid culture of *Escherichia coli* – evaluation work of microorganisms.

E. Strzelec[1*]

[1]*AGH, University of Science and Technology, Department of Fuel Technology, Cracow, Poland*
[*]*strzelec@agh.edu.pl*

**Keywords:** biocatalysts, glycerol, *Escherichia coli*

**Introduction.** Excess of glycerol is an unavoidable by-product in the biodiesel production process. Economic way, ecological solutions and applications for this abundant source of carbon in industry are sought. This poster focuses on the study of the effect of glycerol in the culture of non-metabolized *Escherichia coli* bacteria in a liquid medium.

**Experimental/methodology.** The number of bacteria was measured using a DEN-1 densitometer (BioSan). *Escherichia coli* bacteria were observed under the microscope before, during and after fermentation. The largest growth of bacteria on the medium with the addition of low and high concentrations of glycerin was obtained after three days, after which this number decreased in most measurements. The production of lactic acid during the growth of *Escherichia coli* bacteria in the lactose broth model medium was monitored by HPLC.

**Results and discussion.** Based on the obtained results, it can be concluded that unmodified *Escherichia coli* bacteria are a good biocatalyst in glycerol fermentation. One of the fermentation products is lactic acid according to the obtained UV-Vis spectra. HPLC evaluation showed that the *Escherichia coli* had reached the concentration of lactic acid (after 60 hrs fermentation) close to 0,5 g $L^{-1}$.

As a result, glycerol does not deactivate the bacterial environment, favors the growth of microorganisms, can be converted into organic compounds, and the final compounds obtained are mainly lactic acid.

The proposed process is dedicated to research on the applicability of such solutions in industry (e.g. Orlen company from Poland). The reason for this type of planned research, solutions and proposals for the petrochemical market is also the requirement of a percentage share of bioprocess technology in refineries (biorefineries). In addition, innovation consists in the use of unmodified bacteria and the use of crude glycerol - the omission of the technological process of purification significantly reduces costs. In result, the idea of this project fits perfectly into the Circular Economy policy.

**Keywords:** ethanol, butanol, butadiene, MgO, MgO-$SiO_2$, MgO-$Al_2O_3$,

**Introduction.** The formation of carbon-carbon bonds is of great importance in chemical technologies. Bioethanol, as a renewable source, can serve as raw material of important chemical products, such as, biofuels and biochemicals. Recently, the heterogeneous catalytic ethanol-coupling reactions, giving 1,3-butadiene (Lebedev reaction) or n-butanol (Guerbet reaction) were receiving special attention. It was proposed that the successive reactions of ethanol take place on a single multifunctional catalyst that either contains spatially separated active sites with hydrogenation/dehydrogenation, C-C coupling and optionally dehydrating activity, or on a catalyst in which ensembles of active sites are able to induce all the mentioned transformations of a 4-carbon activated surface complex.

A common intermediate of the Lebedev and Gourbet reactions is crotyl alcohol. The 1,3-butadiene is formed by dehydration, whereas butanol is obtained by hydrogenation of this intermediate. It is well known that over MgO-$SiO_2$ and MgO-$Al_2O_3$ mixed oxide catalysts butadiene and butanol is formed, respectively, with high selectivity. Neat MgO is also known to have a high catalytic efficiency in ethanol coupling, mainly producing butanol and crotyl alcohol. Our present study concerns the role of transition metal oxide additives on the ethanol coupling reactions.

**Experimental/methodology.** Structure and properties of catalyst preparations was characterized by XRD, STEM, EDS, N2 physisorption. The binding of acidic and basic adsorbates, such as CO2, $CDCl_3$, and $NH_3$, pyridine, respectively, to the catalyst surface was studied by TPD, and FT-IR measurements. Catalytic reactions were carried out using a fixed bed, continuous flow microreactor at atmospheric pressure. The adsorbed intermediate species formed in the reaction were identified by operando FT-IR measurements.

**Results and discussion.** Butadiene and butanol were the main ethanol conversion products formed over MgO-$SiO_2$ and MgO-$Al_2O_3$ catalysts, respectively, whereas butanol and crotyl alcohol were obtained over pure MgO catalyst. The effect of transitional metal oxide promoters was investigated on the activity of pure MgO. Over $Y_2O_3$, $Ga_2O_3$, ZnO, and CuO promoted catalysts the product distribution was similar to that obtained by pure MgO catalyst under identical reaction conditions. However, the conversion was slightly higher due to the Lewis acidic character of the additives and butadiene also appeared among the products. Relative to above mentioned catalysts, promotion of MgO by $Nb_2O_5$ or $Ta_2O_5$ resulted in higher dehydrogenating activity, and high butadiene selectivity, while the formation of butanol and crotonaldehyde was suppressed. High acetaldehyde selectivity showed that $In_2O_3$ promoter increased dehydrogenation activity. The modification $ZrO_2$ strongly enhanced dehydration, bringing about high butadiene and ethylene selectivities.

Catalytic test reactions using promoted mixed oxides are in progress, as well as, reactions of possible intermediates, and their mixtures.

**Keywords:** Fatty alcohol synthesis, homologation, ethanol

**Introduction.** C1-C6 aliphatic alcohols have diverse applications depending on their carbon chain length and structure and isobutanol has recently attracted attention for its properties as a drop-in fuel. Therefore, production of these fatty alcohols from renewable resources leads to realization of biorefinery. We have proposed a method to upgrade to desired C3 or higher (C3+) alcohols by using ethanol (EtOH) as a base feedstock and methanol (MeOH) as an homologation feedstock. Previously, we found that C3 or iso-C4 alcohols are produced by using $Cu/ZrO_2$ catalyst[1]. In this study, we clarified the reaction mechanism based on a kinetic model analysis to understand the catalyst design guidelines for upgrading to C3+ alcohols.

**Experimental/methodology.** The catalyst, 5 wt% $Cu/ZrO_2$, was reduced with $H_2$+Ar gas before the reaction as an activation process. In the synthesis experiment, the feedstock was vaporized, mixed with Ar, and fed to the catalyst bed set at 300°C at a given concentration. As operating factors, the MeOH/EtOH molar ratio was varied from 0-5 and the contact time (W/F) from 0.01-0.04 g·min/cm$^3$-cat. In each experiment, the component concentrations in the effluent gas were measured by on-line GC-TCD. The carbon-based yield $Y_i$ of component i was then calculated from the measured values at steady state.

**Results and discussion.** The kinetic model for the synthesis of C3+ alcohols from EtOH is based on the following reaction mechanism. A schematic diagram of the reaction mechanism considered is shown in Fig. 1. In the case of EtOH alone (a), the dehydrogenation of EtOH (step 1) is followed by aldol condensation of acetaldehyde(C2) (step 2) to form n-C4 aldehyde (n-C4 ald.) and subsequent hydrogenation (step 3) to form n-C4 alcohol (n-C4 alc.)[2]. The formation of ethyl acetate (EA) (step 4) was considered as a side reaction. Next, in the case of EtOH+MeOH (b), the aldol condensation and hydrogenation of C2 with MeOH was considered to result in the homologation and branching of the carbon chain from n-C3 species to iso-C4 species (steps 5-8). In addition, further homologation (step 9) was also considered. As side reactions, the formation of methyl acetate (MA) from C2 (step 10) and the formation of CO and $CO_2$ from MeOH (steps 11 and 12) were also considered. In addition, the formation of acetic acid (C2 acid) and crotyl alcohol (Cro. alc.) (steps 13, 14) were also considered[3,4]. The formation of alc. by direct coupling of EtOH or EtOH with MeOH was also considered (steps 15-18) since the parallel formation of alc. and ald. was observed in the experiments on the effect of W/F. The reaction in each step is assumed to follow the Langmuir-Hinshelwood mechanism and the model equation was derived. The model constants were estimated by fitting the experimental results at varied MeOH/EtOH ratio and W/F.

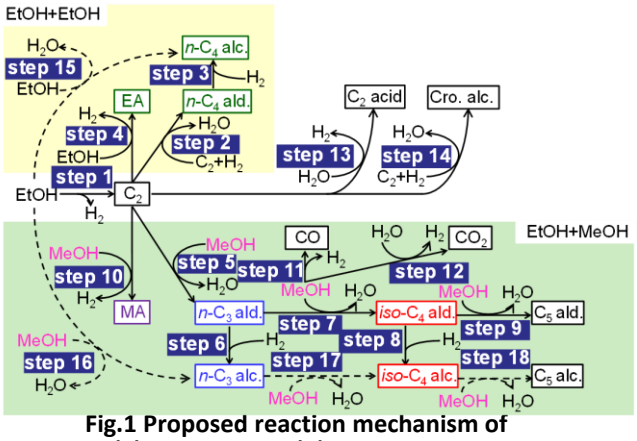

**Fig.1 Proposed reaction mechanism of (a)EtOH + EtOH, (b)EtOH + MeOH**

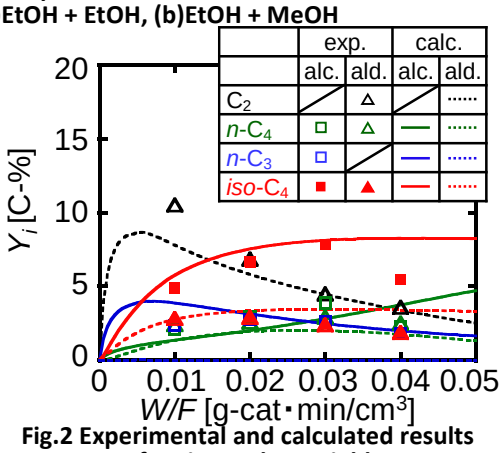

**Fig.2 Experimental and calculated results of main products yield**

Fig. 2 shows the effect of W/F on the main product yield at MeOH/EtOH=2. The calculated results (line) are in good agreement with the experimental results (plot), indicating that the reaction mechanism was captured by the model.

# Aldol condensation of furfurals with acetone: challenges and opportunities

A. Tampieri[1,2], N. Barrabés[1], F. Medina[2], K. Föttinger[1*]

[1]*Institute of Materials Chemistry, Technische Universität Wien, Vienna, Austria*
[2]*Chemical Engineering Department, Universitat Rovira i Virgili, Tarragona, Spain*
[*]*karin.foettinger@tuwien.ac.at*

**Keywords:** Aldol condensation, hydrotalcite, *in situ*/*operando*, ATR-IR, NMR.

**Introduction.** In response to the environmental changes due to the utilization of fossil fuels for the production of energy and chemicals, biomass has been proposed as an alternative and sustainable raw material. Bio-derived furanic aldehydes such as furfural and 5-hydroxymethylfurfural (HMF) can undergo aldol condensations with acetone to yield condensation products with higher carbon numbers that are precursors to renewable hydrocarbon fuels, polymeric materials and dyes [1]. Much research has focused on heterogeneous catalysts; in this regard, Mg:Al hydrotalcites and derived solids proved to be premium aldol condensation catalysts [2]. The use of heterogeneous catalyst could facilitate the purification processes, and they could be designed to drive the selectivities; however, the high oxygen content of bio-derived molecules and the presence of multiple unsaturations promotes the establishment of strong interactions with the catalytic surface, which may lead to deactivation [3].

**Experimental/methodology.** The parent Mg:Al hydrotalcites were synthesised via the coprecipitation method; the hydrotalcites were calcined to obtain the corresponding mixed metal oxide; this solid was immersed in pure water to obtain the rehydrated hydrotalcite. Our previous work includes extensive characterisation of the catalysts [3], while the present work focuses on the use of FT-IR and UV-Vis. The catalysts were tested in the neat liquid-phase aldol condensation of furfurals with acetone in a round bottom flask, and the collected liquid samples were analysed by GC-FID. Online and *in situ*/*operando* ATR-IR and in situ NMR were also used to study the catalytic system under operation.

**Results and discussion.** The results of the catalytic tests of the cross-condensations and of the self-condensation of acetone allowed the comparison of the different reactivity of the two aldehydes. These results, together with the spectroscopic studies of the liquid and/or solid phases, were used to gather insights into the reaction and deactivation mechanisms. Online and *in situ*/*operando* ATR-IR was used to monitor the reaction over time and to study the interaction of the reaction species with the solid catalyst, especially the formation of deactivating organic matter that covers the surface. *In situ* NMR was used to study the ongoing reaction, assessing its stereoselectivity, and to study the reaction of deuterated species in the catalytic system, shedding light on the behaviour of elusive intermediates. NaOH was also used as a catalyst to gather additional mechanistic information.

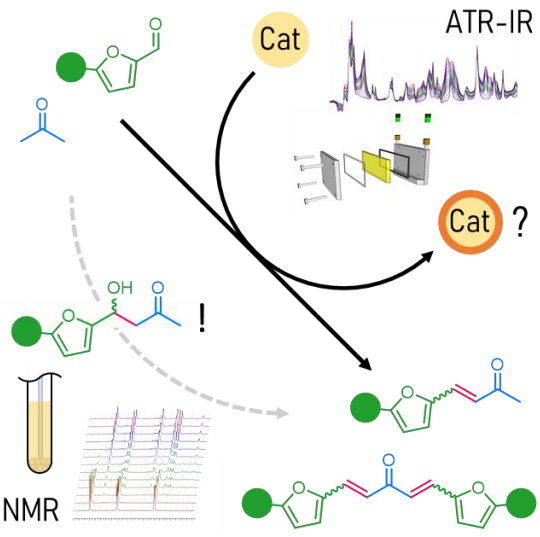

**Figure 1. Aldol condensation of furfurals with acetone, and main findings.**

# Utilizing Deep Eutectic Solvents (DES) for the Enhanced Production of 5-Hydroxymethylfurfural and Furfural from Biomass in Innovative Multiphase Systems

N. Thanheuser,[a,c] J. Esteban,[b] A. J. Vorholt,[a] W. Leitner [a,c]

*[a]Max Planck Institute for Chemical Energy Conversion, Mülheim an der Ruhr, Germany; [b]Department of Chemical Engineering, The University of Manchester, Manchester, United Kingdom; [c]Institut für Technische und Makromolekulare Chemie, RWTH Aachen, Aachen, Germany.*

**Keywords:** Biomass, Multiphase Catalysis, 5-Hydroxymethylfurfural, Furfural; Deep Eutectic Solvents

**Introduction.** Owing to fossil-based resource depletion, the valorization of lignocellulosic biomass derived sugars has gained more interest for the production of chemicals. 5-hydroxymethylfurfural (HMF) and furfural are highly valued building blocks that can be obtained by the dehydration of glucose, fructose and xylose. To prevent the formation of undesired side reactions that occur in monophasic aqueous systems, a multiphase approach can be followed, whereby a reaction with *in situ* extraction takes place, utilizing the concept of process intensification .[1,2] With regard to Green Chemistry, the choice of solvents is a matter of interest. Therefore, environmental, health and safety (EHS) as well as the performance of the chosen solvent have to be considered. Several solvent selection guides have been established taking the EHS parameters into account.[3] To assess the performance, the Conductor-like Screening MOdel for Real Solvents (COSMO-RS) is a proven tool for screening different candidates based on structural information of the molecules. COSMO-RS screenings among a pool of selected solvent candidates gave methyl propionate and ethyl acetate as best performing extraction phases. As for the reaction phase, even though water provides a safe and productive reaction medium, it promotes the unwanted ring opening rehydration of HMF to formic and levulinic acid and self-condensation leading to undesired polymers and humins.[4]

DES are formed by the combination of a hydrogend bond acceptor (HBA) and donor (HBD), amongst being classified as green solvents, provide a higher selectivity towards HMF and suppress rehydration of the product thus by-product generation. The formation of DESs with acidic HBDs (e.g. carboxylic acids) initiates the acid catalyzed dehydration reaction. Applied in a biphasic reaction approach, which provides easier product separation, they potentially improve yields and selectivity towards HMF.

**Experimental/methodology.** In a biphasic system with MIBK as extracting phase, dehydration reactions were performed undermicrowave irradiation with ethylene diaminetetraaceticacid (EDTA) as a catalyst due to its thermomorphic behaviour at temperatures above 140 to 170 °C. Dehydration reactions employing DESs in a biphasic system were carried out under reflux between 80 and 100 °C.

**Results and discussion.** For an aqueous reaction phase, MIBK shows a promising performance with the advantage of not undergoing hydrolysis under the typical acidic conditions of the reaction compared to methyl propionate and ethyl acetate. The modification of the reaction phase to DESs, resulted in an almost complete suppresion of by-product formation. The best result $Y_{HMF}$= 51 %; $X_{Fructose}$ = 92 %; $S_{HMF}$= 55 % was observed at 80 °C after 0.5 h with no formation of formic and levulinic acid as well as no formation of solid by-products (humins). Since the partition coefficients observerd for HMF and Furfural were not as high as in the case of aqueous biphasic systems, a COSMO-RS solvent screening for the extraction of HMF from Choline-Chloride:Oxalic acid DES was performed. *α*-pinene and *n*-heptane were experimentally tested due to their high ranking in the predictions, but extraction performance compared to MIBK proved worse. However, acetonitrile is a promising extraction agent,[5] which in combination with a self-consuming DES system made of ChCl and various C6 and C5 carbohydrates, offers a possible reaction system.

**Keywords:** biomass valorisation, furfural oxidation, high-throughput experimentation

**Introduction.** Reducing the carbon footprint of chemical industries involves the use of biobased compounds, such as furfural (FF) which is a renewable platform molecule[1]. Base-free oxidation of FF using metal catalysts is a sustainable approach to produce furoic acid (FA) and maleic acid (MA)[2]. In this study, bimetallic $Au_xPt_y$ and $Au_xPd_y$ catalysts with different metals ratios supported on $TiO_2$ were tuned to provide experimental evidence for the modulation of their selectivity to FA and MA in FF conversion.

**Experimental**

Bimetallic systems have been synthesized using the REALCAT high-throughput platform, by applying a DoE methodology (central composite design) to study 2 different parameters (metal loading and metals ratios) on the selectivity of the FF oxidation reaction. All catalysts were characterized using different techniques such as Inductively coupled plasma (ICP) and X-Ray Diffraction (XRD). Furfural oxidation tests using the bimetallic catalysts were carried out on the REALCAT platform in a Screening Pressure Reactors system (SPR) from UnchainedLabs.

**Results and discussion.**

The selectivities of $Au_xPt_y$ and $Au_xPd_y$ bimetallic systems supported on $TiO_2$ with different molar ratios (1:3, 1:1, and 3:1) and metal loading (0.5, 1.25, and 2%) in the various products of oxidation of furfural are shown on Figure 1 at isoconversion of FF (around 30%). The products distribution changed significantly depending on the composition of the catalytic system[3]. Au-Pd systems were found to generally exhibit a higher selectivity towards FA than Au-Pt systems. Gold-rich catalysts promote the oxidation of FF to FA and MA selectivity is dependent on the amount of Pt or Pd.

Studying the composition and the structure of the Au-Pd and Au-Pt bimetallic catalysts is a key factor for designing more active catalysts and to find the relationships between their structures and their catalytic performances.

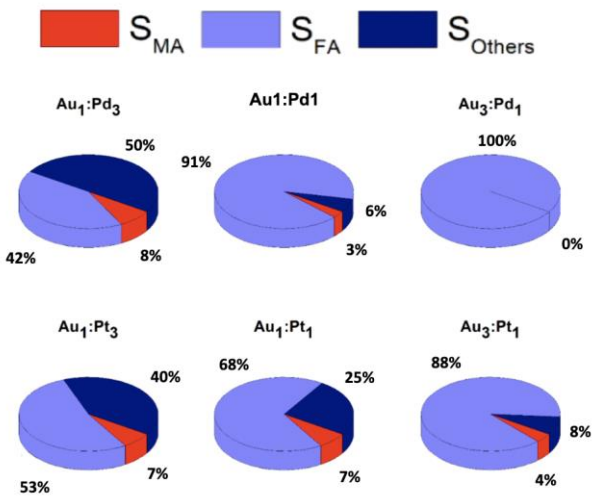

**Figure 1 : Selectivity charts for the bimetallic catalysts (at similar conversions, 30%)**

# Oxidative cleavage of vicinal diols over Fe/MFI: correlation of Fe speciation with catalytic activity

P. Treu[1*], B. B. Sarma[1,2], J.-D. Grunwaldt[1,2], E. Saraci[1,2*]

[1]*Institute of Catalysis Research and Technology, KIT, Eggenstein-Leopoldshafen, Karlsruhe, Germany*
[2]*Institute for Chemical Technology and Polymer Chemistry, KIT, Karlsruhe, Germany*
**philipp.treu@kit.edu, erisa.saraci@kit.edu*

**Introduction.** Oxidative cleavage of vicinal diols where each carbon is oxidized to an aldehyde or carboxylic acid is an attractive way of upgrading bio-derived polyols [1]. Supported monomeric Fe catalysts, in particular, have shown efficiency in the oxidation of methane [2] while also being a comparatively cheap, benign and sustainable heterogeneous catalyst material. Here, we show the unprecedented use of Fe/MFI catalysts in the oxidative cleavage of C–C bonds of ethylene glycol (EG) as model compound in biomass derived platform molecules.

**Experimental/methodology.** Catalysts with different Fe-loadings were prepared *via* incipient wetness impregnation. UV-Vis in combination with electron mircroscopy (STEM), X-ray absorption spectroscopy (XAS) and $N_2$-physisorption were used to study the Fe-speciation on the zeolite support. Catalytic activity tests were used to derive structure-activity relationships, elucidating the active site of the catalyst.

**Results and discussion.** Up to a loading of 0.5 wt% monomeric Fe-sites are the dominating Fe-species, while at higher loadings an increasing amount of oligomeric and even bulk $Fe_2O_3$ can be observed (Figure 1a). Additionally, the reaction rate of the oxidative cleavage of EG increased linearly with to 0.5 wt% Fe then it leveled out for higher Fe-loadings (Figure 1b, black plot), while the turnover rate (TOR) decreases steadily with increasing Fe-loading (Figure 1b, red plot). The correlation between the nature of the Fe-sites and activity can be seen in Figure 1c, where the TOR is plotted against the relative amounts of monomeric and oligo+bulk species. Notably, the monomeric Fe-sites are responsible for the increasing TOR of the reaction, while oligo+bulk Fe-species have no major contribution to the catalytic activity and may even be detrimental. These results demonstrate that the optimal catalyst for the heterogeneously catalyzed EG cleavage should have well distributed monomeric Fe-sites and no/minimal amount of oligomeric/bulk Fe species [3]. In addition, investigation of the active Fe-species using operando XAS measurements show the state of the catalyst under reaction conditions, further underlining the importance of monomeric Fe-species**.** Bulkier molecules containing vicinal diol groups were also tested showing the relevance of Fe/MFI catalysts for this reaction, providing new capabilities the valorization of biomass *via* oxidative cleavage.

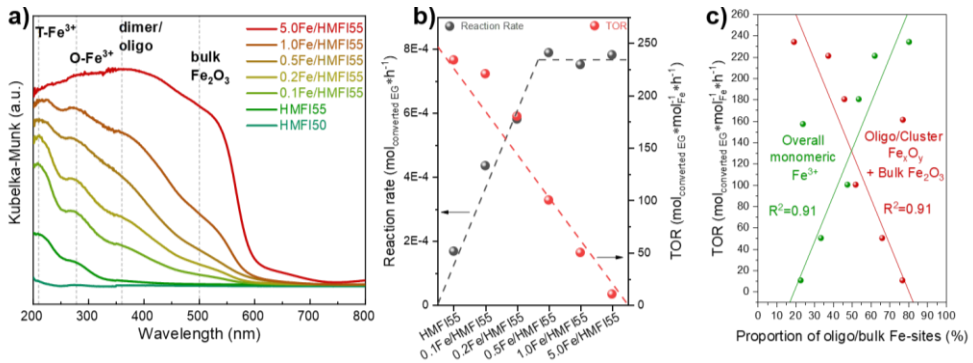

**Figure 1. a) Diffuse reflectance UV-vis spectra of Fe/HMFI55 catalysts. Absorption wavelength positions of various Fe-species are shown by the dotted lines. b) Reaction rate and TOR of HMFI55 with varying Fe-loading. Dashed lines are provided to guide the eyes. Reaction conditions: $n_{EG}$=0.715 mmol; $n_{H_2O_2}$=3.6 mmol; $V_{H_2O}$=10 ml; $m_{cat}$=100 mg; T=323 K. k has been calculated at interpolated reaction time for X=50%. c) Positive and negative correlation between TOR and relative amount of monomeric and oligomeric/bulk Fe-species, respectively.**

**Keywords:** methane, hydrogen, reforming, nickel

**Introduction.** In recent years, the world has begun an intensive study of processes involving biogas as an alternative source of not only energy, but also raw materials for petrochemical production due to the inevitable depletion of non-renewable energy sources and raw materials for petrochemical production. Biogas, resulting from the anaerobic fermentation of biomass and any organic waste, is a practically inexhaustible renewable resource for obtaining valuable products such as hydrogen, synthesis gas and hydrocarbons.

**Experimental/methodology.** The results of carbon dioxide reforming of $CH_4$ (model biogas) on the Ni-Co-Mg-Ce catalysts prepared by solution combustion synthesis (SCS) and impregnation of moisture capacity methods were compared. The studies were carried out at various space velocities, temperatures, composition of the reaction mixture and other parameters. $CH_4$ and $CO_2$ diluted with an inert gas (Ar) in the presence and absence of water vapor was used for reforming.

**Results and discussion.** Dry reforming of methane was studied at GHSV = 860 $h^{-1}$ and the ratio of the components of the reaction mixture $CH_4 : CO_2 : Ar = 33.3 : 33.3 : 33.3$ as well as at GHSV = 2500 $h^{-1}$ when the ratio of the components of the mixture of $CH_4 : CO_2 : Ar = 46.7 : 23.3 : 30.0$. Figure 1 shows the effect of space velocity and the addition of water vapor on the conversion of raw materials and the yield of reaction products. It can be seen from the figure that when the space velocity decreases from 2500 $h^{-1}$ to 860 $h^{-1}$, the $CH_4$ conversion, the yields of $H_2$ and CO increase, and the addition of water vapor further increases the conversion of the feed and the yield of $H_2$.

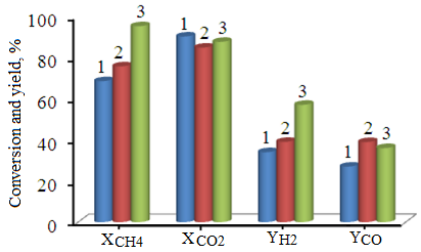

**Fig. 1. The effect of space velocity and the addition of water vapor on the conversion of raw materials and the yield of reaction products. 1 - 2500 $h^{-1}$ – $H_2O$, 2 - 860 $h^{-1}$ – $H_2O$, 3 - 860 $h^{-1}$ + $H_2O$**

Similar experiments were carried out on the same composition of the catalyst, prepared by the method of impregnation by moisture capacity at space velocities of 860 and 2500 $h^{-1}$ at 850 and 900°C in the presence and absence of water vapor. Comparative results show that the preparation of catalyst by impregnation is inferior to the SCS method, in which higher values of feed conversion and $H_2$ yield are obtained. As a result of the temperature change, it was found that carrying out the process at 900°C allows one to achieve high values of both yield and selectivity for $H_2$ and CO, but the $H_2$/CO ratio decreases from 6.1 (T = 700°C) to 3.9 (T = 900°C) at GHSV = 2500 $h^{-1}$. The characteristics of the catalysts by BET, XRD, TEM, SEM, TPD methods were determined and the features of the synthesis of spinels and metal alloys, which play a decisive role in the activation of the samples, were analyzed.

**Keywords:** Furfural, aldol condensation, hydrodeoxygenation, NiCu, $SiO_2$, γ-$Al_2O_3$, SIRAL 1

**Introduction.** Furfural is a platform molecule which can be obtained from dehydration of biomass-derived sugars, and is expected to play a vital role in future biorefineries [1]. In a promising route to produce diesel and jet fuels, for example, furfural condensation with acetone is performed to produce species with adequate carbon numbers, 4-(2-Furyl)-3-buten-2-one (FAc) being one of the main products. Subsequent hydrodeoxygenation (HDO) of the condensation products results in a blend of stabilized molecules with improved energy density. However, the used HDO catalyst should be able to transform a variety of moieties, i.e. furan rings, unsaturated bonds and carbonyl groups, which is challenging. Prior work has shown that the utilization of acid sites at mild HDO temperatures is crucial to achieve a complete removal of the oxygen moiety and to induce ring opening, but can lead to coking as well [2,3]. Moreover, the use of NiCu has been found to be effective in the hydrogenation of these biomolecules [3]. An investigation is, however, yet to be performed on the acidity effects of NiCu catalysts in FAc HDO at mild conditions. In this work the support used for the NiCu catalyst is systematically varied from non-acidic to mildly acidic and the effects on hydrogenation, hydrodeoxygenation, ring opening and coking are assessed.

**Experimental/methodology.** The catalysts were synthesized using incipient wetness impregnation of the metal precursors: $Ni(NO_3)_2.6H_2O$ and $Cu(NO_3)_2.3H_2O$ on $SiO_2$, γ-$Al_2O_3$ and SIRAL 1. Ni and Cu (ratio Ni/Cu = 1/1 mol/mol) were added in 20 wt%. Hereafter, the catalysts were calcined at 450 °C for 4 h. The catalysts were characterized via $N_2$- sorption, $NH_3$-TPD, $H_2$-TPR, XRD, XPS and TEM-EDX. The catalyst performance was assessed in a 300 mL high-pressure batch reactor. 1 g of 4-(2-Furyl)-3-buten-2-one and 150 mL of solvent was loaded into the reactor. The system was then heated up to the desired reaction temperature and pressurized with $H_2$ under slow stirring speed (100 rpm). Once the reaction conditions were reached, the stirring speed was set to 1000 rpm, and the start time was noted. Samples were taken at regular time intervals during the course of reaction.

**Results and discussion.** The effect of acid sites on the reaction mechanism of FAc HDO has been elucidated. The necessity of support acidity is clear, since the $SiO_2$ supported catalyst could practically only hydrogenate FAc. A bifunctional catalyst is thus necessary at mild HDO conditions where metal sites hydrogenate the reactant and acid sites break the C-O bond. Preliminary results have shown that stronger acid sites however result in more coking. The best performing catalyst is further used to optimize the reaction conditions to maximize the yield of hydrocarbons.

# Biogas reforming over Ni supported on hierarchical zeolites: The effect of biogas composition and $O_2$ co-feeding

Amanda de C. P. Guimarães[1], Andressa A. A. Silva[2], Rita de C. C. Simões[2], Cristiane A. Henriques[1], Lisiane V. Mattos[2*]

**Keywords:** Dry reforming, biogas, hierarchical zeolites.

**Introduction.** Biogas presents high levels of $CO_2$, resulting in emissions into the atmosphere that contribute to the greenhouse effect increase. The conversion of biogas into synthesis gas by $CO_2$ reforming of methane (DRM – dry reforming of methane) has been considered a promising alternative for obtaining products with a higher added value, such as $H_2$. Ni-based catalysts have been extensively studied for the DRM due to their low cost and high activity, but this metal is prone to coking. The nickel particle size significantly affects the nucleation rate of carbon. Thus, one approach to minimize carbon formation is to control metal particle size and avoid metal sintering by using support with a high surface area, such as zeolites. Catalysts supported on zeolites are widely used due to their unique properties, such as high thermal stability and uniform microporosity. The use of hierarchical zeolites, obtained from desilication and dealumination/desilication processes, promote the increase of mesopores to increase the accessibility of pores and active sites and confine metallic nanoparticles. Therefore, catalysts supported on hierarchical zeolites have been identified as promising for biogas reforming. Adding oxygen to the feed can also avoid carbon formation and decrease the energy input required in the reformer since the partial oxidation of methane is an exothermic reaction. Moreover, fluctuations in the biogas composition can affect the catalysts' performance, which depends on the organic matter. Then, this work aims to study the effect of feed composition on the performance of Ni (1 and 3 wt.% of Ni) supported on ZSM-5 and USY zeolites with a hierarchical porous system during DRM.

**Experimental/methodology.** ZSM-5 zeolite was desilicated with sodium carbonate to form mesopores [1], while USY zeolite underwent two subsequent treatments, dealumination with $H_4$EDTA and desilication with sodium hydroxide and TPAOH to form the hierarchical structure [2]. The catalysts were characterized by X-ray diffraction (XRD), scanning electron microscope (SEM), and nitrogen adsorption. DRM was carried out at 1073 K with a 1:1 $CH_4/CO_2$ molar ratio during 24 h time on stream (TOS). The catalyst with the best performance was also tested at a 1.5:1 $CH_4/CO_2$ molar ratio and 1.5:1:0.25 $CH_4/CO_2/O_2$ molar ratio.

**Results and discussion.** The X-ray diffractograms of the catalysts are similar to that of the respective parent zeolite, showing that the treatments performed did not cause the structure collapse. For both zeolites, no significant changes were observed in the volume of micropores after the alkaline treatments. However, the results showed that the alkaline treatment caused an increase in mesoporosity compared to the parent zeolites. Besides, the ZSM-5 zeolite has a greater volume of mesopores than the USY. The values of initial methane and $CO_2$ conversions were slightly higher for the desilicated 3Ni/ZSM-5, but all samples presented a deactivation during the reaction. Comparing the catalysts supported on zeolite of the same topology, the increase in Ni content and volume of mesopores led to an increase in the catalytic activity. With increasing $CO_2$ concentration in the feed, the $H_2/CO$ molar ratio slightly decreases due to the reverse Boudouard reaction. Thus, at a $CH_4/CO_2$ molar ratio of 1.5, $H_2$ selectivity is favored. The addition of $O_2$ to the feed increased the $H_2/CO$ molar ratio from 0.66 to 1.0. Furthermore, the presence of $O_2$ improved the catalyst stability during 24 h TOS for DRM. This increase in stability was likely due to the lower carbon formation.

**Introduction.** Ni-based catalysts have been studied for the DRM due to its low cost and high activity but Ni is prone to coking, with carbon formation being favored in large Ni particles. Thus, new preparation methods have been proposed in the literature aiming at a better control of the Ni particle size during the DRM reaction and, consequently, an improved resistance to carbon deposition (1). The desilication of MFI-type zeolites has been shown to be an efficient post-synthesis method for generating mesoporosity by preferentially removing Si from the interior of the crystals through the use of an alkaline solution. These new structures could maintain the metallic particles confined, preventing their sintering (2). Therefore, the main objective of this work is to evaluate the effect of alkaline solution concentration and Si/Al ratio on the performance of Ni catalysts supported on desilicated HZSM-5 zeolites for DRM.

**Experimental/methodology**. A series of commercial ZSM-5 zeolites with different $SiO_2/Al_2O_3$ molar ratio (23, 50, 80, 280, Zeolyst) were used as supports. The zeolites were calcined under $N_2$ at 525°C for 12h. The catalysts were prepared by incipient wetness impregnation of the supports with an aqueous solution of $Ni(NO_3)_2{\cdot}6H_2O$ in order to obtain 1 wt % of the metal. The fresh catalysts were treated with an aqueous solution of $Na_2CO_3$ at two different concentrations, 0.3 and 0.6 mol/L, at 80 °C for 12h (3). Then, all samples were reduced under $H_2$ atmosphere at 800°C for 30min. The desilicated samples will be designed as Ni/ZX_Ydsc, where X is the $SiO_2/Al_2O_3$ molar ratio and Y is the concentration of $Na_2CO_3$. The catalysts were characterized by $N_2$ adsorption, XRD, SEM, TEM and TGA. DRM was carried out at 800°C, using a $CH_4$:$CO_2$ molar ratio of 1.0.

**Results and discussion.** The $N_2$ adsorption/desorption isotherms results revealed that the desilication treatment led to an increase in the mesoporosity of the samples with the appearance of a hysteresis loop for the desilicated catalysts. Increasing the concentration of alkaline solution increased the mesopourous volume for all samples. For the samples treated with the 0.6 mol/L $NaCO_3$ solution, the volume of mesopourous decreased in the following order: Ni/Z280_0.6dsc >Ni/Z80_0.6dsc >Ni/Z50_0.6dsc >Ni/Z23_0.6dsc. This result showed that the increase of the Si/Al molar ratio favored the formation of mesoporosity. For untreated samples, Ni/Z280 and Ni/Z80 exibited the highest methane conversion during DRM. However, these catalyst underwent a continous deactivation during 24 h time on stream (TOS) for DRM, while the $CH_4$ conversion remained constant for Ni/Z50. Ni/Z23 showed no activity. The desilication treatment improved the methane conversion, which was more significant for the samples treated with the 0.6 mol/L $NaCO_3$ solution. Ni/280_dsc exhibited the highest value of methane conversion and remained quite stable during 24 h of TOS. These results indicate that the use of a higher alkaline solution concentration and higher Si/Al ratio improved the performance of the catalysts. This is likely due to the higher mesoporosity formed, which could contribute to the confinement of the metallic particles, avoiding its sintering.

# Comparison between the crystalline phases of $ZrO_2$ in methyl levulinate reduction to γ-valerolactone: a theoretical and experimental study

Alessia Ventimiglia[1], Riccardo Bacchiocchi[1], Nikolaos Dimitratos[1], Ivan Rivalta[1], Tommaso Tabanelli[1*]

[1]*Dipartimento di Chimica Industriale "Toso Montanari", University of Bologna, Viale del Risorgimento 4, 40136-Bologna, Italy*

[*]*tommaso.tabanelli@unibo.it*

**Keywords:** GVL, biomass, DFT, H-transfer

**Introduction.** Zirconia ($ZrO_2$) is a polymorphic oxide present in different allotropic forms; thanks to its amphoteric properties, $ZrO_2$ is used as support for heterogeneous catalyst or as catalyst itself; in particular, it is used in hydrogenation, oxidation and isomerization processes[1]. Its ability to promote the H-transfer reaction by using alcohols as H-donor in the reduction of levulinic acid derivatives to γ-valerolactone (GVL) has been studied recently[2]. In particular, reduction of Methyl levulinate (ML) using ethanol as H-donors in gas-phase is presented in this work. First, there is a cyclization of ML, with the formation of the intermediate angelica lactones (ALs); subsequently, the double bond is hydrogenated by H-transfer, leading to the formation of the final product, GVL**.** Herein, an investigation and comparison of two different crystalline phase zirconia catalysts with a similar specific surface area, a tetragonal (*t*-$ZrO_2$) and a monoclinic (*m*-$ZrO_2$) one, is reported. Indeed, these two zirconia phases possess differing symmetry and a differing coordination of the exposed suface atoms, leading to different catalytic activity. **Experimental/methodology.** The catalysts were synthesized by precipitation for *t*-$ZrO_2$ and hydrothermal for the *m*-$ZrO_2$ and then characterized in order to evaluate their crystallinity, surface area and the number of Lewis acid and basic sites. Finally, they were tested in the H-transfer reaction of ML to GVL in a continuous gas phase reactor using ethanol as H-donor. In order to better understand its catalytic properties, a computational study based on density functional theory and atomistic modeling of $ZrO_2$ clusters of the two crystalline phase under study was performed[3]. **Results and discussion.** *t*-$ZrO_2$ has proven to be a suitable catalyst for this reaction: indeed, it is selective toward the formation of GVL (yield 70%). However, by carrying out the reaction under the same conditions with *m*-$ZrO_2$ catalyst, the catalytic activity was reduced and deactivation was observed (Figure 1).

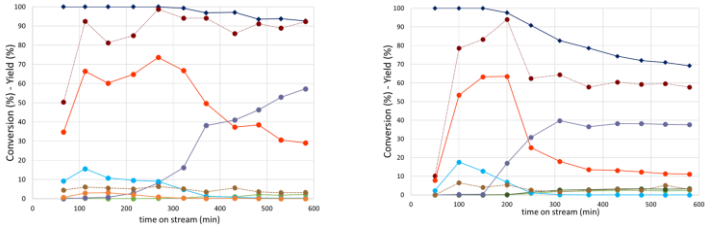

**Figure 1.** ML reduction using EtOH as H-donor over t-ZrO2 (left) and m-ZrO2 (right).Reaction conditions: molar ratio ML:EtOH=1:10, T=250 °C, t=1 s, %mol $N_2$:ML:EtOH=90.1:0.9:9. Conversion (◆); EL (●); GVL (●); Ethyl GVL (●); aAL (●); bAL (●); Others (●); Yields sum/Conversion (●).

To understand the faster deactivation of *m*-$ZrO_2$ when compared to *t*-$ZrO_2$, we focused on the adsorption of the intermediate of the reaction, ALs, on the two phases. Indeed, one of the possible reasons for the different reactivities of the two crystalline phases is the deactivation of the catalyst by formation of heavy products that block the catalytically active surface sites[4]. The computational results clearly show the stronger interaction of ALs with *m*-$ZrO_2$ phase respect to *t*-$ZrO_2$, which leads to a higher formation of oligomers, thereby promoting surface deactivation.

[2]*State University of Campinas, Campinas-SP, Brazil*
[*]*jean@ufscar.br*

**Introduction.** The platform molecules 5-hydroxymethylfurfural (HMF) and furfural can be obtained by the dehydration of the monosaccharides fructose and xylose, respectively, by Brønsted acid catalysis. Templated mesoporous sulfonic carbons (TMSC) have shown outstanding performance as catalysts for these reactions, along with high hydrothermal stability [1]. Therefore, herein, different TMSC were prepared for converting fructose and xylose into HMF and furfural, respectively.

**Experimental/Methodology.** Carbons of the TMSC were prepared according to the literature: CMK-3 [2], CMK-5 [3], CMK-8 [2], S-CMK-8 [4] and C-Chi [5]. They were pyrolyzed at 550 °C (Carbon-550) or 1000 °C (Carbon-1000) and functionalized, respectively, by sulfonation with fuming sulfuric acid (Carbon-SA) or 4-benzenediazonium sulfonate (Carbon-PSA). All materials were characterized by XRD, $N_2$ physisorption at 77 K, TGA in $O_2$, RAMAN, FTIR, XPS, and potentiometric titration. The conversion of the monosaccharides was performed at 130°C for fructose and 160 °C for xylose using THF containing 20 wt. % of water as solvent.

**Results and Discussion.** XRD confirmed the formation of the expected carbon structures and $N_2$ physisorption showed that they are mesoporous (3-4 nm) and present high surface areas (700-1900 $m^2\ g^{-1}$). TGA in $O_2$, RAMAN and C 1s XPS demonstrated that Carbons-1000 present longer defective graphene layers and lower amount of oxidized functional groups than Carbons-550. After functionalization, the catalysts lost the long-range pore organization and had a decrease of their surface areas (450-700 $m^2\ g^{-1}$), although their pore sizes were not affected. In addition, their carbon matrices presented longer defective graphene layers and higher amount of oxidized functional groups. The sulfonic groups were identified by FTIR and S 2p XPS, and a linear correlation between contribution of $SO_3H$ species vs percentage of stronger sites, by potentiometric titration, was found (Figure 1A). The catalytic results showed that the best synthetized catalysts were CMK-3-PSA, CMK-5-PSA, CMK-8-PSA and S-CMK-8-PSA (group CMKs-PSA), achieving HMF and furfural yields close to 65 % and 40 %, respectively. These results were comparable to those of the commercial Amberlysts 15 and 40, however, a correlation between the $TON_{Platform}$ and the percentage of stronger sites was found (Figure 1B), presenting a volcano plot with maximum for the CMKs-PSA catalysts (70-80 % of stronger sites). The $TOF_{Monosaccharide}$ and $TOF_{Platform}$ for these catalysts were determined, and the ratio $TOF_{Platform}/TOF_{Monosaccharide}$ (Figure 1C) showed that CMK-3-PSA is the best catalyst, with ratio of 0.52 for the conversion of fructose into HMF, and 0.27 for the conversion of xylose into furfural.

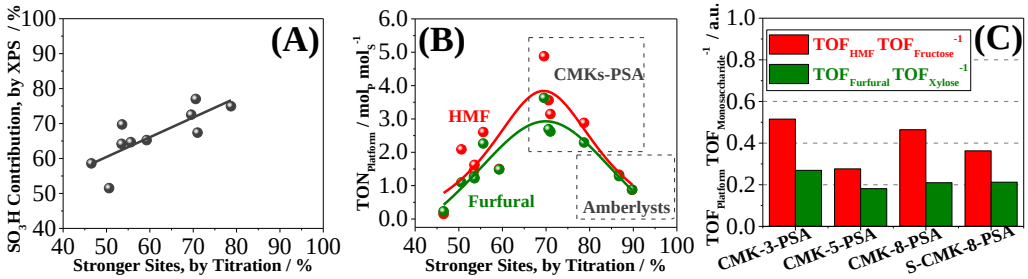

**Figure 1.** Correlation between stronger sites vs $SO_3H$ contribution of the catalysts synthetized (A). Correlation between stronger sites vs $TON_{Platform}$ of the catalysts synthetized and Amberlysts (B). $TOF_{Platform}/TOF_{Monosaccharide}$ ratio of the CMKs-PSA catalysts (C).

**Keywords:** biofuels, bio-oil hydrotreatment, hydrodeoxygenation, unsupported catalyst, molybdenum sulfide, slurry hydrotreatment

**Introduction.** Thermochemically liquefied lignocellulosic biomass, for example fast pyrolysis bio-oil and hydrothermal liquefaction biocrude, are promising feedstocks for sustainable biobased hydrocarbons [1]. However, the high oxygen content, thermal instability and bio-based impurities limit the use of these feeds to heating oil and co-feeding to oil refineries in small quantities, and the lack of technoeconomically viable upgrading routes is the key bottleneck for commercialization of lignocellulosic biomass based hydrocarbon feedstock [1, 2]. Slurry hydrotreatment has been proposed as a potential technology for bio-oil upgrading, enabling addition, removal and circulation of catalyst and unconverted feed during reactor operation and therefore solving the severe bottlenecks of coke formation and catalyst poisoning from thermally unstable and impurity-containing feed [2, 3].

**Experimental.** Unsupported promoted molybdenum sulfide based catalysts for slurry hydrotreatment of bio-oil were synthetised by hydrothermal precipitation variating synthesis conditions, such as temperature and pH. The catalysts were characterised with XRD, physisorption, XPS, ICP-AES and SEM-EDS, and tested for hydrotreatment of model compound isoeugenol in batch reactor at 300 °C and 30 bar. Furthermore, the catalysts were tested in semi-batch hydrotreatment of fast pyrolysis bio-oil to compare the performance and evaluate the conclusions drawn from model compound experiments. The semi-batch experiments were performed at 300-400 °C and 30-100 bar with continuous hydrogen feed through the reactor to monitor the effect of process conditions to hydrotreatment severity. In addition, catalyst stability was studied by performing catalyst reuse experiments with both, model compounds and bio-oil, and spent catalysts were characterized to monitor potential changes in morphology and composition. Catalyst performance was compared to traditional supported hydrotreatment catalyst as a benchmark.

**Results and discussion.** Characterization and model compound experiment results show the significant effect of synthesis parameters on the catalyst composition. This work enables tailoring the catalyst for different bio-oil feeds to achieve targeted hydrotreatment performance. In hydrotreatment of real bio-oil feed, unsupported catalysts matched the performance of supported catalyst with comparable loading of active sulfide, as shown in preliminary results in Figure 1. The trends from model compound experiments to real biofeed performance were evaluated.

**Figure 1. Comparison of performance of VTT-prepared unsupported catalyst and traditional hydrotreatment catalyst in pyrolysis bio-oil hydrotreatment in semi-batch reactor.**

**Introduction**

Phenolic monomers are mainly derived from fossil resources and have a wide range of applications, *e.g.*, the production of fine chemicals and fuels. One path to diminish the fossil resource dependence leads towards production of bio-aromatics from lignocellulosic biomass. An interesting approach is the catalytic liquefaction technique. It is preliminarily driven by deconstruction or depolymerization of biomass-specific macromolecules (hemicellulose and lignin) into monomers in green solvents (water, methanol, ethanol, propanol, tetraline, etc.) over efficient catalysts, while only crystalline cellulose remains intact [1][2].

**Experimental**

The wood depolymerisation studies were performed in supercritical ethanol (243 °C) over $Pd/NbOPO_4$ catalyst under hydrogen (initial pressure at RT, 5 bar). 4 g of fresh birch (dry weight, particle size ≤ 250 µm, 32 wt-% moisture content) was first soaked in 90 ml ethanol overnight. Thereafter, the desired amount of $Pd/NbOPO_4$ catalyst (reduced at 400 °C for 3 h and stored in 10 ml ethanol) was added to the reaction medium. The reactor was heated 10 °C/min and stirred slowly during heating. The reaction starting point was taken at the point when the reaction medium reached the desired temperature. The course of the reaction was followed by taking liquid samples from the reactor at different time intervals. The fresh wood, spent solid phases and liquid products were characterised with various analytical techniques such as GC-FID, p-XRD, SEM, TEM, SEC and the catalyst leaching was measured by ICP-OES.

**Results and discussion**

For the first time, a tandem catalytic material, 5 wt-% $Pd/NbOPO_4$, was utilized in the depolymerization of wood in supercritical ethanol under low initial hydrogen pressure. The results indicated that with fresh birch, 34 wt-% of lignin monomer yield with 84 wt-% delignification efficiency were obtained. The total lignin monomer content extracted from the fresh birch is composed of 77 wt-% of dimethoxyphenols and 17 wt-% with the guaiacol structure. Major lignin monomer product was homosyringaldehyde (62 wt-%). It was concluded that the depolymerization occurred via breaking of the ether bonds in lignin, including ether hydrolysis by Lewis acid sites over the solid acid catalyst and with subsequent deoxygenation of monophenols over Pd. (Fig. 1.)

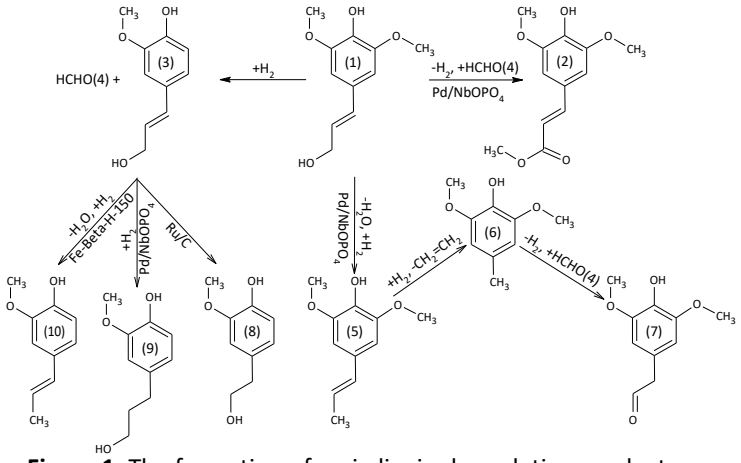

**Figure 1.** The formation of main lignin degradation products: sinapyl alcohol (1), methyl sinapate (2), coniferyl alcohol (3), formaldehyde (4), 4-propenyl syringol (5), 4-methyl syringol (6), homosyringaldehyde (7), 4-n-propanolguaiacol (8), dihydroconiferyl alcohol (9), and isoeugenol (10)

**Keywords:** Furfural, methyl isobutyl ketone, aldol condensation, single reactor.

**Introduction.** Furfural (FF) is a valuable building block to access a variety of relevant industrial products and intermediates. Herein we report a robust catalytic system based on a bifunctional $Pd/Al_2O_3$ catalyst for conducting the single-reactor tandem solvent-free aldol condensation / hydrogenation of FF and methyl isobutyl ketone (MIBK) to access a renewable biosolvent and biofuel precursor in the branched alkane range at high yield. The process comprises two steps (**Figure 1**): (1) aldol condensation/ crotonization, and (2) selective hydrogenation of the aldol condensation adduct. The activity and robustness of the catalyst was investigated in batch and continuous dual fixed-bed reactors to devise conditions for upscaling.

**Experimental/methodology.** γ-Alumina spheres (Sasol), calcined at 400 °C for 4 h, was used as acid catalyst. Bifunctional $Pd/Al_2O_3$ was prepared by wet impregnation of palladium acetate on alumina spheres in 30 mL acetone. The sample was dried overnight at 80 °C, calcined at 400 °C for 4 h, and reduced at 200 °C for 4 h under $H_2$. The single reactor condensation – hydrogenation reaction of FF and MIBK was carried out in: (1) a stainless steel autoclave reactor (30 mL), and (2) dual-type ($Al_2O_3$-$Pd/Al_2O_3$) continuous fixed bed reactor. The reaction products were analyzed and quantified by gas chromatography on a Thermo Scientific Trace 1100 GC equipped with a flame ionization detector (FID) and a HP-5 capillary column with 5 wt% phenyl groups (length 30 m; inner diameter 0.25 mm).

**Results and discussion.** γ-Alumina (spheres) calcined at 400 °C revealed as a robust catalyst for the aldol condensation/crotonization reaction of FF (5.2 wt%) with MIBK, affording quantitative synthesis of (E)-1-(furan-2-yl)-5-methylhex-1-en-3-one at 160 °C for 12 in batch mode with *ca*. 100% carbon balance. The reaction rate decreased at higher FF concentration due to inhibition of Lewis acid centers by adsorbed FF as inferred from kinetic modeling. The spent catalyst could be reused for at least six consecutive catalytic runs without loss of activity due to lack of poisoning of active Lewis acid centers of medium strength as inferred by FT-IR spectroscopy implemented with adsorbed pyridine and $NH_3$-TPD. With these results, we conceived a single-reactor tandem process over $Pd/Al_2O_3$ for the aldol condensation of FF and MIBK, followed by hydrogenation with $H_2$. The system reached an overall 86% yield of 1-(tetrahydrofuran-2-yl)-5-methylhexan-3-one at 180 °C (5.2 wt% FF) after 9 h in batch mode. The catalyst was also operated in a dual-type continuous fixed-bed reactor reaching 55% FF conversion and 60% and 35% selectivity to 1-(furan-2-yl)-5-methylhexan-3-one and (E)-1-(furan-2-yl)-5-methylhex-1-en-3-one, respectively, at 170 °C after 12 h continuous operation at high FF concentration (18 wt%).

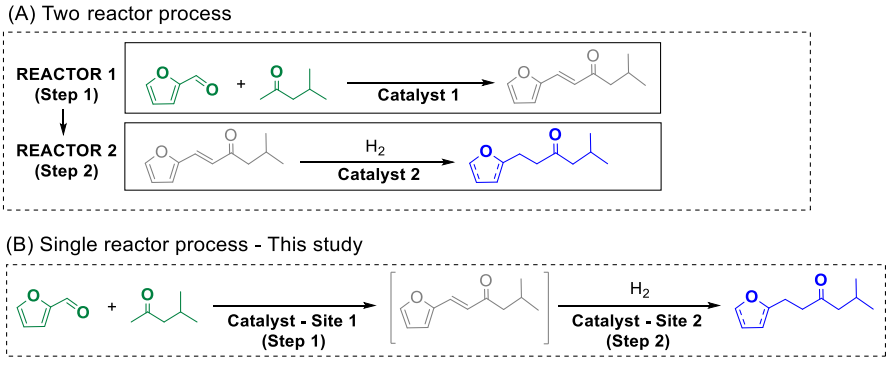

**Figure 1. Two-reactor vs. single reactor tandem process for the synthesis of hydrogenated derivatives from FF.**

**Keywords:** zeolite A, zeolite X, transesterification

**Introduction.** K/NaX and K/NaY catalysts are active for transesterification of Jatropha seed oil and palm oil [1-4]. Recently, Kosawatthanakun et al. [4] reported that K/NaX is a better catalyst than K/NaY due to its higher basicity and better stability. NaX and NaY have the same structure with a cavity size of 0.74 nm but different Si/Al ratio, namely, 1.2 and 2.4, respectively [4]. In this work, K/NaA is compared with K/NaX. NaA has Si/Al ratio of 1.0, close to NaX, but a cavity size of 0.43 is smaller than NaX.

**Experimental/methodology.** K/NaA and K/NaX are prepared with a method from [3,4] by impregnation of potassium acetate buffer on commercial zeolites, characterized by XRD, $CO_2$-TPD, FTIR, and $N_2$-adsorption-desorption analysis, and tested in transesterification of palm oil with methanol [3,4]. The biodiesel yield was determined by a gas chromatograph coupled with a flame ionization detector.

**Results and discussion.** The XRD patterns of calcined K/NaA and K/NaX (Figure a,b) indicate that NaA is more stable than NaX under the same preparation procedure. Figure c shows that the basicity of K/NaA (0.68 mmol$CO_2$/g) is higher than K/NaX (0.37 mmol$CO_2$/g). Figure d shows that K/NaA gives a higher biodiesel yield than K/NaX. However, both catalysts show deactivations in the second and third cycles.

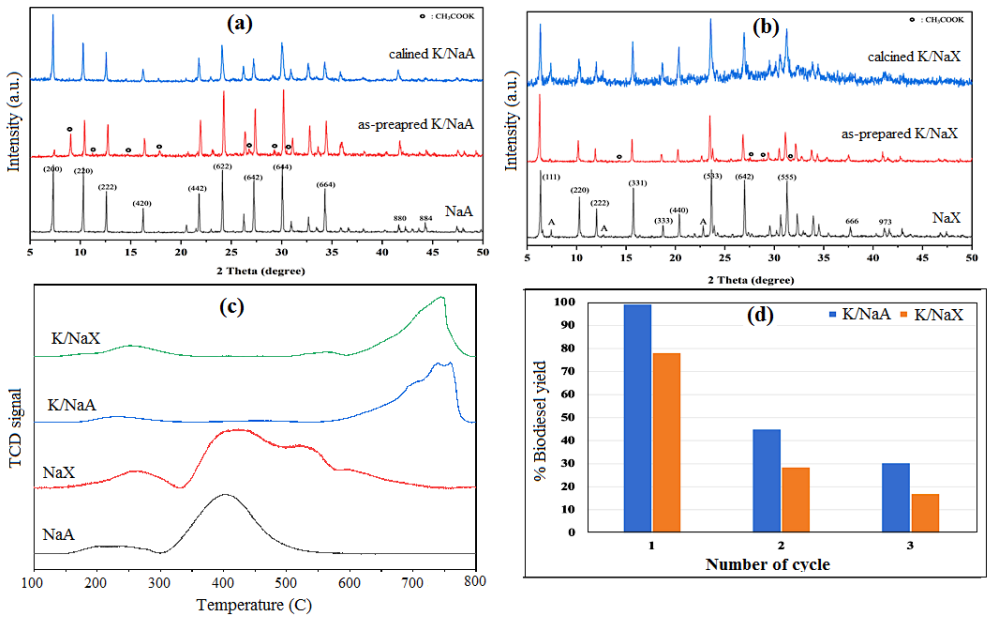

Figure (a) XRD patterns of 12K/NaA, (b) XRD patterns of 12K/NaX, (c) $CO_2$-TPD profile of calcined catalysts compared with the parent zeolites, and (d) biodiesel yields from 3 cycles at 60 °C for 3 h.

**Keywords:** Lignin valorisation, aryl ethers, photocatalysis, non-precious nanocatalysts

**Introduction.** Lignin, a major component of lignocellulosic biomass, is the only large-volume renewable aromatic source in nature. Although currently underutilized, it has a great potential to be valorized to produce aromatic bulk and fine chemicals. The different aromatic subunits in lignin are connected by various types of C-O and C-C linkages. The aryl ether C-O linkages are more abundant and more reactive, and have been considered as the key target to be cleaved for selective and controlled lignin depolymerization. Several efficient thermal-catalysis methods have been developed for the selective cleavage of aryl ether C-O linkages, but harsh conditions and precious metals are always needed.

**Results and discussion.** Here we developed novel visible-light-driven procedures for this purpose using heterogeneous catalysts of non-precious TiN nanoparticles and $ZrO_2$ supported Ni nanoparticles. (1) Commercially available TiN nanoparticles were employed to cleave the C-O bond in a β-O-4 dimer model, phenethyl phenyl ether (PPE), with high selectivity to equivalent styrene and phenol under very mild conditions with isopropanol as the green solvent. Direct photon energy input and a free radical mechanism were responsible for this reaction. In addition, the Ti-N-O structure in TiN samples was confirmed to be the active site for cleavage of the C-O bond in PPE in the light reaction.[1,2] (2) Using non-plasmonic Ni nanoparticles, three aryl ether bonds in lignin were successfully cleaved under mild conditions with excellent conversion and good to excellent selectivity under visible light irradiation. We used solar irradiation to demonstrate a significant reduction in the total energy consumption. The light irradiation excited interband transitions in Ni nanoparticles and the resultant energetic electrons enhanced the activity of reductive cleavage of the aryl ethers. Its application potential was illustrated by the depolymerization of dealkaline lignin to give a total monomer yield of 9.84 wt% with vanillin, guaiacol, and apocynin as the three major products.[3]

**Keywords:** jet fuel, renewable sources, catalyst, MOFs, aldol condensation

**Introduction.**

There has been a substantial interest in conversion of biomass to materials, chemicals and fuels. Several strategies for production of renewable jet fuel with a much lower environmental footprint than fuels currently in use have been explored [1]. One of such options is aldol condensation of furfural with biomass derived ketones, e.g. cyclopentanone – Figure 1, followed by subsequent hydrodeoxygenation [2]. There is a very limited number of studies on heterogeneous catalytic aldol condensation, which prompted a detailed investigation of furfural aldol condensation with cyclopentanone using a range of catalysts with base properties

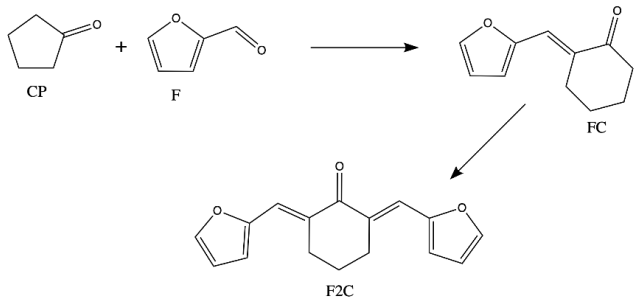

**Fig. 1. Reaction scheme for the aldol condensation of cyclopentanone and furfural.**

**Experimental/methodology.**

In this work, the aldol condensation of cyclopentanone and furfural was investigated at 40 – 60 °C, in the presence or absence of a solvent (alcohols, water and their mixtures) in a glass reactor equipped with magnetic stirring under $N_2$ atmosphere. As a catalyst, materials with different porosity and basicity were selected, namely: hydrotalcites, CaO, NaOH, $NaAlO_2$ and a range of MOFs of UiO-66 structure, Cs-forms of hierarchical zeolites, basic metal oxides deposited onto hierarchical zeolites, etc.

Samples were analysed by gas-chromatography and gas-chromatography coupled to a mass-spectrometer. Fresh and spent catalysts were characterized by a range of physico-chemical methods such as SEM-EDX, TEM, ICP-OES, TPR, $CO_2$-TPD, TGA, $N_2$-physisorption and soluble coke extraction analysed by GC-MS. The products were separated from the catalyst and reagents by dilution with ethyl acetate and further filtration. The chemical structure of products was confirmed by gas chromatography with a mass detector and FID, as well as by NMR.

**Results and discussion.**

Basicity of the catalysts was determining activity, while the ratio between the condensation products (FC to $F_2C$) was seen to be dependent on the excess of the ketone as well as on the type of solvent and the fraction of alcohol. More details on the catalyst preparation, characterization and catalytic tests will be given in the final presentation.

# Alcohol dehydration on Lewis and Brønsted acid sites of tungsten-oxide based catalysts

Florian Zahn[1], Niklas Pfriem[1], Johannes A. Lercher[1*]

[1] *Department of Chemistry and Catalysis Research Center, TU München, Garching, Germany*
[*] *johannes.lercher@tum.de*

**Keywords:** alcohol dehydration, tungstated materials, support effects

**Introduction**

Supported metal oxides have been widely used for acid-catalyzed reactions in recent centuries due to their thermal stability and acid strength. Tungsten oxide-based solid acids have been previously employed as suitable catalysts in gas-phase isomerization reactions, alcohol dehydration, and liquid-phase upgrading processes of biomass-derived feedstocks [1-2]. Until now, the literature lacks an understanding of the mechanisms of alcohol dehydration over tungsten oxide-based Lewis acids and how the nature of the LAS impacts alcohol dehydration [3]. In this work, we doped tungsten oxide on zirconia ($WO_x/ZrO_2$) and $\gamma$-alumina ($WO_x/Al_2O_3$) to achieve a stable and active catalyst domain consisting of both BAS and LAS to invest the influence of LAS on the dehydration of cyclohexanol. To distinguish between LAS- and BAS-catalyzed dehydration, we perform in-situ titration experiments and use IR experiments.

**Experimental/methodology**

A series of $WO_x$/support ($ZrO_2$, $\gamma$-$Al_2O_3$) catalysts were synthesized *via* incipient wetness impregnation of $Zr(OH)_4$/ $\gamma$-$Al_2O_3$ with aqueous solutions of ammonium metatungstate hydrate containing desired amounts of tungsten. The dried samples were calcined in flowing synthetic air at 973 K for four hours and then cooled to room temperature. The catalysts were characterized by AAS, BET, PXRD, Raman spectroscopy, and IR spectroscopy of adsorbed pyridine. Dehydration of cyclohexanol was carried out in a 300 ml Hastelloy Parr reactor. In a typical experiment, 100 mL of a 0.05 – 1.0 M cyclohexanol solution (solvent: decalin) and ~100 mg of catalyst were added to the reactor. The distinction between acid sites, i.e. Brønsted acid sites (BAS) and Lewis acid sites (LAS), was achieved by titration experiments with pyridine, 2,6-di-tert-butylpyridine (DTBP), and piperidine under reaction conditions.

**Results and discussion**

For all tested catalysts, the dehydration rates decreased linearly with increasing titrant uptake for all three organic base titrants, irrespective of the catalyst. However, complete suppression of the dehydration rate was not achieved by either pyridine or DTBP. Fully suppression occurs only with piperidine for the -alumina supported catalyst. Overall, we have on $WO_x/ZrO_2$ catalysts at least three classes of sites: (1) active sites that bind all three titrants and contribute most to the catalytic activity; (2) weak acid sites that do not bind pyridine/DTBP but bind piperidine and are inactive for dehydration; (3) weak acid sites that bind none of the N-titrants but are catalytically active. The inactive acid sites and the sites responsible for the remaining dehydration rates may be weak BAS or LAS. Their exact chemical identity cannot be determined from these experiments and will be further discussed with IR experiments.

**Significance**

We provide an understanding of LAS-catalyzed dehydration routes for heterogeneous tungstate catalysts, using cyclohexanol as an alcohol representative for a class of molecules derived from biomass upgrading reactions. This work is expected to lead to improved metal-oxide catalyst design for biomass upgrading reactions.

# In-depth study of reductive catalytic fractionation of biomass towards highly functional lignin oligomers as bio-based polymer substrates

Yingtuan Zhang[1] and Bert F. Sels[1*]

[1]*Center for Sustainable Catalysis and Engineering, Faculty of Bioscience Engineering, KU Leuven, Heverlee 3001, Belgium.*

**bert.sels@kuleuven.be*

**Keywords: lignin, reductive catalytic fractionation(RCF), bio-based, polymer**

**Introduction.** As the most abundant natural source of renewable aromatic molecules on earth[1], lignin, particularly lignin oligomers, has been considered a promising substrate for bio-based polymers[2]. In the recently developed reductive catalytic fractionation(RCF) of biomass under the 'lignin-first' biorefinery concept, a considerable amount of phenolic lignin oligomers is generated[3]. However, an in-depth study of the RCF process targeting highly functional lignin oligomers as bio-based polymer substrates is still absent. Here, we report a systematic study of the RCF process towards highly functional lignin oligomers as bio-based polymer substrates.

**Experimental/methodology.** Lignocellulosic substrates including birch, pine and flax shives were studied as being a syringyl-unit-rich hardwood, a guaiacyl-unit-rich softwood and an unvalorized industrial byproduct. Similarly, catalysts including Pd, Ru, and Ni and solvents including methanol, ethylene glycol and a 50:50 butanol-water solution were investigated to discover the optimized solvent-catalyst system. To monitor the product, the molecular weight distribution of the produced lignin oligomers was characterized by gel permeation chromatography, while the OH content was determined by P-NMR.

**Results and discussion.** Starting from a conventional Ru-Methanol system, and ending in some new combination such as the Ni-Ethylene glycol system, it was discovered that different catalyst-solvent systems had significant effects on the lignin oligomers' structure—molecular weight and hydroxyl groups content. Besides, the changes in hydrogen pressure, temperature and time had a direct effect on the reaction's severeness, which consequently influenced mainly the lignin oligomer's yield as shown in Figure 1.

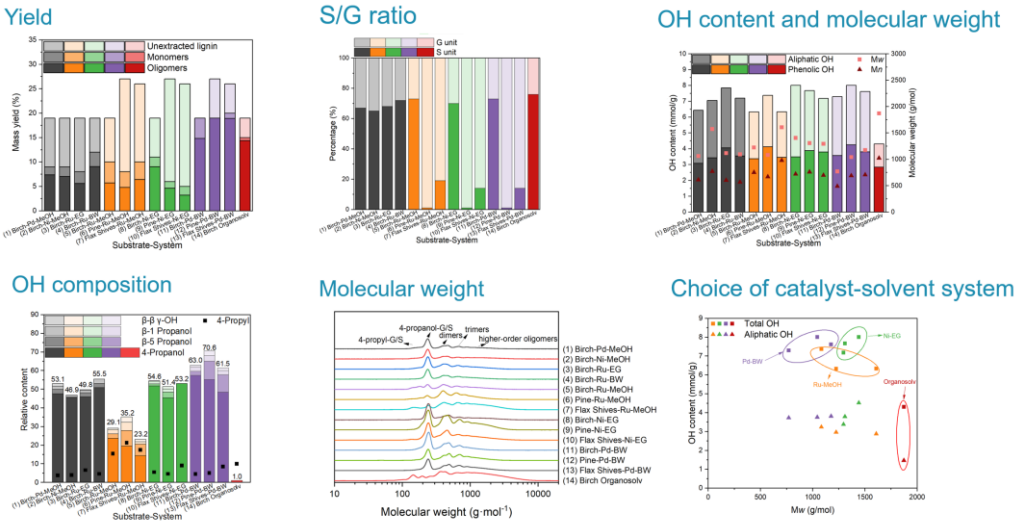

Figure 1. The influence of various RCF parameters on the properties of lignin oligomers.

# Conversion of lactic acid to acrylic acid over Ba-modified SBA-15

Rong Zhao[1], Jong Wook Bae[1*]

[1]*School of Chemical Engineering, Sungkyunkwan University(SKKU), 2066 Seobu-ro, Jangan-gu, Suwon, Gyeonggi-do,16419, Republic of KoreaCountry*

**Keywords:** biomass, dehydration, lactic acid, acrylic acid, barium, catalyst

**Introduction.** Acrylic acid has been used to produce adhesives, textiles, dispersants, thickeners, and so on [**1,2**]. The selective catalytic oxidation of propylene or propane from non-renewable chemicals was responsible for a significant pollution, expensive investment and several issues to be resolved. Catalytic conversion of lactic acid to acrylic acid (LTA) on heterogeneous catalysts with appropriate acidity and basicity has been attracted due to lactic acid can be obtained cheaply through the fermentation of various biomass resources [**3**]. It is unavoidable that the LTA reaction can be followed by competitive reactions according to the strong reactivity of its hydroxyl and carboxyl groups. This research revealed the effective conversion of lactic acid into acrylic acid by utilizing efficient catalyst (high conversion and selectivity on the Ba-incorporated SBA-15) in a fixed bed reactor.

**Experimental/methodology.** The preparation of the catalysts is as follows: Firstly, the ordered mesoporous silicon-based SBA-15 support was prepared by using a P123 template, and the precursor materials Ba $(OH)_2 \cdot 8H_2O$ were dissolved in a certain amount of deionized water. And then impregnated the precursor on the SBA-15 support by using the dry impregnation method. Finally, the catalysts obtained after drying and calcination were recorded as Ba (x)/SBA-15, where x represents the content ratio of Ba metal. The activity test was carried out on a fixed-layer reactor. First, the catalyst was loaded into the middle of the reactor in the form of a sandwich (wrapped with quartz wool), and then 30wt% of the lactic acid aqueous solution was pumped into the reactor. After the pretreatment at 200 °C for 2h under a flow of $N_2$ gas, the reactor was heated to 350 °C and the sample collected every 1 h and analysze with FID- equipped GC.

**Results and discussion.** All the catalysts synthesized showed highly ordered mesoporous structures, and the SBA-15 support itself showed a poor LTA activity (LA conversion of 23.0%, and AA selectivity of 11.93%). With an increase of Ba content, the conversion and selectivity of LA were continuously increased and the conversion of lactic acid was increased up to 94.7% with AA selectivity of 87.6% on the Ba(17)/SBA-15. However, with the further increase of Ba contents, the accumulated Ba oxides seem to block the active sites, resulting in showing a lower AA selectivity as shown in **Figure 1**. The excellent activity of the Ba (17)/SBA-15 was mainly attributed to the appropriate surface acidic and basic sites as shownin **Figure 1**.

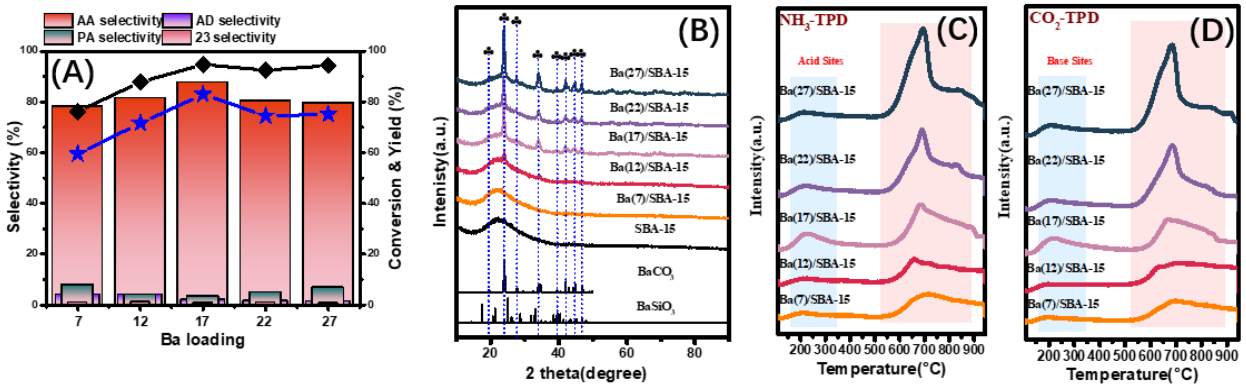

**Figure 1**. (A) LTA activity, (B) XRD patterns, (C) $NH_3$-TPD patterns on the fresh Ba(X)/SBA-15, and (D) $CO_2$-TPD patterns on the fresh Ba(X)/SBA-15 catalysts.

**Keywords:** Butan-1-ol conversion; Guerbet reaction; Carbon support; Hydroxyapatite.

**Introduction.** Alcohols obtained by fermentation of renewable non-food biomass are promising source of raw materials for obtaining industrially important compounds, including unsaturated hydrocarbons and oxygenates. Butan-1-ol (BuOH) can be received by the ABE process and Guerbet condensation of bio-ethanol (EtOH-to-BuOH). BuOH can be used as a precursor for the synthesis of 2-ethylhexan-1-ol (required for the production of solvents, plasticizers, soaps, diesel additives etc.) by BuOH condensation (BuOH-to-2-EH) over alkali cation zeolites, metal oxide systems and hydroxyapatites, $Ca_{10}(PO_4)_6(OH)_6$ (HAP). The last are highly selective catalysts towards the target BuOH in the EtOH-to-BuOH process [1].

This work highlights several approaches to obtain an active and highly selective catalyst for the BuOH-to-2-EH process. The first consists of the modification of Ca-containing HAP structure by partial replacement of $Ca^{2+}$ with $Mg^{2+}$ and $Sr^{2+}$ [2]. The second involves the deposition of Ca-containing HAP on various types of carbonaceous materials (CM) [3].

**Experimental/methodology.** The HAP catalysts were synthesized by the method described elsewhere [2]. The preparation of carbon-supported HAP samples was performed by wet mixing the components, namely HAP and various carbonaceous materials. Physical-chemical characteristics of the catalysts were studied by XRD, FE-SEM with EDX, $N_2$-ad/desorption, $^1H$ and $^{31}P$ MAS NMR, Raman spectroscopy, XPS, EPR, TPD-$NH_3$/$CO_2$. The catalytic activity tests of the prepared samples were performed in a fixed-bed flow quartz reactor under atmospheric pressure.

**Results and discussion**. It was found that the partial replacement of calcium in the HAP structure by 2.5 % mol. magnesium leads to redistribution of the number and strength of basic and acidic surface sites necessary for the BuOH dehydrogenation and aldol-crotonic condensation, respectively (Scheme). Such balance between the surface-active sites allows to achieve the high selectivity towards 2-EH (77.5 % at 573 K) in the BuOH-to-2-EH process. In the case of the BuOH conversion over carbon-supported HAP catalysts, the alcohol conversion and selectivity towards target product are highly dependent on the nature of the carbonaceous materials. The highest yield of 2-EH (up to 21%) is achieved on HAP/activated coconut charcoal. HAP modification by magnesium also leads to increasing the catalyst resistance to deactivation with time-on-stream, which opens up prospects for using of hydroxyapatites in the BuOH-to-2-EH process.

**Scheme. Guerbet reaction mechanism: 1 - initial alcohol dehydrogenation to aldehyde, 2 - aldol condensation, 3 - crotonic condensation, 4 - hydrogenation and/or reduction of unsaturated aldehyde.**

# The kinetics of fatty acid hydrodeoxygenation

M. Žula[1*], M. Grilc[1], B. Likozar[1]

[1] *Department of Catalysis and Chemical Reaction Engineering, National Institute of Chemistry, Hajdrihova 19, 1000 Ljubljana, Slovenia*

**Keywords:** Hydrodeoxygenation, sulfided NiMo,fatty acids, reaction kinetics

**Introduction.** Fatty acids and triglycerides are one of the most promising medium term renewable sources for the preparation of fuels and chemicals. Their similarity to the crude oil promises broad application with minimal adaptation of existing systems. Thus, the commercial application would enter an already established huge market of fuels and chemicals. The sources for triglycerides are broad and range from microalgae oil to waste cooking oil, all of which can be catalytically converted to fuels and chemicals [1]. To understand mechanisms and describe its kinetics a mathematical model was written.

**Experimental.** The experiments were conducted in a 75 mL Parr batch reactors in a temperature range between 225 and 275 °C in a hydrogen atmosphere at pressures between 30 and 70 bar. In a typical experiment 1 g of palmitic acid reacted with 0.1-0.4 g of sulfided NiMo catalyst. To expand the understanding of the mechanisms, the intermediates – in the form of fatty alcohol, ester in the hydrogen and nitrogen atmosphere were also modeled. The catalyst parameters in the form of surface area, metal loading, pore size and volume, XRD, SEM, TEM and $NH_3$-TPD were reported. Additionally, the quantum calculations were performed using GPAW ASE software.

**Results and discussion.** The resulting model differs from the convential Langmuir-Hinshelwood models [2] by the separation of the liquid and solid phase with the longterm goal of including a solid phase descriptions and data in kinetic models. We show that for such model to be able to describe the kinetics of the process the adsorption selecitvity is highly relevant. As some models have previously shown the alcohols will be barely reactive while the fatty acid is present while aldehydes and alkenes will be present in relatively low quantities in liquid phase. The concentration of the solvent and the product will not impact the kinetics due to very low adsorption energy. Thus, in the model the products were unable to adsorb on the catalyst surface, while the alcohols had a lower adsorption rate than other presents species which was determined experimentaly using fatty alcohol feedstock alone and in combination with the fatty acid. To confirm the findings theoretically, the adsorption energies for the long-chain species were calculated and have shown that the model findings are indeed correct. The model and experimental results for pressure variation are presented in Figure 1.

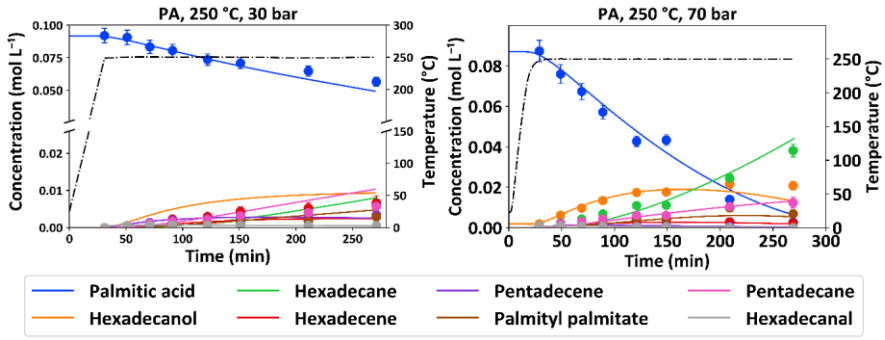

**Figure 1: The model results for the variation of hydrogen pressure.**

**Keywords:** oxidative cleavage, polydopamine, ruthenium, palm oil

**Introduction.** Oxidative cleavage (OC) involves the rupture of carbon-carbon double bonds in alkenes for the production of carbonyl compounds of high added value.[1] Most of the works related to this matter are focused on small and aromatic alkenes, but only few of them address unsaturated fatty acids (UFAs).[1,2] Yet UFAs can be cleaved into dicarboxylic acids, eventually with an odd number of carbon atoms rare in nature and highly demanded for polymer and pharmaceutic applications. This is typically the case of azelaic acid accessible by OC of oleic and linoleic acids, making these reactions particularly interesting.[2] To date, OC of UFAs is mainly performed using homogenous catalysts which are pollutant and cannot be recovered. On the other hand, current heterogeneous catalysts display poor activity due to the poor contact amid the UFA and the active phase.[1-3] To solve this issue, we demonstrate the efficiency of a Ru (namely a very active element in OC of UFAs),[3] catalyst supported on carbon black functionalized with polydopamine (PDA). The latter is a natural polymer containing catechol and amine groups available to chelate Ru for the oxidative cleavage of UFAs inside Palm oil.

**Experimental/methodology.** Precisely, oxidized carbon black (CBO) was put in contact with an aqueous dopamine solution under basic conditions in order to trigger the self-polymerization process over the support. The support plus the deposited polymer (CBO-PDA) was recovered by centrifugation and dried at room temperature overnight. Ru was deposited on CBO-PDA surface by wet impregnation using a $RuCl_3$ aqueous solution to achieve a 2 wt% load. OC tests were carried out with Ecuadorian palm oil using 100 mg of CBO-PDA-Ru catalyst along with $NaIO_4$ as oxidizing agent at room temperature for 24 hours under agitation and air atmosphere.

**Results and discussion.** Figure 1 displays FTIR spectra with the characteristic bands of the polymer on CBO surface while $N_2$ physisorption isotherms confirm a decrease in surface area after PDA deposition on macroporous CBO. Ru 3p core level appears as a doublet at 463.5 and 485.7 eV attributed to Ru(III)-catechol species as a result of Ru interactions with PDA functional groups. The catalyst with $NaIO_4$ was assessed in the OC of oleic and linoleic acids inside palm oil maintaining its catalytic activity up to 5 recycles for azelaic acid production (Yield ~95%). This new catalyst opens a novel route to the production of a high value-added product with medicinal applications from a cheap feedstock as palm oil.

# Selective one-step hydrotreatment of methyl palmitate over Co- and Mo-supported beta zeolite

S. U. Lee, T. W. Kim, K. E. Jeong, S. Y. Jeong, C. U. Kim*

*Chemical & Process Technology Division, Korea Research Institute of Chemical Technology, Yuseong, Daejeon, 34114, South Korea*
**cukim@krict.re.kr*

**Introduction.** For producing a drop-in bio jet fuel, one-step hydrotreatment, which includes deoxygenation, isomerization and cracking in one step, is essential to overcome the typical biofuel drawbacks due to high oxygen content, out of jet fuel range hydrocarbons, and low isomerization degree. In this study, Co-or/and Mo-supported Beta(25) zeolites with various Co/Mo ratios were prepared as transition metal-supported zeolite catalysts for selective one-step hydrotreatment to produce bio jet fuel range hydrocarbons.[1]

**Experimental/methodology.**

1. Synthesis of catalysts: Co- or/and Mo-supported Beta(25) zeolites were prepared by wet-impregnation method, and denoted as "$Co_xMo_y$/Beta(25)", where 'x' and 'y' are the weight % of Co and Mo.
2. Catalytic performance tests of methyl palmitate as a biofuel model component of fatty acid methyl esters were carried out in a semi-batch reaction system (280 °C, 20 bar, 2 h).

**Results and discussion.** With controlling the Co/Mo ratios, $Co_xMo_y$/Beta(25) comprises not only $Co_3O_4$ and $MoO_3$, but also $CoMoO_4$ due to the preference for the formation of $CoMoO_4$ (Table1). Regrarding Co metal phase, $Co_2Mo_{10}$/Beta(25) and $Co_3Mo_{10}$/Beta(25) consist of $CoMoO_4$, and start to concurrently appear $Co_3O_4$ from $Co_5Mo_{10}$/Beta(25). Importantly, the Co metal phase strongly influences the acidic properties of Beta(25) by the formation of Lewis (L) acid sites with different strengths as $Co_3O_4$ and $CoMoO_4$ for strong and weak L acid sites, respectively (Table 1). In hydrotreatment of methyl palmitate (Figure 1), deoxygenation of methyl palmitate is preceded by Co with the aid of strong L acid sites. Among $Co_xMo_y$/Beta(25), Mo plays the role to suppress cracking and increase the selectivity for light alkanes, and Beta(25) can enhance isomerization with hydrogenation promoted by Co. From the results, $Co_5Mo_{10}$/Beta(25) zeolites achieved the highest $C_8$–$C_{16}$ selectivity of 89.7 wt% including isomer ratio of 83.8% in organic liquid product with the conversion of 94.2%.

**Table 1. Acidic properties of groups by metal phases.**

| Group | Sample | Metal phase | $NH_3$-TPD | FTIR of adsorbed pyridine | | |
|---|---|---|---|---|---|---|
| | | | Acid sites (mmol/g) | B* (mmol/g) | L* (mmol/g) | B/L* |
| I | $Co_{10}$/Beta(25) | $Co_3O_4$ | 1.33 | 0.17 | 1.16 | 0.15 |
| II | $Co_{10}Mo_5$/Beta(25) | $Co_3O_4$ + $CoMoO_4$ | 1.37 | 0.19 | 1.18 | 0.16 |
| | $Co_{10}Mo_{10}$/Beta(25) | | 1.20 | 0.18 | 1.02 | 0.18 |
| | $Co_5Mo_{10}$/Beta(25) | | 1.37 | 0.20 | 1.17 | 0.17 |
| III | $Co_3Mo_{10}$/Beta(25) | $CoMoO_4$ + $MoO_3$ | 1.14 | 0.21 | 0.93 | 0.23 |
| | $Co_2Mo_{10}$/Beta(25) | | 1.20 | 0.31 | 0.89 | 0.35 |
| IV | $Mo_{10}$/Beta(25) | $MoO_3$ | 1.19 | 0.78 | 0.41 | 1.89 |
| | Beta(25) | - | 1.24 | 0.58 | 0.66 | 0.88 |

# Impact of catalytic hydrotreatment over simulated pyrolysis oil for bio-char formation

Elham Nejadmoghadam[1], Abdenour Achour[1], Olov Öhrman[2], Prakhar Arora[2], Louise Olsson[1], Derek Creaser[1*]

[1]*Chemistry and Chemical Engineering, Chalmers University of Technology, Gothenburg, Sweden*

[*]*derek.creaser@chalmers.se*

**Introduction.** Pyrolysis oil obtained from biomass has inferior properties such as low energy density due to high oxygen and water content, high acidity, and immiscibility with petroleum-derived fuels, which limit its utilization. Therefore, catalytic upgrading is essential to apply it as a high-quality fuel. A two-stage hydrotreatment is therefore beneficial in which pyrolysis oil is first stabilized at a lower temperature (150−300°C) before it is heated to a high temperature (350−400°C) where the majority of the oxygen removal takes place [1]. In this study, we aim to minimize and understand the nature of solids formed at the mild conditions over various ɣ-alumina supported catalysts.

**Experimental/methodology.** Monometallic (Pd, Pt, Rh, Re), 2 wt. % and bimetallic (NiMo), 5 wt.% Ni and 15 wt.% Mo catalysts supported on pre-calcined ɣ-alumina were prepared. Acetic acid, hydroxyacetone, benzaldehyde, guaiacol, 5-hydroxymethylfurfural (HMF), and levoglucosan were selected to represent acids, ketones, aldehydes, phenols, furans, and sugars respectively in real pyrolysis oil. This simulated pyrolysis oil in hexadecane was heated to 180°C , with 60 bar of $H_2$. Thereafter the reaction was continued for 4h at 180°C. After collecting the liquid product, the catalyst and solid residue in the reactor were removed with acetone and dried. Soluble and insoluble (char) extractions of the total solid product were separated through DMSO rinsing. The soluble fraction contains more oxygenates while the insoluble fraction is largely carbonaceous compounds.

**Results and discussion.** Various catalysts present different behaviors in mild hydrotreatment of simulated pyrolysis oil. The solid yields obtained from mild hydrotreatment are given in Figure 1(a). Among these catalysts, $Pd/Al_2O_3$ was the most active catalyst in mild hydrotreatment of simulated pyrolysis oil to produce minimum solid/char yields. The presence of $Pd/Al_2O_3$ and $Rh/Al_2O_3$ catalysts causes a large portion of the solid product to be DMSO soluble while it was the opposite for the other catalysts. The results also show NiMo catalyst performs much better compared with Re and Pt in terms of suppressing the solid formation. We also found a correlation between the color of liquid products and the yield of solids. This evidence indicates the higher yield of solids is accompanied by the darker yellow coloration of the liquid sample which suggests that the DMSO soluble fraction is humin formed during the mild hydrotreatment of levoglucosan and HMF [2], [3]. Different loadings of Pd over $Al_2O_3$ (2 to 5 wt%) were also investigated (see Figure 1b). Higher amounts of total solids were found by increasing the catalyst metallic loadings from 2 to 5wt%. However, they were mostly composed of the soluble fraction for 5 wt% $Pd/Al_2O_3$.

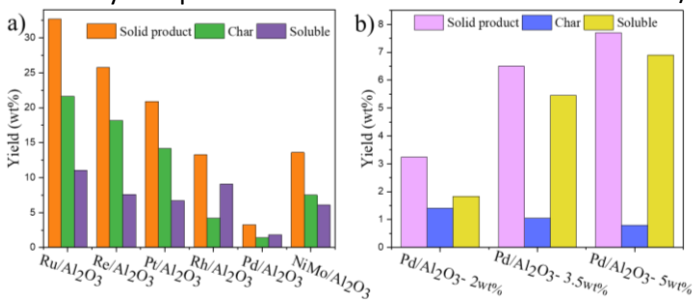

**Figure 1. The yield of total solid, char and soluble fractions from stabilization of simulated pyrolysis oil (180°C, 60 bar of $H_2$, 4 h). a) in presence of different catalysts. b) in presence of $Pd/Al_2O_3$ catalysts with loading 2-5 wt%.**

**Keywords:** $CO_2$ hydrogenation, Ni catalysts, Intermetallics, Power to Methane, Carbon capture and utilization

**Introduction.** In the frame of green-houses gas reduction, the development of $CO_2$ capture and utilization technologies is recognized as a key-target to achieve carbon neutral economy by 2050 and attracted the attention of catalysis community in the optic to reduce emissions arising by the energy sector and develop circular economy approaches. In literature, Ru and Ni are recognised as active phases [1], and the addition of suitable promoters manganese [2], lanthanum [3,4] and cerium [5] among others have been investigated; however, their optimum loading might be different as a function of the support and preparation procedure, thus being still matter of debate, and moreover a comparison with suitable intermetallics seems to be fruitful.

**Experimental/methodology.** A series of catalytic materials have been prepared by classical and novel synthetic routes i.e., sequential incipient wetness impregnation, co-impregnation, etc, by keeping a constant Ni loading of 13.6 wt.%, found as optimum from previous studies. Promoters loading have been varied in the range 0-37 wt.%. In parallel, aluminium/nickel, lanthanum/nickel, and cerium/nickel intermetallic compounds have been prepared weighing the metals in the proper stoichiometric ratio. The samples were prepared using an arc melting unit under argon atmosphere. Both fresh and exhaust catalysts have been fully characterized by BET, XRD, FE-SEM, IR, UV-vis-NIR. The assessment of catalytic performances has been carried out at atmospheric pressure and by both increasing and decreasing the reaction temperature in the range 523-773 K in diluted conditions and by keeping a GHSV of 55000 $h^{-1}$. Evaluation of catalytic performance in on-demand application has been also assessed.

**Results and discussion.** Supported catalytic materials have been found performant in the investigated reaction, by achieving remarkable conversion and methane selectivities at low temperature and, approaching thermodynamic equilibrium at higher temperatures i.e., above 673 K. Interesting results have been also obtained for intermetallic derived catalysts, allowing the understanding of such novel application of these materials. In the case of La- supported $Ni/Al_2O_3$ catalysts, results confirmed a quite remarkable effect of the followed preparation procedure. In the present work, Ce-based catalysts resulted more active than La-based ones and best methane yield is 92% at 623 K.

**Keywords:** Ceria-zirconia; Ni; $CO_2$; SNG; PtG

**Introduction**

Utilizing $CO_2$ in power-to-gas (P2G) is a novel concept in low carbon gas technologies. EU aim is to net zero carbon emissions by 2050 to achieve low to zero Carbon Society [1]. Two approaches exist to the current problem, either the use of non-carbon energy and fuel technologies or to convert the abundant $CO_2$ gas to valuable compounds. The former one is the long-term solution and the later can be a present solution. If the net gained $CO_2$ can be effectively utilized to make synthetic fuels, it can significantly reduce carbon emissions. Producing synthetic natural gas (SNG) *i.e.* mainly $CH_4$ from $CO_2$, which is also called as methanation, is of great interest in the scientific and industrial community [2].

$$CO_2 + 4H_2 \rightleftarrows CH_4 + 2H_2O,\ \Delta H^0_{298K} = -206\ kJ\ mol^{-1}$$

**Experimental/methodology**

First, $CeO_2$-$ZrO_2$ supports were prepared with molar compositions ceria and zirconia precursors by co-precipitation method. In the next step, sequential wet impregnation was done by using dopant tungstate salt ($WO_3$) & Ni 10 wt.% loadings. The catalysts was characterised by XRD, TEM, TPR, TPD, ICP, etc. The activities of the catalysts were tested in $CO_2$ methanation. The methanation reaction was performed in a quartz fixed bed reactor uder atmospheric pressure. Typically, in each experiment, catalyst powder was packed in the reactor which was fixed vertically inside a furnace and a thermocouple was embedded in the middle of catalyst bed to measure the reaction temperature. The catalyst was then reduced under 15%$H_2$/$N_2$ flow of 85 mL.min$^{-1}$for 30 min at 400°C. The gaseous reactant mixture *i.e.* $CO_2$:$H_2$:$N_2$ (1:4:16) was fed to the reactor with $N_2$ and total volumetric flow rate of 800 mL.min$^{-1}$.

**Results and discussion**

In this work $CO_2$ methanation is studied over Ni modified $WO_3$ doped $CeO_2$-$ZrO_2$ mixed oxides catalysts with different Ce/Zr molar ratios and the $WO_3$ loadings (1-6 wt.%). As predicted effect of temperature had profound influence and compared the results with the equilibrium conversion. The nature of the support and the composition determine the metal-support interactions and its role in enhanced activity. Overall, the catalyst with optimized $CeO_2$-$ZrO_2$ 50 wt.% and addition of 6 wt.% $WO_3$ was found to be the most desirable composition in gaining highest activity. The degree of Ni dispersion and the optimal strength of basicity and the reducibility varied with the support composition. The catalyst was stable during the time of stream for 10 h over NW6C5Z5 (Ni 10 wt.%, W: 6 wt.% with $CeO_2ZrO_2$ 50 wt.%).

# $CO_2$ methanation over Ru and Ni based catalysts: towards a comprehensive kinetic model through a multi-technique study

Clara Larghi, Alessandro Porta, Roberto Matarrese, Carlo Giorgio Visconti* and Luca Lietti
*Department of Energy, Politecnico di Milano, Milano 20156 (Italy)*
**carlo.visconti@polimi.it*

**Introduction.** In the last years, the interest in $CO_2$ methanation has grown exponentially as it has proved to be a valid solution for both $CO_2$ reutilization and renewable energy storage. The most credited active metals for $CO_2$ methanation catalysis are Ru and Ni. The former is known to be the most active at low temperatures; however, because of its high cost, Ni is sometimes preferred despite its lower turnover-frequency (TOF) [1]. For these reasons, the metal loading in Ru-based catalysts is usually low (0.5-5 wt.%), while the amount of nickel required to achieve comparable performances is up to one order of magnitude higher. This work aims at developing a comprehensive kinetic model for $CO_2$ methanation on Ru and Ni catalysts through experimental data fitting and the exploitation of mechanistic information collected through *spatially-resolved operando* FT-IR spectroscopy and tests at short contact times.

**Materials and Methods.** Ru-based catalysts with loadings in the range 0.25-8 wt.% were prepared by dry impregnation of $Ru(NO)(NO_3)_3$ aqueous solutions on γ-$Al_2O_3$ (Sasol Puralox, $d_p$ = 0.1 mm). Ni-based catalysts, with loading spanning from 5-88 wt.%, were prepared by dry-impregnation, deposition-precipitation or co-precipitation, starting from $Ni(NO_2)_3$ (hexahydrate) and γ-$Al_2O_3$ (Sasol Puralox, $d_p$ = 0.1 mm) or $Al(NO_3)_3$ (nonahydrate). All the catalysts were characterized by $H_2$-TPR, $N_2$ adsorption isotherms, SEM-EDX, ICP-AES and $H_2$ pulse chemisorption, and tested at 0 barg, 150-390°C and space velocity in the range 10-130000 L(STP)/h/$g_{cat}$. The composition of the stream was quantified by an Agilent 990 micro-GC. *Spatially resolved operando* FT-IR measurements were taken at the inlet and outlet of a self-supporting catalyst wafer (GHSV = 125-850 L(STP)/h/$g_{cat}$) using a Bruker Vertex 70 FT-IR spectrometer, while analyzing the gas phase leaving the reactor by means of a MKS Multigas 2030 FT-IR spectrometer.

**Results and Discussion.** Through a first catalyst screening, the appropriate selection of precursors and preparation methods allowed us to exploit the structure sensitivity of the reaction, leading to materials with optimized average crystallite sizes: an impregnated 4% $Ru/Al_2O_3$ catalyst (TOF= 0.11 $s^{-1}$ at 250°C, $d_c$ = 5 nm) and a coprecipitated catalyst with an equimolar Ni/Al ratio (Ni 45 wt.%, TOF=0.03 $s^{-1}$ at 250°C, $d_c$ = 7 nm). In the two optimized samples, the difference in the intrinsic activity of the metals was effectively balanced by the overall metal loading, so that catalytic materials with similar active phase dispersion and activity a constant GHSV/$g_{cat}$ were obtained (Figure 1a). Then, a set of dedicated tests was carried out at short contact times. Figure 1b shows the results obtained on the Ru-based catalyst: when reducing the contact time, the C-selectivity to CO pointed at 100% in the entire temperature range. The same trends were observed on the Ni-based catalyst, confirming that in both cases CO is a key intermediate. Coupling these results with the ones obtained by *spatially-resolved operando* FT-IR measurements, it was possible to formulate an appropriate kinetic scheme that can properly describe both the $CO_2$ consumption and CO formation (Figure 1c) on both Ru and Ni-based catalysts in a wide range of operating conditions.

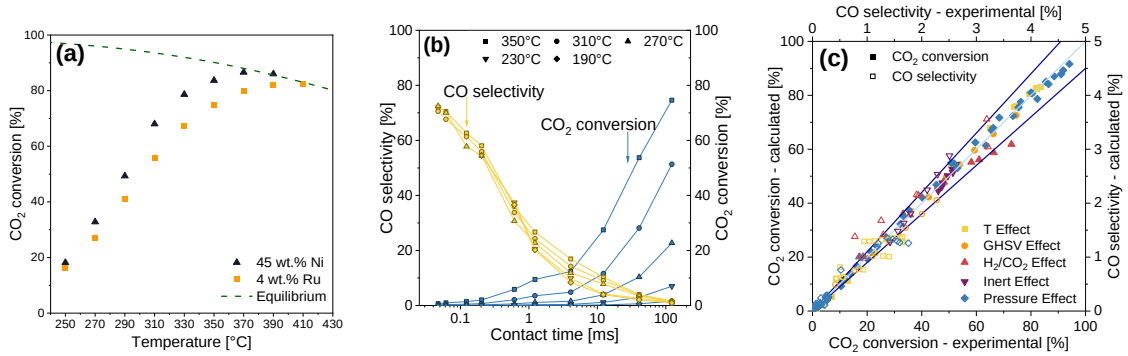

**Figure 1.** (a) $CO_2$ conversion of reference Ru and Ni catalysts; (b) $CO_2$ conversion and CO selectivity of reference Ru catalyst. P.C.: 0 barg, $H_2/CO_2$ = 4; (c) parity plot of $CO_2$ conversion and CO selectivity on Ru catalyst.

**Keywords:** $CO_2$ methantion, BEA zeolite, nickel, deactivation

**Introduction.** Conversion of waste carbon dioxide with green hydrogen to the useful products, such as methane or methanol has been widely discussed as the method of greenhouse gas abatement together with renewable energy storage, as elements of the hydrogen economy. The methanation of $CO_2$ can be carried out at low temperatures by using relatively low-cost supported nickel catalysts [1,2]. However, nickel nanoparticles deposited on oxide supports may agglomerate during this exothermic reaction, leading to a decrease in catalyst activity. Moreover the traces of sulfur compounds in the feed stream can induce rapid and irreversible deactivation of the catalysts [3]. The aim of our studies was development of methanation catalysts with high activity, selectivity and improved resistance towards sintering and poisoning.

**Experimental.** The catalysts containing 10 wt.% Ni were preprated by the application of unmodiffied and dealuminated BEA zeolites as supports [4,5]. The properties of catalysts on the different operation stages were investigated by the application of versatile experimental methods, including X-ray diffraction, high-resolution transmission electron microscopy, FTIR, MAS NMR, $NH_3$ TPD [5]. The state of catalysts before and after reaction was investigated by quasi in-situ photoelectron spectroscopy (XPS) [5]. The course of reaction was determined by the application of in-situ diffuse infrared Fourier-transform spectroscopy (DRIFTS). The activity, selectivity and durability studies of catalysts in in the $CO_2$ methanation reaction were performed using fixed-bed continuous-flow quartz microreactor [5]. Similar studies were carried out for determination of $H_2S$ poisoning resistance of catalysts.

**Results and discussion.** Reduction of catalysts prepared by the impregnation of unmodified BEA zeolite led to the formation of nickel nanoparticles of wide size distribution and versatile morphology, in part deposited on the external surface of zeolite grains. The increase in crystallite size and migration of nanoparticles to the outer part of grains with time-on-stream in the $CO_2$ methanation reaction performed at high temperature was observed. This resulted in the decrease in $CO_2$ conversion and selectivity towards methane. Such effects were attributed to relatively high hydrophilicity of the surface of unmodified BEA zeolite support. Stepwise poisoning of catalysts in the presence of the traces of $H_2S$ in the feed stream led to the drop of $CO_2$ conversion and simultaneously to decrease in methane selectivity.

In turn, bounding of nickel precursor in the vacant sites formed upon zeolite dealumination resulted in the slower agglomeration of nickel nuclei and formation of very small metallic nanoparticles, nested only within zeolite grains. The obtained catalyst exhibited high activity, selectivity to methane and, at the same time, significantly improved sintering and $H_2S$ poisoning resistance. TEM and XRD studies showed no decrease in crystallite size with time-on stream in $CO_2$ methanation reaction. The improved properties of catalysts were related to the higher dispersion of nickel, directly related to the increase in the number of active sites on metallic nickel crystallites, certain structural changes of the support, slowing down the agglomeration processes of the nickel crystallites, as well as changes in the surface properties of zeolite lattice, associated with a decrease in the acidity and hydrophilicity of surface.

**Corresponding authors: xiaowei.chen@uca.es, juanjose.delgado@uca.es*

**Introduction.** Methane dry reforming with $CO_2$ (DRM) is considered as an alternative process to produce hydrogen. Plenty of efforts have been made using Ni-based catalysts on different supports, specially on alumina[1]. Until to now, only a few work reported Ni supported on manganese monoxide for this reaction[2]. A series of Ni-MnO catalysts with different Ni:Mn molar ratios have been synthesized. The objective is to understand the influence of Ni loadings on the catalytic activity for DRM.

**Experimental.** Ni-MnO catalysts have been synthesized using hydrothermal method. The synthesis was carried out on a custom-built six-port autoclave[3]. 50 mL of aqueous solution of 62.6 mM $KMnO_4$ and 3.13, 6.26, 15.65 or 25.04 mM $Ni(NO_3)_2$ was added to Teflon liner vessels. 5 mL of absolute ethanol was dropwise added to the above-mentioned solution. The autoclave was heated to 100 °C with a rotating speed of 50 rpm and kept at 100 °C for 12 h. The sample was dried overnight and calcined at 500 °C for 6 h. After reduction at 500 °C, the catalysts are named xNi-MnO (x=0.05, 0.1, 0.25 and 0.4). Catalytic test was performed using 50 mg of catalyst diluted by 100 mg of SiC. After pretreatment at 500 °C, the catalytic reaction was run at 750 °C for 24 h in a reaction mixture of 25 mL/min $CH_4$ and 25 mL/min $CO_2$.

**Results and discussion.** XRD results of these Ni-MnO catalysts indicate the formation of metallic Ni and MnO phases after reduction. ICP results show that the Ni loadings are very close to their theoretical values. Figure 1a shows $CO_2$ conversion of DRM over these reduced catalysts. The 0.25Ni-MnO catalyst exhibits the highest activity and the most stable $CO_2$ conversion among these Ni-MnO catalysts. Meanwhile, the highest $H_2$/CO ratio around 0.8 is observed over the same catalyst. The order of catalytic activity and $H_2$/CO ratio of these catalysts is as flowings: 0.25Ni-MnO > 0.1Ni-MnO > 0.05Ni-MnO > 0.4Ni-MnO.

The particle size of these catalysts is in a retively wide range up to 180 nm. Element maps of EDX results indicate that K partially covers Ni particles over 0.05Ni-MnO (Figure1b) and 0.1Ni-MnO catalysts, which is due to existence of potassium in cryptomelane phase before reduction. This might be the reason why these two catalysts present lower catalytic activitites than other catalysts. However, no K on Ni particles can be observed over 0.25Ni-MnO and 0.4Ni-MnO catalysts, which mainly consist of $Mn_2O_3$ and $NiMnO_3$ phases before reduction. Carbon nanofibers formed over Spent 0.25Ni-MnO catalyst after DRM reaction (Figures 1c and 1d) and it can be consumed during reaction.

# Integrated capture and methanation of $CO_2$ using mono- and bimetallic Ni and Ni-Ru catalysts along with a Na-$Al_2O_3$ sorbent

A. I. Tsiotsias[1], C. Giotas[1], A.I. Latsiou[1], N.D. Charisiou[1], M.A. Goula[1*]

**Keywords:** $CO_2$ capture, $CO_2$ methanation, dual function materials, bimetallic catalysts.

**Introduction.** The conversion of emitted $CO_2$ into renewable methane aims to create a closed carbon cycle with net zero $CO_2$ emissions [1]. In recent years, the development of dual-function materials (DFMs) that can realize both functions of $CO_2$ capture and conversion to methane at the same temperature, in an integrated process, has gained increased traction [2]. Many of them utilize a physical mixture of sorbent and catalyst, as this approach enables the concurrent optimization of both active phases [2]. In this work, we employ mono- and bimetallic catalysts (Ni and Ni-Ru) supported on Pr-doped $CeO_2$, along with a $Na_2O/Al_2O_3$ sorbent, while varying the weight percentage of the catalyst in the DFM physical mixture.

**Experimental/methodology.** The 12% $Na_2O/Al_2O_3$ sorbent, 10% Ni/Pr-$CeO_2$ and 1% Ru, 10% Ni/Pr-$CeO_2$ catalysts were prepared via wet impregnation of the corresponding nitrate salts on a commercial $Al_2O_3$ support and a $Ce_{0.9}Pr_{0.1}O_{2-\delta}$ (Pr-$CeO_2$) support prepared via a modified Pechini method, respectively [1]. During the testing, 0.4 g of the dual-function material (sorbent-catalyst physical mixture in different weight ratios) was reduced under 10% $H_2$/Ar at 400 °C for 30 min, followed by temperature drop at 300 °C. 10% $CO_2$/Ar (50 ml/min) was then flown into the reactor for 15 min, followed by a 5 min Ar purge and finally, the flow was changed to 10% $H_2$/Ar (50 ml/min) for another 30 min (gas analysis via mass spectrometry).

**Results and discussion.** Figure 1 shows the evolution of the gas outlet $CH_4$ composition with time during the hydrogenation stage, following the $CO_2$ capture and Ar purge. It is essential to strike a delicate balance beween the supply of sorption and catalytically active sites, as both are needed during this integrated process. For example, 100 wt% of the Ni/Pr-$CeO_2$ catalyst alone yields only a meager amount of $CH_4$. $CH_4$ yield maxes out for 50 wt% Ni/Pr-$CeO_2$ catalyst at the DFM physical mixture at 0.41 mmol/g, while 0.33 mmol/g are produced for 25 wt% Ni/Pr-$CeO_2$ catalyst. It is also rational to think, that a lower catalyst amount results to obvious cost benefits. When the Ni-Ru bimetallic catalyst was tested, maximum $CH_4$ yield was observed for 25 wt% of NiRu/Pr-$CeO_2$ catalyst at 0.51 mmol/g, meaning that the more active bimetallic catalyst can boost $CH_4$ production while being in lower amounts at the DFM physical mixture.

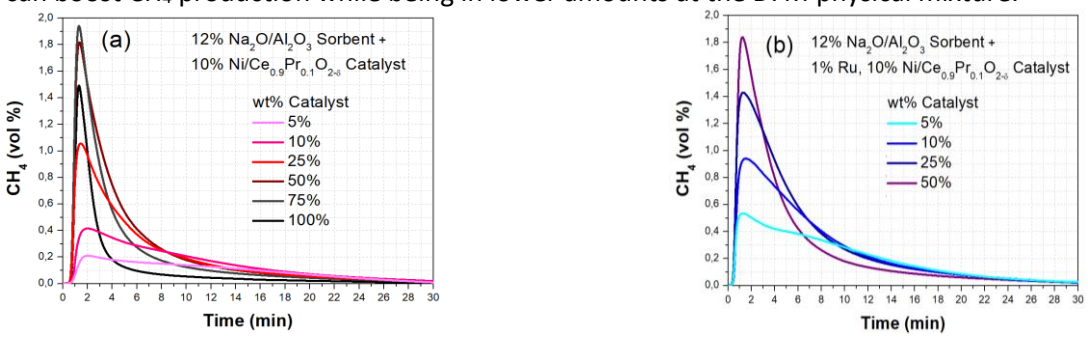

**Figure 1: $CH_4$ yield during the hydrogenation stage for (a) Ni/Pr-$CeO_2$ and (b) NiRu/Pr-$CeO_2$ catalysts.**

# Biogas upgrading through $CO_2$ methanation in a polytropic - distributed feed fixed bed reactor

P. Durán, P. Aragüés-Aldea, E. Francés, J.A. Peña, J. Herguido*

*Catalysis, Molecular Separations and Reactor Engineering Group (CREG) - Aragon Institute of Engineering Research (I3A), Universidad Zaragoza, 50018 Zaragoza (Spain)* * *jhergui@unizar.es*

**Keywords:** methanation, biogas, power to gas, distributed feeding, improved selectivity

**Introduction.** The conversion of $CO_2$ present in a raw biogas into more $CH_4$, using renewable-based hydrogen, could represent an interesting upgrading approach under the frame of *Power-to-Gas* (*PtG*) strategy. The involved *Sabatier* reaction is currently being studied woldwide, mainly using conventional catalytic fixed bed reactors. However, in a previous work [1] the alternative of a fixed bed polytropic-feed reactor (i.e., with several side gas inlets) was experimentally analyzed. It was found that a side distribution of $CO_2$ (so-called *'Poly-$CO_2$'* configuration) clearly led to improvements of performance in terms of both a conversion enhancement at all temperatures and a noteworthy lowering in selectivity to CO. The aim of this work is to extend the study to the methanation of a $CH_4$+$CO_2$ gas stream, simulating a biogas, and to compare it with the former results for a methane-free stream of $CO_2$.

**Experimental/methodology.** The experimental set-up was based on a 12 cm high fixed-bed reactor with different side feeding points and an upper main one. For a given WHSV (e.g., 108 $g_{CO2}.g_{cat}^{-1}.h^{-1}$) different feeding configuration were analyzed at different temperatures (400-250°C), always keeping the global ratios $H_2$:$CO_2$ = 4:1 and $CH_4$:$CO_2$ = 7:3. Apart from conversions and selectivities, the detailed temperature profile along the bed was also registered.

**Results and discussion.** The side distribution of biogas in the so-called *'Poly-Bio'* configuration (Fig. 1), always allowed a clear increase in activity, and also a flatter temperature profile, compared to the conventional co-feeding. In addition, for any achieved conversion the *'Poly-Bio'* arrangement always becomes less selective to CO than the conventional one, regardless of the working WHSV and chosen temperature (Fig. 2). Therefore, the previously observed advantages of distributed feeding [1] have also been achieved for biogas upgrading through $CO_2$ methanation.

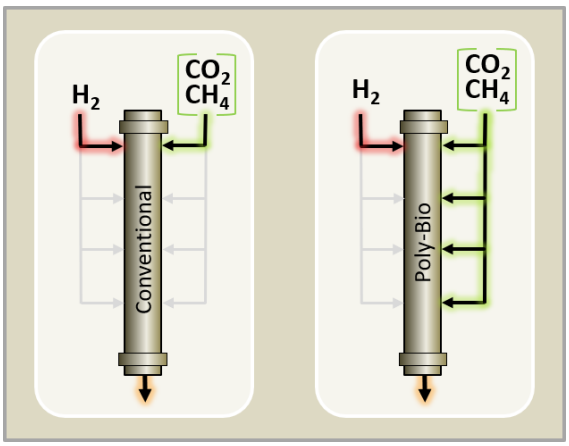

**Fig. 1. Reactor sketch for *'Conventional'* and *'Poly-Bio'* feeding configurations.**

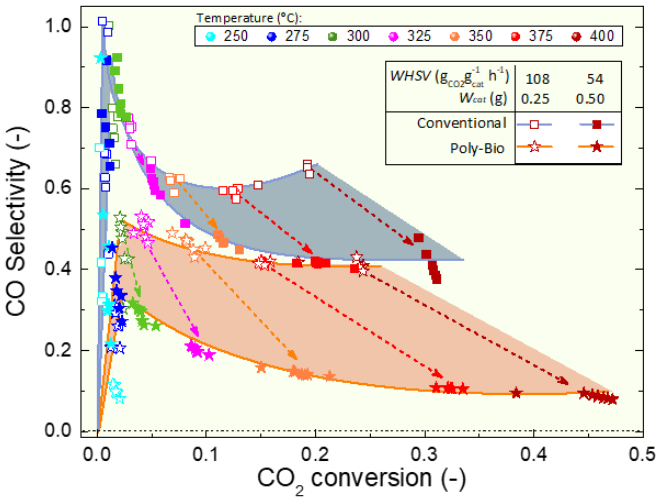

**Fig. 2. Selectivity to CO *vs.* $CO_2$ conversion. Effect of *WHSV* as function of *T* (°C) and feeding mode.**

**Keywords:** Co-Fe alloy nanoparticles, N-doped graphitic carbon, selective CO2 hydrogenation to C2-C4

**Introduction.** Capture and utilization can be a viable strategy to decrease $CO_2$ atmospheric emissions, making it possible to reach the objectives for gradual decarbonization. Further, $CO_2$ hydrogenation can result in different compounds with different number of carbon atoms and functionalities. However, from the economic point of view, hydrocarbons with more than one carbon (C2+) are more attractive since they can be subsequently transformed into olefins or aromatics. Therefore, new catalysts for the $CO_2$ hydrogenation with an increased selectivity toward C2+ products are very important. With this aim, we report that Co-Fe alloy nanoparticles (NPs) of about 10 nm average size wrapped on N-doped graphitic carbon can exhibit selectivity toward C2, C3, and C4 over 50% under optimal conditions at $CO_2$ conversions over 30% [1].

**Experimental/methodology.** The N-doped graphitic carbon was obtained treating 400 mg chitosan in 250 mL acetic acid and 20 mL milli-Q water with an aqueous solution of sodium hydroxide (2 M, 500 mL). The resulted gel microspheres were then washed with distilled water to pH = 7. The resulting hydrogel microspheres were washed by a series of ethanol/water baths with an increasing concentration of ethanol and immersed in 40 mL $CoCl_2$-$FeCl_2$-ethanol solutions with different concentration, for 2 days. After that, the microspheres were reduced with 150 mL of $NaBH_4$-ethanol solutions and then exchanged by supercritical $CO_2$. The resulting aerogel microspheres were finally pyrolyzed under Ar flow at 900 C for 2 h.

**Results and discussion.** The resulted composites were fully characterized using textural, spectral, and diffractometric techniques (Figure 1, a). The reaction was structural sensitive with the highest selectivity to C2-C4 for catalysts with sizes in the range 10.5-14 nm (Figure 1, b). DFT calculations carried out at PBE-D3/def2-SVP level of theory taking 20 atoms with a composition Co14Fe6 prove the selectivity can be indeed controlled through the electron density by a strong interaction with the graphitic carbon support and fine-tuning of the particle size distribution (Figure 1, c).

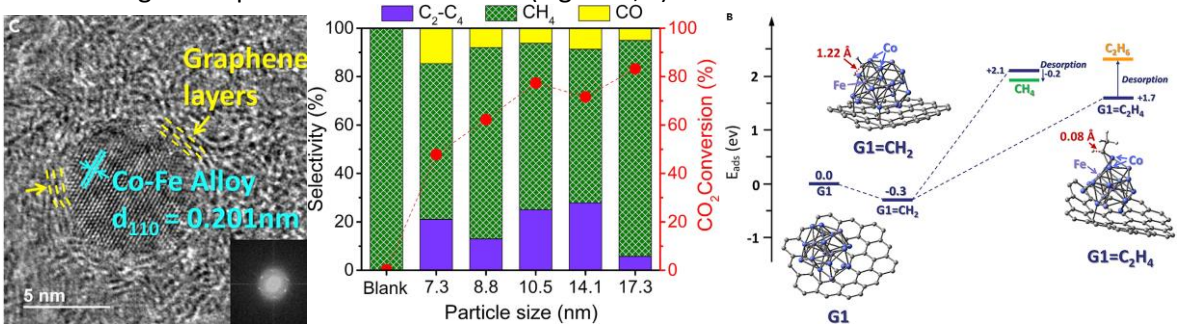

Figure 1. Structure of the graphitic catalysts (a), conversion of $CO_2$ and selectivity of the reaction (b) and DFT calculations (c)

In summary, this study has shown the importance of size control in Co-Fe NPs wrapped on N-doped graphitic carbon to favor the C-C bond formation during $CO_2$ hydrogenation.

**Introduction.**

Carbon dioxide rational utilization is one of the most important goals for science and engineering, because of rapid climate changes and global warming caused by the increased anthropogenic emissions of this greenhouse gas. One of the possible solutions to control the atmospheric concentration of this gas is $CO_2$ hydrogenation to light olefins (LO) – platform molecules [1] for the synthesis of clean fuels, polymers and different organic molecules. The methanol-mediated approach implies $CO_2$ hydrogenation to LO over bifunctional catalysts containing a transition metal oxide for methanol synthesis and a zeolite for methanol to olefins (MTO) reaction [2]. This work is dedicated to the investigation of principal impact of each component in such catalysts on their final performance (activity, selectivity). For this purpose, a series of metal-oxide-zeolite hybrid catalysts were synthesised, characterized and tested in $CO_2$ hydrogenation and model reactions. Several general selectivity-conversion correlations have been uncovered for direct $CO_2$ hydrogenation to LO.

**Experimental/methodology.**

Zn-, In-, Mn-, Cr-, Ga- and Zr-based mixed oxides were synthesized by co-precipitation and impregnation and then calcined at 300-500°C. The obtained materials were physically mixed with several commercial SAPO-34 zeolites of different Si/Al ratio. The catalytic experiments were realized in both lab-scale three-microreactor setup and high throughput Avantium Flowrence unit at 375°C, 10-30 bar, 1-4 NL/h/$g_{cat}$ and $CO_2$:$H_2$ ratio of 1:3. The catalysts were also tested in ethylene hydrogenation and methanol conversion at 375°C, 10 bar and different flow rates. The catalysts were characterized by XRD, XAFS, TPR and TEM-EDX. The mechanism and kinetics of $CO_2$ and $H_2$ activation were elucidated by temporal analysis of products (TAP).

**Results and discussion.**

The $CO_2$ hydrogenation over numerous synthesized catalysts showed a decrease in CO-free selectivity to LO fraction with increase in total yield of hydrocarbons (Figure 1). The conducted kinetic and characterisation experiments suggest that the metal-oxide part of bifunctional catalyst determines only the methanol/CO ratio but does not noticeably participate in the MTO process and secondary olefin hydrogenation reactions to paraffins. In opposite, acidity of zeolite part regulates the hydrocarbon selectivity and strong acid sites are responsible for hydrogen transfer reactions. These findings were further confirmed by TAP and model reactions. Ethylene hydrogenation tests were indicative of the crucial role of water and $CO_2$ in inhibition of olefin hydrogenation over metal oxides and hence of their very minor participation in the MTO reactions.

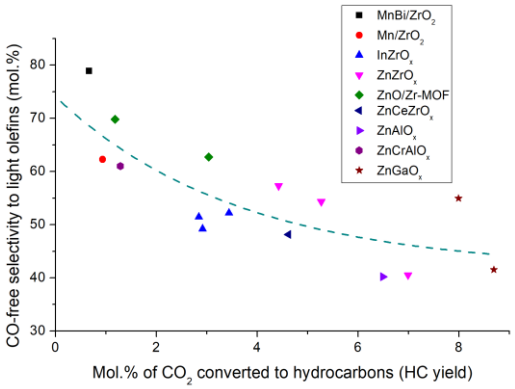

**Figure 1. General dependence of CO-free LO selectivity on hydrocarbon yield for a variety of oxide-zeolite hybrid catalysts.**

# Carbon Nitride-modified Support Materials for Cobalt-based Catalysts for the Hydrogenation of $CO_2$

A. Barthelmeß[1], M. Wolf[1*]

[1]*Karlsruhe Institute of Technology, Karlsruhe, Germany*
[*]*moritz.wolf@kit.edu*

**Introduction**. Carbon dioxide ($CO_2$) is a major contributor to climate change and its utilization as a feedstock is crucial in combating its effects.[1] Hydrogenation of $CO_2$ is a promising for the prodution of valuable hydrocarbons. Methanation of $CO_2$ has been demonstrated on a large scale while enabling utilization of existing natural gas distribution infrastructure.[2] Metal nanoparticles (MNPs) such as Ni, Fe, and Cu, supported on large surface area inorganic metal oxide supports, are commonly used as catalysts for this process. Previous research has shown the importance of well-designed interaction between the metal and support, which is crucial for catalyst activity, selectivity, and deactivation.[1]
Polymerized carbon nitride ($C_3N_4$) is gaining attention in catalysis research as a photocatalyst due to its unique properties, which make it also attractive as catalyst support material.[3, 4] The application of $C_3N_4$ as a support induces a change in the electron density at the catalytically active metal centers, which leads to increased chemical reactivity.[4] Furthermore, $C_3N_4$ has a high concentration of nitrogen and an abundance of incompletely condensed amino groups. The tertiary and aromatic amines may act as a Lewis base catalyst with numerous active sites. In the process of methanation, the Lewis acidic $CO_2$ carbon center can be targeted and the LUMO orbital can be filled through the transfer of electrons leading to a bent shape and loss of linearity, which ultimately leads to enhanced co-activation of $CO_2$.[3, 5]

**Experimental/methodology**. The conventional method for preparing $C_3N_4$ involves the polymerization of melamine, but typically results in low BET surface areas and non-porous systems.[4] In this study, we target the preparation of mesoporous $C_3N_4$ materials with different morphologies to investigate their applicability as support for the methanation of $CO_2$ when decorated with different metal nanoparticles. To improve the mechanical stability of the material, we coated commercial $Al_2O_3$ with $C_3N_4$. Additionally, the synthesis in molten salts resulted in mesoporous $C_3N_4$ samples.[6] The prepared $C_3N_4$(-modified) materials were then decorated with separately synthesized $Co_3O_4$ nanoparticles.[7]

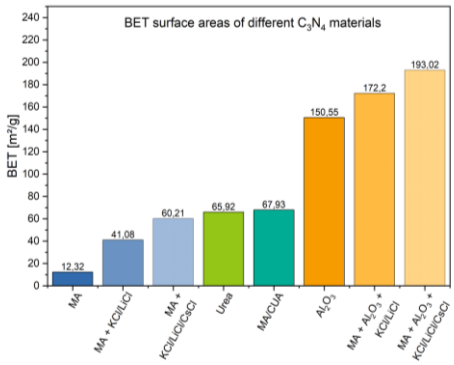

**Fig. 1: BET surface areas of different $C_3N_4$ materials from various precursors (MA: melamine; CUA: cyanuric acid; urea) and preparation methods. After calcination at 550 °C, the coated $Al_2O_3$ samples contain 17 wt.% $C_3N_4$ derived from melamine.**

**Results and discussion.** Analysis of the BET surface areas of the different materialsshowed a significant increase from bulk $C_3N_4$ to mesoporous $C_3N_4$ from the molten salt syntheses to $Al_2O_3$-coated structures (Fig. 1). Catalytic testing of a $Co/Al_2O_3@C_3N_4$ catalyst upon reduction in $H_2$ was conducted in a compact profile reactor[8] to study conversion of $CO_2$ to $CH_4$ and to identify potential synergetic effects of $C_3N_4$. The results indicate an accelerated conversion of $CO_2$ towards CO for $C_3N_4$-modified catalysts. Aside from the comparison of differently manufactured $C_3N_4$ supports to investigate the influence of surface properties and porosity, we have also produced $C_3N_4$ material in tubular form or as spheres.

**Keywords:** $CO_2$ hydrogenation, Reverse water-gas shift reaction, Metal phosphode.

**Introduction.** Extensive efforts are needed to develop $CO_2$ utilization (Carbon recycling) technologies by using green hydrogen. Both the Sabatier reaction ($CO_2+4H_2 \rightarrow CH_4+ 2H_2O$) and the reverse water-gas shift (RWGS) reaction ($CO_2+H_2 \rightarrow CO+H_2O$) proceed competitively at ambient pressure [1]. To achieve the selective formation of $CH_4$ or CO by $CO_2$ hydrogenation, it is necessary to reveal the dominant factor for changing the selectivity in $CO_2$ hydrogenation. We found that the RWGS reaction proceeds selectively by phosphorus-loaded Rh catalyst while the Sabatier reaction proceeds mainly on $Rh/TiO_2$ (Fig. 1). In order to elucidate the role of phosphorus in $CO_2$ hydrogenation, phosphorus-loaded Rh catalysts were prepared and the relationship between structure and catalysis was investigated.

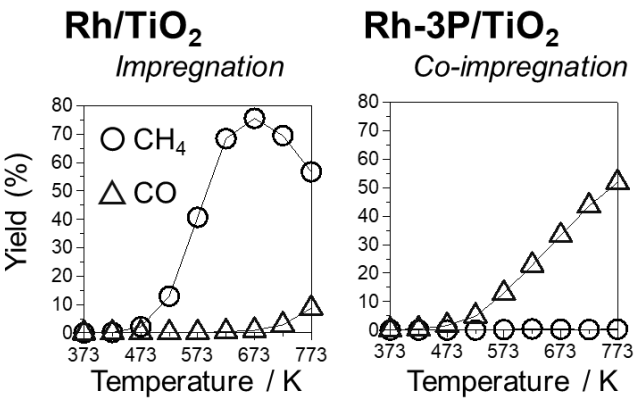

**Fig. 1 $CO_2$ hydrogenation over $Rh/TiO_2$ and $Rh\text{-}3P/TiO_2$. $CO_2/H_2/N_2/He$ = 10/40/5/45 mL $min^{-1}$, GHSV = 60000 mL $g_{cat}^{-1}$ $h^{-1}$**

**Results and discussion.** The catalysts were reduced with $H_2$ at 673 K for 1 h prior to reaction and structural analysis. Rh K-edge XAFS analysis indicated that Rh phosphide ($Rh_2P$) was formed on $Rh\text{-}3P/TiO_2$. In addition, TEM and XRD results indicate that $Rh_2P$ NPs were highly dispersed on $Rh\text{-}3P/TiO_2$. In Rh 3d XPS of catalysts reduced at 673 K, the binding energy for $Rh\text{-}3P/TiO_2$ is higher than that for $Rh/TiO_2$, indicating that the state of Rh in $Rh\text{-}3P/TiO_2$ and in $Rh/TiO_2$ are cationic and metallic, respectively. The band due to linearly adsorbed CO in the CO-DRIFT spectra was observed on $Rh/TiO_2$ (2082.3 and 2095.9 $cm^{-1}$) and (2085.5 and 2098.9 $cm^{-1}$), respectively. The peak position indicates that the C-O bond distance in adsorbed CO on $Rh\text{-}3P/TiO_2$ is shorter than that on $Rh/TiO_2$ by decreasing the $\pi$ back-donation of the d-electron of Rh to the $\pi^*$ orbital in the C-O bond. Therefore, the cleavage of C-O bond of CO molecule was strongly suppressed on $Rh\text{-}3P/TiO_2$. In fact, no CO hydrogenation took place on $Rh\text{-}3P/TiO_2$. The $H_2/D_2$ exchange reaction was performed at 298 K to evaluate the $H_2$ activation ability. $Rh\text{-}3P/TiO_2$ exhibited a higher exchange rate than $Rh/TiO_2$. Based on the kinetic analysis, the reaction orders of $H_2$ and $CO_2$ were estimated to be 0.7 and 0.0 for $Rh\text{-}3P/TiO_2$, and 0.0 and 1.3 for $Rh/TiO_2$, respectively. These results indicate that the rate-determining step (RDS) of $CO_2$ hydrogenation to CO over $Rh\text{-}3P/TiO_2$ would be the reaction process involving $CO_2$ (adsorption or activation). In the case of $Rh/TiO_2$, the activation of $H_2$ or the bond formation (C-H or O-H) processes is the RDS to form $CH_4$.

We have successfully controlled the selectivity of $CO_2$ hydrogenation by adding phosphorus to the supported Rh catalyst. CO was produced with 100% selectivity on the P-loaded catalyst. Structural analysis revealed that rhodium phosphide NPs ($Rh_2P$ NPs) were formed on the P-loaded catalyst. The cationic Rh species in $Rh_2P$ were found to selectively produce CO by preventing the cleavage of the C-O bond of the CO molecule.

# Selective $CO_2$ Hydrogenation to Methyl Formate using $CO_2$ as the Sole Carbon Source

Roland C. Turnell-Ritson[1,*], Paul J. Dyson[1]

[1]*École polytechnique fédérale de Lausanne, Lausanne, Switzerland*
[*]*roland.turnell-ritson@epfl.ch*

**Keywords:** $CO_2$ hydrogenation, methyl formate, zeolites, sustainability

**Introduction.** Atmospheric concentration of $CO_2$ is still increasing, despite international efforts to curb emissions. The removal of $CO_2$ from the atmosphere is a high cost endeavour, necessitating economic incentives for carbon capture. More importantly, the use of the near-unlimited $C_1$ resource of atmospheric $CO_2$ as a building block for process chemicals is essential to a sustainable future.[1] We have developed efficient catalysts for the hydrogenation of $CO_2$ to formic acid (FA), methanol and CO. Additionally, we have combined these $C_1$ building blocks into methyl formate (MF) in one pot. Our catalysts are based on the encapsulation of noble metal complexes and sub-nanoparticles in the pores of zeolites, leveraging the acidity of the support and the principle of nanoconfinement to accelerate these multi-step reactions.

**Experimental/methodology.** Noble metal precursors were encapsulated within the pores of zeolites, and subsequently manipulated *via* reduction, oxidation, or "ship-in-a-bottle"-type synthesis to generate the active catalyst. Catalytic hydrogenation of $CO_2$ was performed in a batch reactor below 250°C with pressures in the range 20-100 bar. The product selectivity can further be tuned using various solvents.

**Results and discussion.** A Ru-based catalyst was developed for the hydrogenation of $CO_2$ to FA, and simultaneously facilitates fast esterification to MF (TOF > 60 $h^{-1}$), comparable to similar catalysts which operate at higher temperatures and pressures.[2,3] A second series of catalysts, both from the literature and developed in our lab, are capable of $CO_2$ and FA hydrogenation to MeOH under the applied conditions. Combining two appropriate catalysts, MF in which both C atoms derive from $CO_2$ is formed. In the presence of a methoxide additive, the MF can be decarbonylated to give high CO concentrations (>20%) at a much lower temperature than traditional reverse water gas shift reactions.[4] The structures of these catalysts will be discussed, and the reaction mechanisms will be explored to understand the key catalyst features which enable their reactivity. The present work allows the formation of three major $C_1$ synthons widely used in industry using $CO_2$ under relatively mild conditions at accelerated rates. Further, attempts to couple $CO_2$ hydrogenation with C-C bond-forming reactions will be described, as we progress towards the sustainable and selective synthesis of $C_{2+}$ products from atmospheric carbon.

**Keywords:** $CO_2$ conversion, Fischer-Tropsch Synthesis, Reverse Water-Gas-Shift, $C_{5+}$ hydrocarbons

**Introduction.** Converting $CO_2$ and renewable $H_2$ into valuable chemicals and fuels would simultaneously decrease $CO_2$ emissions and displace fossil resources. $CO_2$ hydrogenation to hydrocarbons ($CO_2$-FTS) requires the reduction of $CO_2$ to CO via the reverse water gas shift (RWGS) reaction followed by the conversion of CO to hydrocarbons via the Fischer-Tropsch Synthesis (FTS) reaction[1]. The iron-based catalyst is a promising starting point as a bifunctional catalyst for $CO_2$-FT, due to its ability to catalyze both reactions[2]. The delicate balance between the RWGS and FTS reactivities is a challenge to maximize long chain hydrocarbon ($C_{5+}$) selectivity. Both RWGS and FTS are structure sensitive and this study aims to investigate the influences of iron nanoparticle size and dispersion on the interplay between RWGS and FTS.

**Experimental/methodology.** The carbon-supported iron-based catalysts with 5 %, 10 %, and 20 % iron weight loading (with potassium promoter) were prepared by incipient wetness impregnation. $N_2$ physisorption, XRD, $H_2$-TPR, ICP-OES, and TEM were used to identify the chemical and physical properties of the catalysts. Prior to the reaction in a fixed-bed reactor, the catalysts were reduced with diluted $H_2$ flow at 400 °C for 2 h, followed by $H_2$/CO carburization at 280 °C for 20 h. After reduction and carburization, the catalysts were evaluated at 300 °C, 11 bar, $H_2/CO_2$ = 3, 1500 - 18000 $h^{-1}$. The products were analyzed by online with a GC equipped with TCD and FID.

**Results and discussion.** From TEM, the average particle sizes of the carburized catalysts with different iron loading were 8 - 11 nm. The figure provides an overview of the catalytic performance at 300 °C, 11 bar, $H_2/CO_2$ = 3, 1500 - 18000 $h^{-1}$. At 16 % $CO_2$ conversion, CO selectivity was >92 % for all catalysts, suggesting that RWGS was the primary and dominating reaction. At 35 % $CO_2$ conversion, CO selectivity decreased to <30 %, confirming that FTS was the secondary reaction and $CO_2$-FT proceeds via CO. At both conversion levels, the catalyst with a higher iron loading and larger average Fe particle size produced more hydrocarbons. A possible explanation is the presence of more terrace sites which enhance the CO adsorption and stabilize CH* species, thereby promoting C-C coupling[3]. This contribution will discuss separately the effect of particle size and dispersion, so as to unravel the origin of structure-sensitivity in the $CO_2$-FTS process.

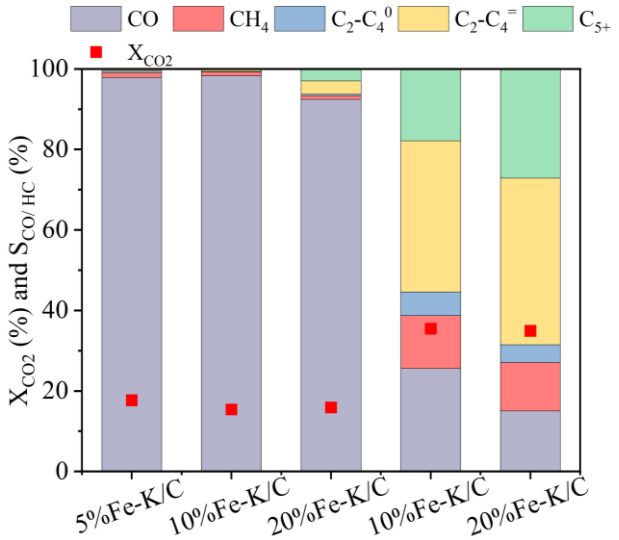

**Figure. $CO_2$ hydrogenation performance over different catalysts at $CO_2$ conversion = 16% and 35%.**

**Keywords:** Reverse water-gas shift, Small-pore zeolite, Hydroformylation

**Introduction.** The hydroformylation of olefins to aldehydes is one of the largest homogeneously catalyzed processes used in industry, with an annual production exceeding 10 Mton.[1] Given its large scale, using $CO_2/H_2$ as a syngas surrogate for this reaction would avoid the use of toxic CO and valorize $CO_2$ into valuable chemicals using green $H_2$. Combining the $CO_2$ reduction towards CO (reverse water-gas shift reaction) with a CO-consuming reaction (e.g. hydroformylation) in a one-pot system creates several incompatibilities regarding their respective reaction conditions, like the hydrogenation of the alkene and the instability of the homogeneous catalyst at the unusually low $CO:H_2$ ratios. In this work, these limitations were overcome by using two catalysts using a one-pot system: a metal-loaded small-pore zeolite for the RWGS, and a homogeneous Rh(I)-phosphine catalyst to perform hydroformylation.

**Experimental/methodology.** Zeolite catalysts were synthesized according to literature.[2,3] Reactions were performed in stainless steel autoclaves (10 mL). The gas phase was monitored using gas phase FTIR. The reaction mixture was analyzed with GC-FID, using *n*-decane as internal standard for quantification.

**Results and discussion.** Different metal loaded small-pore zeolite catalysts were screened for RWGS under conditions closely related to hydroformylation. The encapsulation of noble metals in the small-pore zeolites was then assessed in comparative hydrogenation experiments. The best performing zeolite was finally used in one-pot hydroformylation experiments with only $CO_2$ and $H_2$. Initial screening of reaction conditions of combined reactions is shown in Table 1. Matching of the reaction rates for RWGS and hydroformylation is key to achieve high TON as a low RWGS-rate results in Rh-catalyzed substrate hydrogenation. The zeolite catalyst is essential (entry 1), as no CO or hydroformylation products were observed in its absence. The triphenylphosphine (TPP, entry 2) ligand outperformed its phosphite alternative (TPPO, entry 3) and the bulky chelating BiPhePhos ligand (entry 4). Summarizing, suitable metal@8MR catalysts allow sufficient RWGSR in conditions compatible with those needed by the carbonylation catalyst. Thus, the 2-catalyst system successfully enables hydroformylation with $CO_2$ as the carbon building block.

**Table 1. Screening of reaction parameters for hydroformylation of 1a (4-Methoxystyrene) with $CO_2$ and $H_2$.**

| Entry | L (L/Rh) | $pCO_2$ | $pH_2$ | $TON_{Rh}$ |
|---|---|---|---|---|
| **1**[a] | TPP (100/1) | 15 | 5 | 0 |
| **2** | TPP (100/1) | 15 | 5 | 188 |
| **3** | TPPO (10/1) | 15 | 5 | 15 |
| **4** | Biphephos (5/1) | 15 | 5 | 0 |

Reaction conditions: 4-Methoxystyrene **1a** (0.4 mmol), $Rh(acac)(CO)_2$ (0.4 µmol), ligand (0.002 – 0.04 mmol), 250 mg M@8MR, 2mL MIBK, 24 h and 135 °C. [a] No zeolite was added.

**Keywords:** $CO_2$ utilization, mixed oxide, oxygen vacancy

**Introduction.** $CO_2$ capture and utilization is a must for easying the global warming caused by the uses of fossil fuels. The direct deoxygenation of $CO_2$ to CO is one possible route and the similar deoxygenation route may also convert $H_2O$ to $H_2$. Previous works demonstrate this thermal deoxygenation route over oxygen vacancies of $CeO_2$ at temperatures above 700 °C. [1-3] The vacancy formation temperature and the deoxygenation reaction temperature will govern the energy demand for such $CO_2$ utilization approach. A deoxygenation temperature at mid-temperature range is desirable which can lead to integration with oxygen-conducting inorganic membrane to facilitate sustainable $CO_2$ utilization process. $CeO_2$-based mixed oxides are known to have dopant-dependent properties of oxygen vacancies which can possibly govern the reactivity for $CO_2$ deoxygenation. In this study, various $CeO_2$-based mixed oxides are prepared by coprepreciptaion and their reactivity toward $CO_2$ deoxygenation is evaluated.

**Experimental/methodology.** The mixed oxides were all prepared from nitrate precursors using a coprecipitation method at a constant pH of 12 maintained by NaOH addition, named as M-$CeO_2$. The filtered solid was dried and then calcined to 700 °C. The prepared samples were analyzed by sequential TPR (under 10% $H_2/N_2$) and TPRx-$CO_2$ (under 5 % $CO_2$/Ar), both from 50 °C to 700 °C at a ramp rate of 5 °C/min, using a housemade microreactor system equipped with TCD and MS detection of effluent stream.

**Results and discussion.** The mixed oxides examined include Zr-, Gd-, Sm-, Fe-, Co-, Cu-, and In-$CeO_2$. The commonly used oxygen ion conductors, Sm- and Gd-$CeO_2$, did not show significant $CO_2$ deoxygenation activity in sequential TPR and TPRx-$CO_2$ tests, neither did Zr-, Cu-, or Co-$CeO_2$. Fe- and In-$CeO_2$ showed reactivity for mid-temperature $CO_2$ deoxygenation under the test conditions, with a calculated CO yield above 90 % (based on consumed $CO_2$). XRD analyses indicate that $Fe_2O_3$ and $In_2O_3$ phase were present in the prepared mixed oxides, reduced $Fe^0$ and $In^0$ phases could be identified after TPR, and the oxide phases were found again after TPRx-$CO_2$. Furthermore, the reactivity of both Fe- and In-$CeO_2$ incresed with increasing Fe and In percentage in mixed oxides. This indicates that Fe- and In-related crystallites played an imporatant role in $CO_2$ deoxygenation. Comparatively, neither the physical mixture of $CeO_2$ and $Fe_2O_3$ nor the $Fe_2O_3$ supported on SBA15 offered the same reactivity. This suggests the presence of Ce-Fe (Ce-In) interaction. The isothermal $CO_2$ deoxygenation over $Ce_7Fe_3O_y$ at 600 °C was also examined, wherein the reactivity was enhanced by 50 % when $Ce_7Fe_3O_y$ powders were put over a 1.6-mm-thick stand-alone GDC (Ga-doped $CeO_2$) membrane within an in-house-made membrane reactor. This indicates the feasibility of integrating $CO_2$ deoxygenation mixed oxide with oxygen conducting membrane at mid-temperature range, as a viable $CO_2$-to-CO utilization process.

**Keywords:** dual function material, integrated carbon dioxide capture and utilization, circular economy

**Introduction.** The alarming increase in $CO_2$ emissions, mainly due to fossil fuel consumption, creates an urgent requirement for $CO_2$ reduction. Thus, the novel concept of integrated carbon capture and utilization (ICCU) has gained interest considering environmental and industrial aspects. [1] Dual Function Materials (DFM), containing sorbent species that selectively adsorb $CO_2$ and a catalyst that utilizes it, can be successfully implemented in this concept near a renewable $H_2$ generation facility to reduce both the economic and energy requirements. [2] Therefore, sustainable $CO_2$ valorization can be achieved with the production of chemical fuels and value-added chemicals. [1] Herein, methanol stands out as an appealing end-product considering its high energy density to be used as transport fuel. Methanol can also be used as a building block for other chemicals required in industry. [3]
In this context, this work aims to design appropriate DFMs to produce methanol from captured $CO_2$.
**Experimental/methodology.** DFMs are prepared using Ca, K, and Na as $CO_2$ adsorbing species, and Ni and Ga for catalytic $CO_2$ hydrogenation to methanol. Preparation of the samples involves supported adsorbent preparation followed by the impregnation of catalytic materials. The required amounts of the $SiO_2$ support and $NaNO_3$, $KNO_3$, or $Ca(NO_3)_2{\cdot}4H_2O$ are mixed with deionized water at room temperature with a magnetic stirrer. The excess water is removed in a rotary evaporator under reduced pressure. The samples are dried overnight at 120 °C and calcined at 400 °C for 4 hours. The required amounts of $Ni(NO_3)_2{\cdot}6H_2O$ and $Ga(NO_3)_3{\cdot}xH_2O$ are mixed with the supported adsorbent and deionized water. Excess water is removed in a rotary evaporator under reduced pressure and samples are dried overnight at 120 °C.
The DFMs are reduced at 700 °C under pure $H_2$ flow prior to the catalytic tests. Carbon dioxide capture and utilization tests are performed on a tubular fixed-bed quartz reactor at atmospheric pressure varying temperature and flow rates of $CO_2$ and $H_2$. The preliminary results are analyzed via a mass spectrometer.
**Results and discussion.** NiGa-Ca/$SiO_2$ sample starts producing methanol under $H_2$ flow even in TPR during temperature programmed surface reaction tests. Although the observed amount is low in concentration, the result is important as it can be seen as an indication of DFM adsorbing $CO_2$ from the ambient atmosphere and converting this to methanol in $H_2$ flow at 300 °C (Figure 1).

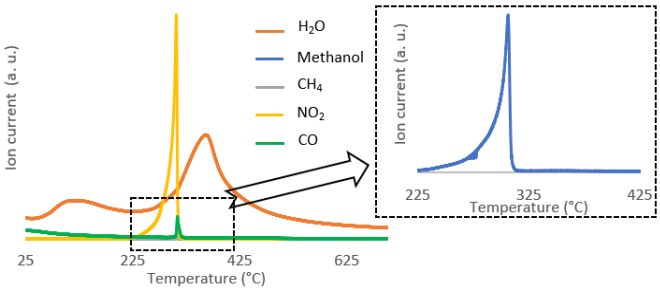

**Figure 1.** Ion current vs temperature data during TPR for NiGa-Ca/$SiO_2$.

Thus, the preliminary results revealed that methanol can be produced on the NiGa phase of the DFM from captured $CO_2$. More catalytic and characterization tests are required to determine the activity and selectivity of DFMs for carbon dioxide hydrogenation to methanol.

The utilisation of $CO_2$ for the synthesis of value-added chemicals has gained increasing interest for the past decade.[1] One promising method is atom-economically transferring $CO_2$ and epoxides into cyclic carbonates relevant to a wide range of applications as green solvents, lithium-battery electrolytes, intermediates for organic synthesis, and monomers for preparation polymers.[2] The novel organocatalysts are synthesised by modification of the conventional halide salts or ionic liquids with hydrogen bond donor (HBD) groups, which can activate the epoxides by forming hydrogen bonds with the oxygen atom of epoxide, facilitating the ring-opening step of the nucleophiles.[3]

In this project, we selected three large-scale available dyes, rhodamine B (RhB), rhodamine 6G (Rh6G) and methylene blue (MB), which contain a big xanthene core and a chloride anion as a nucleophile. These three dyes were first ion-exchanged with KX ( X= Br, I) to obtain a set of nine organocatalysts ( dye-X, X = Cl, Br, I). Their catalytic activity was tested in converting $CO_2$ and styrene oxide into styrene carbonate at 80 °C, 10 bar $CO_2$ for 24 hrs. The structure of the cation, the nature of the anion and the effect of adding $H_2O$ as an external HBD compound on the catalytic activity of dyes were comprehensively investigated. Their catalytic activity largely depends on the counterpart anions, decreasing from $I^-$ > $Br^-$ > $Cl^-$. Additionally, a vast improvement in catalytic activity was achieved by adding 50 mg $H_2O$ as an external HBD compound (96 % styrene carbonate yield with RhB-I and Rh6G-I). However, these dyes are inefficient under lower reaction temperatures (45 °C). Therefore, the new organocatalyst of RhB-Ethyl-PhOH-I (Figure 1) was synthesised and obtained 41 % styrene carbonate yield under mild reaction conditions (45°C, 10 bar $CO_2$, 18 h). Moreover, the organocatalyst of RhB-Ethyl-PhOH-I among the selected epoxide substrates achieved satisfactory corresponding cyclic carbonate yields (Figure 1). Nanofiltration simulated the catalyst recovery, demonstrating a high efficiency of catalyst separation. The organocatalysts of RhB-Ethyl-PhOH-I possess the advantages of efficient catalytic activity, straightforward synthesis method, and ease of separation from the product, which are all assets for the potential for large-scale applications.

| R | Yield / % |
|---|---|
| Methyl | 84 |
| Chloroethyl | 53 |
| Allyl methyl ether | 75 |
| Benzene | 49 |
| Hexyl | 46 |

**Keywords:** Oxalic acid; $TiO_2$ nanotubes; Breakdown; oxygen bubble evolution; Glyoxylic acid; Glycolic acid; Electrocatalysis.

**Introduction.**

The production of $CO_2$-derived chemical feedstocks, coupled with the use of renewable energy, is the challenge of the current century to mitigate the climate change. In this scenario, the electrocatalytic hydrogenation of) in glycolic acid (GC) and/or Glyoxylic acid (GO, ) is one of the most important pathways for the conversion in C2+ valuable chemicals. $TiO_2$ nanotubes (NTs) are very promising electrocatalysts due to their low toxicity and robustness. However, their low productivity makes this route far from commercialization, and their optimization is highly desired [1]. In this work, the experimental conditions were changed to reach the breakdown potential and to study the effect of the TiO2 NTs nanostructure on the catalytic activity and selectivity. Moreover, a thermal and electrochemical pre-treatment were used to obtain a more uniform TiO2 NTs structure and limit the over-etching of NTs during anodization.

**Experimental/methodology.**

Several electrodes were prepared by anodic oxidation of titanium foils varying the applied potential (50 V, 60 V) and the anodizing time (15 min, 60 min). NTs were grown by (i) on as received washed Ti foils, (ii)on thermally (annealing at 450°C for 30 minutes), or (iii) on electrochemically (anodization at 20V for 2 hours in $H_2SO_4$) pre-treated Ti foils.

**Results and discussion.**

The nanostructure was investigated by SEM and discussed in relation to the anodization curves. Longer and rougher NT array are clearly visible for the sample anodized at 60 V compared to the samples obtained at lower potential, suggesting that breakdown conditions are achieved (the anodization current increase) [2]. The NTs array of the electrochemical pre-treated sample is the longest among all investigated samples, and their walls are visibly rougher, probably due to the oxygen bubbles release during the growth process [3]. Roughness and length of NTs walls influence the activity of the catalysts. Indeed, a linear correlation among the NTs length, the selectivity to GC and OX conversion is observed, indicating the NTs length as a critical factor in the electrochemical process. On the other hand, the roughness of the NTs walls could be useful to increase the Faradaic efficiency to GC ($FE_{GC}$) while more smooth nanotubes favour the GO formation. In addition to the effect of the rougher nanostructure on performance, the role of defective oxygen vacancies, due to $Ti^{3+}$ auto doping, measured by X-ray photoelectron spectroscopy (XPS) and confirmed by cyclic voltammetry (CV), was demonstrated by the linear correlation with OX conversion and NT length.

By varying the electrodes nanostructure, it is therefore possible to tune the glycolic acid to glyoxylic acid relative ratio. The best $FE_{GC}$ (86%) and OX conversion (48%) were obtained at -1,1V for electrochemically pre-treated sample.

# Production of eChemicals and eFuels using eREACT™

S. De Sarkar[1*], P. M. Mortensen[1], K. A. Petersen[1]
[1]*Topsoe, Haldor Topsøes Allé 1, Kgs. Lyngby, 2800, Denmark*

**Keywords:** eREACT™, RWGS, eFuels, $CO_2$ utilization

**Introduction.** Topsoe's eREACT™ technology is an excellent example of a step change towards a more sustainable future. It enables direct electrification of the chemical industry by replacing fossil-based energy sources with renewable energy [1]. Many potential applications of eREACT™ have been identified, making it a 'platform' technology. Among these, the eREACT™ for reverse water gas shift (RWGS) can be used to valorize $CO_2$ and biogas, enabling electrofuels (eFuels) production.

**Experimental/methodology.** The proof-of-concept for eREACT™ was established using a bench-scale reactor for steam methane reforming (SMR) and reverse water gas shift (RWGS) applications. The bench-scale eREACT™ reactor has been successfully scaled up to a pilot plant. A number of demonstration runs of eREACT™ with various feed compositions and operating conditions have been carried out in the pilot plant confirming the scale up of the technology.

**Results and discussion.** Tests in the bench-scale eREACT™ reactor for SMR confirmed the desired operation with very low methane slip at the reactor outlet at temperatures of 900°C-950°C. For eFuels applications, RWGS experiments were conducted successfully at 1000°C and above, producing syngas with the target $H_2$/CO ratio suitable for downstream synthesis processes [2].

The pilot operation of eREACT™ with various feed compositions, including biogas (60 mol% $CH_4$; 40% mol% $CO_2$), has been conducted successfully by long-term operation [3]. The expected catalytic performance has been confirmed through various tests, including operation cycles resembling transient conditions during industrial operations.

Process development activities around sustainable aviation fuels (SAF) production, using eREACT™ for RWGS via Fischer-Tropsch (FT) route, has revealed several advantages, including very high carbon efficiency and close to the theoretical minimum hydrogen feed consumption. This means that the electrolysis unit, producing the renewable hydrogen upstream of the eREACT™, can be made as small as possible, thus minimizing capital investment. Furthermore, it results in significantly less overall power consumption in eREACT™ scheme than that in other processes, including the non-electrical RWGS process utilizing either selective or non-selective RWGS catalysts. Additionally, the eREACT™ technology provides synergy in the FT-based eFuels process by allowing conversion of the recycled off-streams from downstream units maximizing the carbon dioxide feed utilization (>95%) in eREACT™ based eFuels process while minimizing the overall power consumption per unit of product.

**Keywords:** $CO_2$ conversion, copper oxide, single crystal catalysts, photo-electro-catalytic (PEC) cells

**Introduction.** The electrocatalytic reduction of $CO_2$ is a promising decarbonisation strategy to address the ever-increasingly limited availability of resources and satisfy the future societal needs. The main challenges for this reaction are the high overpotentials needed to perform the multi-electron transfer, and the poor Faradaic Efficiency (FE) to valuable carbon products especially at higher current density [1]. Understanding of mass transfer phenomena and charge diffusion under realistic working conditions is a prerequisite for the rational design of electrocatalysts/electrodes leading to high carbon selectivity [2]. The aim of this work is to develop novel gas-diffusion electrodes (GDEs) based on earth-abundant materials to be integrated in new engineered artificial leaf-type devices for the efficient production of solar fuels [3].

**Experimental.** CuO nanoplatelets were synthesized by a facile hydrothermal approach at 180°C starting from $CuCl_2 \cdot 2H_2O$ using LiOH or NaOH as the precursors. For the preparation of $CuS_x$-Bi nanocrystals, $BiNO_3$ and S were also added in the reaction bath. The as-prepared electrocatalytic materials were deposited by spray-coating onto carbon-based GDEs and then assembled in a homemade compact electrochemical device for $CO_2$ conversion tests. The electrodes were fully characterized by XRD and SEM, and by Electrochemical Impedance Spectroscopy (EIS) to evaluate the influence of diffusion phenomena on the electrocatalytic performance.

**Results and discussion.** The results showed the high activity of these electrodes in $CO_2$ reduction in near-neutral pH conditions, mainly due to the thin nanoplatelet structure. We observed a different selectivity depending on the precursor used during the preparation, i.e. Na or Li. The catalyst prepared with LiOH was more selective to carbon monoxide (CO), evidencing a FE to CO of 45% (with a current density of 9 mA $cm^{-2}$ at –0.6 V vs. RHE), while using NaOH as the precursor led to a higher FE to formate. The introduction of S and Bi in the catalyst nanoarchitecture (see the resulting structure in the figure) allowed to further increase the selectivity to formate to over 80 % (with a current density of 9 mA $cm^{-2}$ at –1.0 V vs. RHE) and to obtain also the production of C2 products such as oxalic acid. Furthermore, the activity of these catalysts was strongly influenced by the configuration of the electrochemical cell, evidencing the importance of the role of electrode and cell design in determining the performance beyond the properties of the electrocatalytic material itself, at least under reaction conditions relevant to industrial scalability [4]. We used a new engineered compact system designed to minimize energy losses due to overpotential. The integration of this electrochemical cell with a low-cost photovoltaic system is also presented and discussed, paving the way towards the implementation of efficient artificial leaf-type devices for the production of solar fuels.

**Keywords:** RWGS, ME-PSD, Operando FTIR, $CO_2$ hydrogenation, mechanistic study, catalysts

**Introduction.** Catalytic reduction of $CO_2$ to CO via the Reverse Water-gas Shift reaction is attracting renewed interest in producing more sustainable syngas. Many catalysts have been researched, but often suffer from price and selectivity.[1]
To understand and design a good catalyst and improve it, the reaction mechanism is of great interest to understand. Two of the main reaction mechanisms have been proposed, which are a carbonate mechanism and a carbonate-catalyzed mechanism. Which of these mechanisms is often controlled by the $H_2$ dissociation – which can either be homolytic or heterolytic dissociation.[2]
In this work, we present a novel, active and selective catalyst consisting of supported Mn – and we dramatically improve the catalyst by promoting it. Furthermore, we explore the reaction mechanisms hereof with various infrared spectroscopy.

**Experimental/methodology.** The catalysts have been tested in a flow reactor equipped with a water condenser and an NDIR detector, which is tuned for $CH_4$, CO, and $CO_2$.
The operando IR studies were performed in a Nicolet iS50 FTIR spectrometer equipped with a Harrick Praying Mantis Cell with an on-line mass spectrometer by Pfieffer Vacuum OmniStar.

**Results and discussion.** The un-promoted catalysts have shown a conversion of 37% at 1 bar, 650°C with a GHSV of 90.000 in $H_2$:$CO_2$ ratio of 3:1. Furthermore, we did show that by promoting the catalyst, there was a 44% increase in activity compared to the intrinsic activity. Interestingly, the addition of promoters has surprisingly increased activation energy significantly. Therefore, analyzing the reaction mechanism with different operando spectroscopy is of interest. It was clearly determined that it was mainly carbonate species on all the catalyst's surfaces. However, coupling with modulation excitation-phase sensitive detection (ME-PSD) showed that short-lived and active species at the Mn-supported catalysts were carbonates. However, the short-lived and active species on the surface of the promoted catalyst were only bicarbonates and formates.[3] This signified that the reaction undergoes two different mechanisms dependent on whether the sample is promoted or not.

# MXene-based catalysts for $CO_2$ hydrogenation

Y. Yan[1], L. Loupias[2], S. Célérier[2], F. Morfin[1], L. Piccolo[1*]

[1]*IRCELYON, University of Lyon, France*
[2]*IC2MP, University of Poitiers, France*
[*]*laurent.piccolo@ircelyon.univ-lyon1.fr*

**Keywords:** MXenes, $Ti_3C_2T_x$, $Mo_2Ti_2C_3T_x$, single-atom catalysts, $CO_2$ hydrogenation, reverse water-gas shift.

**Introduction.** MXenes are recently discovered 2D carbides, nitrides, or carbonitrides [1]. Depending on their composition, they exhibit intrinsic catalytic properties or can be synergistically promoted with metal nanoparticles or single atoms. Unlike for electro- and photocatalysis, thermal catalysis on MXenes has been little investigated so far. Herein, through a systematic study of $Ti_3C_2T_x$ ("MX") and $Mo_2Ti_2C_3T_x$ ("MoMX") MXenes, as-prepared or loaded with ultradispersed metals, trends connecting the MXene surface state, metal resistance to sintering, and catalytic properties in $CO_2$ hydrogenation are established.

**Experimental/methodology.** $Ti_3C_2T_x$ and $Mo_2Ti_2C_3T_x$ were obtained from the respective $Ti_3AlC_2$ and $Mo_2Ti_2AlC_3$ MAX phases by LiF/HCl and HF etching, respectively [2]. After their delamination in water (plus an intercalation step in TBAOH for $Mo_2Ti_2C_3T_x$), Pt, Pd, Cu and Co were deposited onto the MXenes by incipient wetness impregnation. The samples were then drop casted on silica to avoid restacking (Figure 1, right), pretreated under $H_2$ flow up to 450 °C, and evaluated in a flow-fixed bed reactor at a total reactant pressure of 30 bar ($H_2$:$CO_2$ = 3:1). Pre- and post-reaction characterizations involved XRD, XPS, TGA, SEM, and STEM techniques.

**Results and discussion.** Unlike $Ti_3C_2T_x$, bare $Mo_2Ti_2C_3T_x$ reveals a high activity for the reverse water-gas shift reaction in the 250-350 °C range (Figure 1, top). Furthermore, for both systems, Pt addition at low loading (<1 wt%) enhances the activity and the CO selectivity. In contrast, Pd, Cu and Co negligibly affect the performance of $Mo_2Ti_2C_3T_x$. Together with the metal identity controlling the $H_2$ activation rate, the superior promoting effect of Pt is ascribed to the greater propensity of this metal to atomically and stably anchor at the MXene surface.

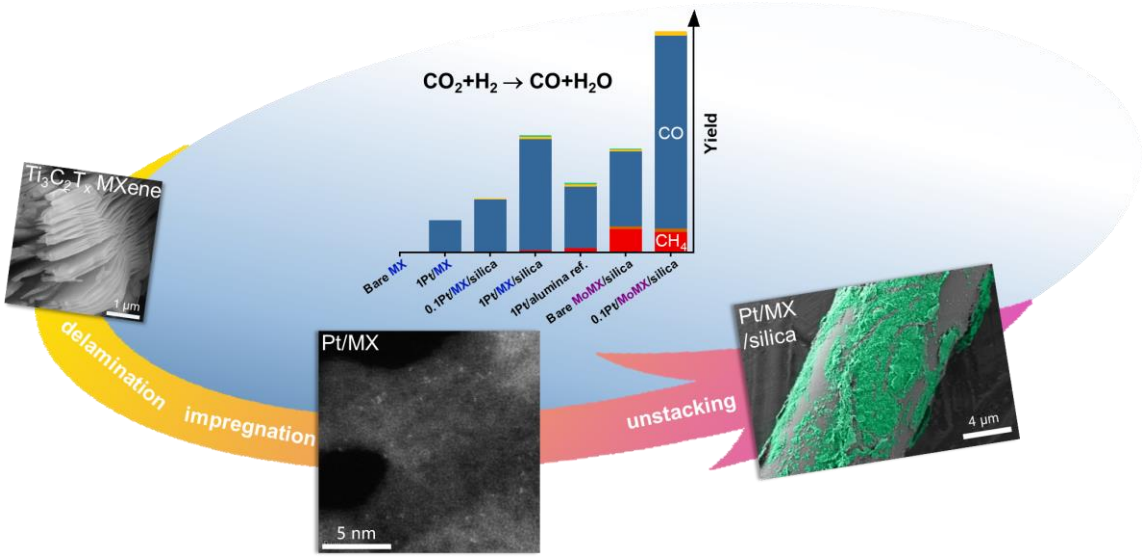

**Figure 1. Main steps in the elaboration of Pt/MXene single-atom catalysts and their conditioning for gas-phase catalysis evaluation. $CO_2$ hydrogenation yields at 275 °C for $Ti_3C_2T_x$ (MX) and $Mo_2Ti_2C_3T_x$ (MoMX)-based catalysts. Blue, red, orange, yellow and green colors correspond to carbon carbon monoxide, methane, higher alkanes, methanol, and dimethyl ether, respectively.**

**Keywords:** $CO_2$ hydrogenation particle size effects, copper nanoparticles, methanol synthesis

**Introduction.** Converting $CO_2$ and renewable $H_2$ into fuels and chemicals is a promising approach to replace fossil resources. Three factors make $CO_2$ hydrogenation to methanol more challenging than conventional methanol synthesis: less favourable thermodynamics, a lower catalyst stability due to the less reducing conditions, and the possiblity of forming CO instead via the reverse water-gas shift reaction. In this study we investigated the particle size effects for $CO_2$ hydrogenation to methanol, by a combination of experimental and computational methods.

**Experimental.** Size-controlled Cu nanoparticles (4-20 nm) were prepared by incipient wetness impregnation of graphitic carbon supports. The rather inert carbon support is crucial to separate size effects from for instance metal-support interaction. The MeOH synthesis performance was tested in a parallel multireactor set-up (Avantium Flowrence) under 40 bar (g) pressure and at 200-260 °C.

**Results.** The catalysts showed a good stability and preservation of the size of the Cu nanoparticles during testing, suitable to fundamentally study the effect of particle size on activity and selectivity. Clear particle size effects were observed. The intrinsic activity (Turn-Over-Frequency or TOF, **frame a**) increased approximately 3-fold when increasing the Cu particle size from 4 to 12 nm. Also the selectivity to either MeOH or CO was a clear function of particle size (**frame b)**. Two distinctly different, yet size independent, activation energies were found for MeOH and for CO production (averaging 63±7 kJ $mol^{-1}$ and 118±6 kJ $mol^{-1}$, respectively). Hence the size dependence was ascribed to a decrease in the fraction of active sites suitable for CO formation with decreasing particle size. Theoretical models and DFT calculations (**frame c)** showed that the origin of the particle size effect is most likely related to the differences in formate coverage for different Cu facets whose abundancy depends on particle size. Hence, the $CO_2$ hydrogenation reaction is intrinsically sensitive to the Cu particle size.

**Relevance :** Understanding the active sites and reaction mechanism for $CO_2$ hydrogenation is crucial to develop effective new catalysts for the production of circular fuels and chemicals .

# Tale of Hot Electrons of Black Gold as Catalyst for Storing Solar Energy into Carbon Dioxide

Rishi Verma and Vivek Polshettiwar*

Department of Chemical Sciences, Tata Institute of Fundamental Research (TIFR), Mumbai, India.
*Email: vivekpol@tifr.res.in, Web: www.nanocat.co.in*

**Keywords:** Black gold, plasmonic, photocatalysis, CO2, nanomaterials

Capture and then conversion of $CO_2$ to valuable chemicals and fuels are the best ways to tackle climate change. We discovered a new nanosilica, Dendritic Fibrous Nano-Silica (DFNS),[1,2] which is now being used by more than 150 groups worldwide for various applications.[1,2] Our group reported several applications of DFNS for catalysis and $CO_2$ capture-conversions, such as Black Gold[3], Defective Nanosilica[4], Solid Acids[5], Lithium Silicates Nanosheets[6] and Magnesium[7] to combat climate change.

In this talk, I will discuss one of our recent discoveries for solar energy harvesting and $CO_2$ utilization, using the concept of *"Black Gold as an Artificial Tree".* We transformed yellow gold into black gold by changing the size and gaps between gold nanoparticles supported on nanosilica spheres (due to plasmonic coupling). Black gold harvest board band light of the solar spectrum, the entire visible region, as well as in the near-infrared region. Using black gold, we have now designed and synthesized nickel-laden dendritic plasmonic colloidosomes of Au (black gold-Ni). The photocatalytic $CO_2$ hydrogenation and organic transformations (hydrogenation, dehydrochlorination etc.), activities of the black gold-Ni increased dramatically to the extent that measurable photoactivity was only observed with the black gold-Ni catalyst, with a very high photocatalytic CO production rate (2464 ± 40 $mmol g_{Ni}^{-1} h^{-1}$) and 95 % selectivity. The catalyst was stable for at least 100 h. Linear dependence of CO production rate on light intensity indicated the non-thermal hot-electron mediated $CO_2$ reduction. Ultrafast transient absorption spectroscopy studies indicated in-direct hot electron transfer from the black Au to the Ni in less than 100 fs, corroborated by a reduction in Au-plasmon electron-phonon lifetime and a bleach signal associated with Ni d-band filling. Operando diffuse reflectance infrared Fourier transform spectroscopy (DRIFTS) showed that $CO_2$ hydrogenation took place by direct dissociation path via linearly bonded Ni-CO intermediates.

**Keywords:** $CO_2$ activation, plasmon, visible light, DRIFTS, Raman, XPS, environmental catalysis

**Introduction.** To date, highly efficient and selective catalytic reduction of $CO_2$ represents one of the greatest challenges in the fields of environmental science and energy technology. One major goal, we all driven by, is to convert this chemically inert molecule into useful fuels or chemicals such as methane, formic acid, methanol, or carbon monoxide, e.g. by thermal, electrochemical, and photochemical routes thus alleviating the adverse effects of $CO_2$ present in the atmosphere.

**Experimental/methodology.** In this work, visible light (λ=400-500 nm) assisted conversion of $CO_2$ on Pt and Pd catalysts supported on pristine and N-doped TiO2 anatase nanoparticles is studied using diffuse reflectance Fourier transform infrared spectroscopy (DRIFTS) measurements. The micro and crystal structure of the catalysts are analyzed by transmission electron microscopy, physisorption (BET-BJH), Raman spectroscopy and X-ray diffraction. The chemical composition was assessed by X-ray photoelectron spectroscopy. The binding energies of the products on the co-catalysts were calculated by density functional theory (DFT).

**Results and discussion.** Based on the DRIFTS, on the surface of $Pd/TiO_2$ minor adsorption of $CO_2$ in the form of carbonates is found, whereas clear formation of CO is visible apart from carbonates on $Pt/TiO_2$. XPS results indicate that the Pt as a co-catalyst is mostly in metallic form but Pd is partly oxidized.

The calculations show that the formed carbonates are chemically bound on both PdO (2.0 eV) and Pt (3.1 eV) but CO forms a stable adsorbate only on Pt (1.7 eV), which is in excellent agreement with the DRIFTS measurements.

The results indicate that there is a possible route of $CO_2$ activation on $TiO_2$ based catalysts using visible light, which suggest that surface plasmons of the co-catalyst metals may indeed contribute to the chemical reactions.

**Keywords:** $CO_2$ methanation, Ni/Hydrotalcite, kinetic study, formate pathway

**Introduction**

$CO_2$ methanation reaction has attracted a renewed interest since it has been regarded as promising alternative for reducing the global $CO_2$ emissions, using renewable hydrogen[1]. Recent reports showed that hydrotalcite (HT) supported Ni catalysts exhibited an excellent performance in $CO_2$ methanation reaction, outperforming those based on traditional supports[2]. The present study deals with the analysis of the effect of Ni loading on the physico-chemical properties and the performance of Ni/HT catalysts. Moreover, a kinetic study has been performed over the optimal formulation to identify the most prevalent mechanism pathway.

**Experimental/methodology**

A commercial hydrotalcite (3:1 Mg:Al molar ratio; Sigma-Aldrich) was first pretreated at 600 °C for 3 h (5 °C/min) in air. Then, it was impregnated with different amounts of nickel(II) acetylacetone (98 wt.%; Sigma Aldrich) in order to prepare Ni/HT catalysts with 5-30 wt.% Ni loadings. The resulting samples were calcined in air at 500 °C for 4 hours (5 °C/min) and subsequently reduced at 800 °C (5 °C/min) for 2 h in 20% $H_2$/He. All catalysts were characterized by ICP-AES, XRD, $N_2$ adsorption-desorption, $H_2$-TPR, $CO_2$-TPD, XPS and HAADF-X EDS microscopy. All catalysts were pelletized, crushed and sieved to obtain a 160–250 µm size fraction to avoid transporting effects. Reactions were performed in the 200-500 °C range feeding a 4:1 $H_2$:$CO_2$ ratio, balanced with He for a total flow of 125 $cm^3\ min^{-1}$ and a WHSV of 30,000 $cm^3\ g^{-1}\ h^{-1}$.

**Results and discussion**

Figure 1a shows the light-off curves for all activated Ni/HT samples in the $CO_2$ methanation reaction. It can be observed that the catalysts with 15-30 wt.% Ni reach the thermodynamic equilibrium at 400 °C. Interestingly, the samples with 15 and 20 wt.% Ni exhibit a similar and the best catalytic performance among the prepared catalysts. Both samples achieved 50% $CO_2$ conversion at 325 °C and 95% selectivity towards $CH_4$. The 15%Ni/HT optimal catalyst was also submitted to 90-hour reaction at 350 °C, where only 2% activity loss was observed. Figure 1b shows ultra-high resolution TEM image of the selected catalyst, which allowed measuring Ni dispersion on the catalyst by particle counting, while EDX analysis showed the distribution of the different elements present at the catalyst surface. Finally, the kinetic study performed in the 270-300 °C temperature range shed light on the prevalence of the formate pathway for the description of the reaction mechanism.

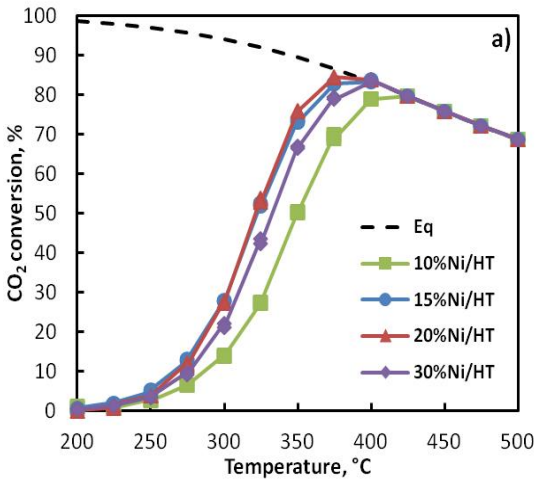

**Figure 1.** Light-off curves for $CO_2$ methanation over Ni/HT catalysts and b) TEM image of 15%Ni/HT sample.

**Keywords:** Photo-activation, $CO_2$ hydrogenation, operando DRIFTS, photothermal catalysis

**Introduction.** Recently, light-induced activations have been successfully employed to improve the performance of heterogeneous catalysis[1]. However, the mechanism underlining potential interplay between electron excitations and surface chemical processes remains elusive. Herein, we demonstrate, with two conventional $CO_2$ hydrogenation reaction systems, the importance of probing surface chemistry information for these light-assisted heterogeneous catalytic reactions. We also demonstrate that the catalyst engineering plays an important role in accessing and promoting light-assisted activation.

**Experimental/methodology.** Photothermal $CO_2$ hydrogenation experiments were performed using either a Harrick flow reactor system at varying pressures (1-21 bar, for methanol synthesis over $Cu/ZnO/Al_2O_3$ (CZA)) or plug flow reactor system at atmospheric pressure (for $CO_2$ methanation over $NiO_x/La_2O_3@TiO_2$ (NLT)). Light-triggered surface reactions/variations were studied *via* X-ray spectroscopies and *in-situ* diffuse reflectance infrared Fourier transform spectroscopy (DRIFTS). Steady-State Isotopic Kinetic Analysis coupled with Diffuse Reflectance Infrared Fourier Transform Spectroscopy (hereby referred to as SSITKA-DRIFTS) was employed to isolate the role of light on promoting rate-determining intermediate steps.

**Results and discussion**. It is shown in Figure 1A and C that light can improve $CO_2$ hydrogenation activity over both CZA and NLT. By probing the surface to explore light-triggered surface reactions via X-ray spectroscopies and in situ diffuse reflectance infrared Fourier transform spectroscopy (DRIFTS), it indicates that electrons originating from the zinc oxide excitation and copper plasmonic excitation serve to activate surface adsorbates, catalysing key elementary processes (namely formate conversion and hydrogen molecule activation), thus providing one explanation for the observed photothermal activity over CZA (Figure 1B)[2]. Furthermore, an isotopic-assisted in situ DRIFTS spectroscopic approach has been established to deliver new evidence and insights on the pivotal role of surface adsorbates in the photo-assisted $CO_2$ methanation reaction at mild operating temperatures. Specifically, experimental observations reveal that photo-activation of the surface formate intermediate is responsible for an eightfold photo-enhancement on NLT catalyst (Figure 1D)[3]. Further studies show that photothermal activity can be enhanced via effective catalyst engineering strategies [4].

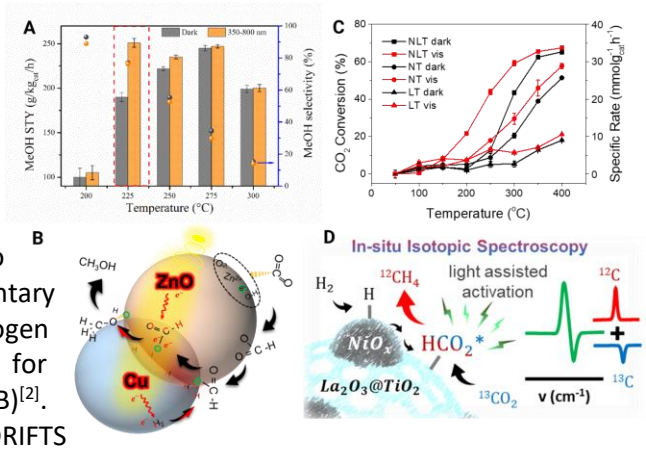

Figure 1. A) methanol space time yield and selectivity under dark and light condition (350-800 nm) over CZA; B) Illustration of synergistic photo-activation over CZA; C) CO2 methanation over NLT; D) Illustration of in-situ isotopic spectroscopy for studying light-assisted intermediate activation over NLT.

**Keywords:** $CO_2$ utilization, ethylene production, ethane dehydrogenation, active sites

**Introduction**

Ethylene is one of the most important commodities in the chemical industry. The abundance of the stranded gas reserves along with the so-called "shale gas revolution" have revitalized the research interest for on-purpose ethylene production, through ethane utilization [1]. $CO_2$ can act as a mild oxidant for ethane dehydrogenation, shifting the reaction equilibrium, via $H_2$ consumption through the Reverse Water-Gas Shift reaction. Iron oxide – based catalysts were reported to preserve the C-C bonds and thus resulting in $C_2H_4$ production [2]. In the present work, the nature of active sites of iron oxide-based catalysts is investigated.

**Experimental/methodology**

Support and catalyst preparation: For the two-step synthesis, 10wt%NiO-MgO-$ZrO_2$ support (named "10NiMgZr") was prepared using a sol-gel auto-combustion method [3]. 5wt% Fe catalysts were prepared by wetness impregnation of the Fe precursor on the 10NiMgZr support. The catalysts were calcinated at 600°C for 3 hours and at 700°C for 5 hours respectively, under continuous air flow and then labeled as Fe-600 (3h) and Fe-700 (5h). One step synthesis was implemented for the preparation of 5wt%Fe-10wt%NiO-MgO-$ZrO_2$ catalyst, using a sol-gel auto-combustion method. The catalyst was calcined at 800°C for 4h, under continuous air flow. Catalyst characterization: Advanced characterizations techniques were performed at BM23 and ID20 beamlines of European Synchrotron Radiation Facility (ESRF). Extended X-ray Absorption Fine Structure (EXAFS) and X-ray Absorption Near-Edge Structure (XANES) were conducted at Fe and Ni *K* edges, while X-ray Raman Scattering spectroscopy (XRS) at O *K* and Mg $L_{2,3}$ edges.

**Results and discussion**

Activity tests were performed for all the catalysts during $CO_2$ – EDH co-feeding at 650°C, P =101.3 kPa and molar feed ratio of $CO_2/C_2H_6$ =1. At the reactor outlet, the main detected product was $C_2H_4$, along with CO, $CH_4$ and minor amounts of $H_2$ and $H_2O$. As it is highlighted in Figure 1, Fe-700 (5h) achieved the best performance, reaching 90% selectivity towards ethylene production, at a conversion level of 23.3%, resulting to a maximum ethylene yield of 21%. The enhanced performance of Fe-700(5h) catalyst was attributed to the incorporation of Fe into the support lattice, under reaction conditions, causing a modification of the Mg geometry, as it was proven by XRS data at Mg $L_{2,3}$ edge and consequently of electronic environment of lattice oxygen. FT-IR spectroscopy combined with in situ adsorption of pyridine showed a four-fold increase of acidity for Fe-700(5h) compared to the Fe-600(3h) catalyst, which might explain the increased selectivity towards ethylene.

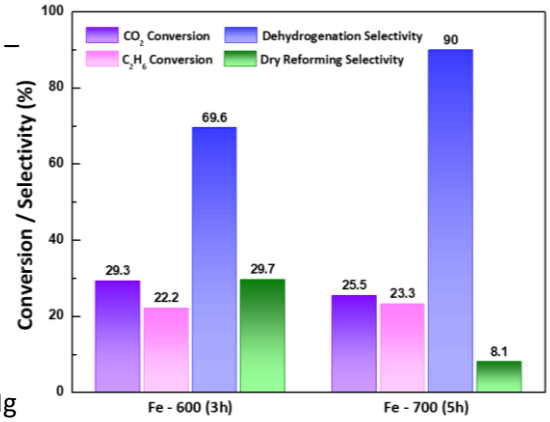

**Figure 1: $C_2H_6$ and $CO_2$ conversions (%) along with selectivities (%) towards $C_2H_4$ and syngas production for the investigated catalysts at 650°C. $W_{cat}/F^0$ =10.8 $kg_{cat}$·s·$mol^{-1}$, TOS = 6h.**

**Keywords:** oxidative dehydrogenation, $CO_2$, ethane, ethylene, molybdenum carbide

**Introduction.** $Mo_2C$ has shown to be a promising catalyst for $CO_2$-activating processes such as $CO_2$ hydrogenation [1], reverse water-gas-shift (RWGS) [2], methane dry-reforming [3] and the oxidative dehydrogenation of short alkanes with $CO_2$ ($CO_2$-ODH) [4, 5]. This study focuses on $CO_2$-ODH, a process that could play a significant role in the synthesis of ethylene through parallel $CO_2$ activation. At present, the continuously rising demand for light olefins is met predominantly via catalytic/thermal dehydrogenation processes of alkanes at temperatures of up to 900 °C. Under these harsh process conditions high $CO_2$ emissions, competing side reactions and catalyst deactivation via coking are major challenges. Co-feeding an oxidant, such as $CO_2$, significantly decreases the reaction temperature [6].
An effective $CO_2$-ODH $Mo_2C$-based catalyst is required to activate $CO_2$, forming oxygen surface species, and simultaneously activate the C-H bond of the alkane. Previously, supported $Mo_2C$ catalysts show great initial activity and high alkene selectivity [4] but are challenged by a poor catalyst stability, caused by oxidation of the carbide phase or carbon deposition [5, 7].
**Experimental/methodology.** In the present study, the deactivation mechanism of molybdenum carbide catalysts under $CO_2$-ODH condtions is investigated via modification of the carbide catalyst as well as the reaction conditions. The $Mo_2C$ nanoparticles are supported on various metal oxide support materials. The effect of the various supports on the chemical and structural properties were investigated using temperature progreammed desorption and activation experiments. The *in situ* activated catalysts were then exposed to a variety of $CO_2$-ODH conditions, in the presence and absence of $H_2$ co-feeding.
**Results and discussion.** Our results show that $Mo_2C$ can readily activate $CO_2$, even in the absence of a reducing co-reactant. The addition of reducible metal oxides as a support material, attempting to achieve a tandem catalyst system balancing $CO_2$ and ethane activation, did not reduce the degree of oxidation sufficiently. Upon co-feeding different concentrations of $H_2$, the oxidation of the catalyst can be prevented, keeping ethylene formation routes intact and results in increased stability. A balance between $CO_2$-ODH and RWGS ensures the removal of oxygen surface species.

# Inverse $Zn^{2+}/CuO_x$ for methanol selective $CO_2$ hydrogenation

Xinwei Ye[1], Kang Cheng[2], Florian Merier[1], Bert M. Weckhuysen[1*]

[1]*Debye Institute for Nanomaterials Science and Institute for Sustainable and Circular Chemistry, Utrecht University, Universiteitsweg 99, 3594 CG Utrecht, the Netherlands*

**Introduction.** Extensive $CO_2$ emissions into the atmosphere overload the carbon cycle in our ecosystem, which has triggered intensive investigations towards $CO_2$ capture and valorization processes.[1] Zinc oxide supported copper catalysts are known for $CO_2$ hydrogenation to methanol, however, high methanol selectivity is still hard to achieved due to the formation of CO as byproduct.[2,3] In this context, conversion of $CO_2$ to methanol is particularly attractive over the catalyst with a confined inverse $Zn^{2+}/CuO_x$ active center (Cu-ZnZEO), i.e. finely dispersed $CuO_x$ clusters confined withih a Zn-doped zeolite. Following the dynamics of reaction intermediates as well as the evolution of the Cu/Zn speciation at working conditions provide insights into the active structures and reaction pathways for high methanol selectivity.

**Experimental.** A series of Cu-ZnZEO catalysts with different Cu/Zn ratios were synthesized. Catalytic $CO_2$ hydrogenation reaction was carried at 220 °C, and 10 bar in a fixed bed reactor. The solid catalysts were characterized with X-ray Diffraction (XRD), UV-Vis Diffuse Reflectance Spectroscopy (UV-Vis DRS) and pyridine-/CO-adsorbed Fourier Transform Infrared (FTIR) spectroscopy, and the reaction pathway was studied via in-situ FT-IR spectroscopy and X-ray Absorption Spectroscopy (XAS).

**Results and discussion.** The monodispersed nature of $Zn^{2+}$ in Cu-ZnZEO was proved by XRD, UV-Vis DRS and CO-adsorbed FT-IR spectroscopy. The CO-adsorbed FT-IR spectroscopy showed Zn ion stayed isolated even after a reduction process,. A higher Space-time Yield (STY) of desired methanol per Cu was obtained in Cu-ZnZEO with the lowest Cu loading, but the STY of CO was unchanged in all the tested Cu-ZnZEO materials. During catalytic $CO_2$ hydrogenation, $Cu^{2+}$ was partially reduced into $Cu^{+}$ and $Zn^{2+}$ was maintained. Adsorbed CO and bridged formate were observed, and methanol yield is found related to the CO adsorbed on isolated $Cu^{+}$, indicating the methanol is selectively produced by the Reverse Water Gas Shift (RWGS) and CO hydrogenation pathway. The CO production is related to the framework of zincosilicate. The *HCOO adsorbed on $Zn^{\delta+}$, however, cannot further convert to methanol due to the high energy barrier in the subsequent hydrogenation steps. However, because the relatively low stability of zincosilicate at the reaction condition, the $Cu^{+}$-O-$Zn^{\delta+}$ interface gradually disappeared during the $CO_2$ hydrogenation reaction, resulting in the phase separation of Cu and Zn and thus a continuous decrease of methanol yield. Structure dynamics from given by in-situ XAS results will be presented in the lecture.

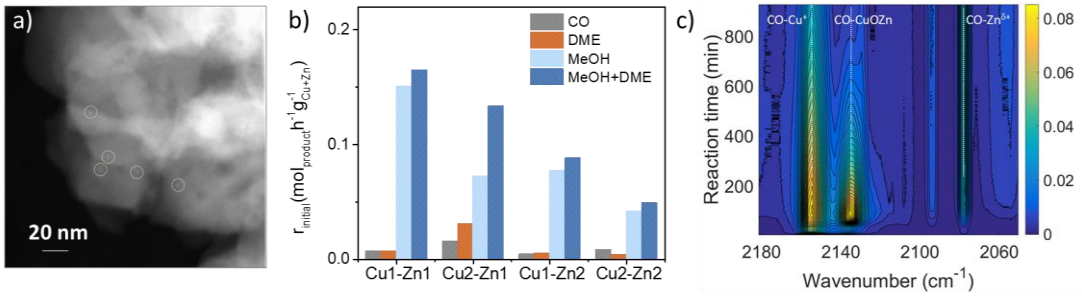

Figure 1. a) Transmission Electron Microscopy (TEM) image b) Initial reaction rate in first 1.5 h, and c) Contour plot of the CO vibrational region at catalytic $CO_2$ hydrogenation conditions of Cu-ZnZEO.

**Introduction.** $CO_2$ removal from flue gases or capturing it from the air and subsequent conversion into value-added chemicals may be part of the solution to slowing global warming [1]. Among several approaches, $CO_2$ hydrogenation to methanol is considered one of the most promising routes for both chemical storage of hydrogen as well as provision of a platform chemical for wide range of chemical transformations. Metal-organic frameworks (MOFs) have attracted great interest in catalysis due to their porous structure and tailorable physicochemical properties [2]. In this work, we report the catalytic performance of Cu clusters supported by UiO-66 MOF in gas-phase $CO_2$ hydrogenation under high pressure. We focused on screening the product selectivity under different reaction conditions by performing kinetic and kinetic isotope effect measurements (KIE) in $CO_2/H_2$ and $CO_2/D_2$ gas mixtures.

**Experimental/methodology**. Cu clusters were loaded into a Zr-based UiO-66 MOF using a solvothermal method described elsewhere [3]. Catalytic performance was investigated in a stainless steel fixed-bed flow reactor with online GC for product analysis. All measurements and characterizations were performed after reductive treatment at 300 °C. The H/D kinetic isotopic effect was studied by switching from $N_2/CO_2/H_2$ to $N_2/CO_2/D_2$ with ratios of 1:3:9 under steady-state conditions. The freshly prepared $Cu_x$/UiO-66 catalysts were characterized by a variety of surface and bulk sensitive methods.

**Results and discussion.** Catalyst tests at 250 °C showed significant changes in the reaction behavior with time-on-stream. First, we observed an initial rapid activation phase in which the highest catalytic activity was reached after 20 hours, and then a decrease until reaching a steady state after about 30 hours on-stream. In correlation with the $CO_2$ conversion rate, we found an increase in ethanol formation, which also decreased over time with the subsequent decrease in $CO_2$ conversion. This contrasts with methanol formation, which increased continuously over time (change in selectivity from 15% to about 40%). Temperature variation under steady-state conditions showed that methanol was always the predominant product, with the highest selectivity of 93.4% obtained at 200 °C. No formation of CO was observed at this temperature, but other products such as dimethyl ether were detected in limited amounts (Fig. 1). Methanol and DME showed an inverse kinetic isotope effect between 0.8 and 0.5 depending on temperature in agreement with the literature [4]. Ethanol was not observed in $D_2$. This indicates a much larger inverse KIE for ethanol, which could be due to a highly limited reaction by a hydrogenation step. These results shall be discussed along with the results of detailed KIE studies and DFT calculations.

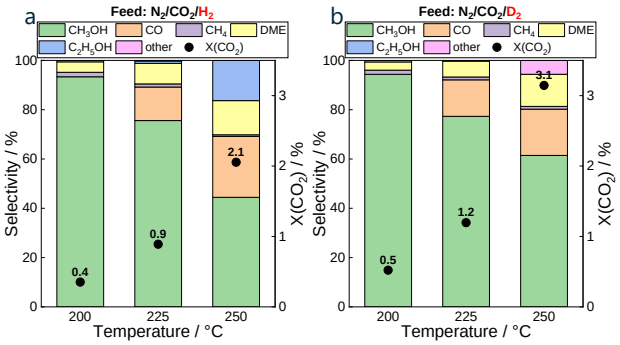

**Figure 1. Relationship of product selectivity to reaction temperature: (a) $N_2/CO_2/H_2$ = 1:3:9, (b) $N_2/CO_2/D_2$ = 1:3:9; P = 50 bar, GHSV = 1906 mL·g$^{-1}_{cat}$h$^{-1}$.**

**Keywords:** Methanol synthesis, oxygen vacancy, $CO_2$ hydrogenation, indium oxide

**Introduction.**

The efficient use of $CO_2$ as a raw material for the chemical industry is an appreciated topic for mitigating greenhouse gas emissions [1] and to reducing the use of fossil fuels. Among the different routes, hydrogenation to $CH_3OH$ has great projection due to its relevance in the industrial and energy sector, which is hindered by a high CO formation. Within the variety of catalysts, $In_2O_3$ has showed outstanding selectivity and stability. Additionally, $ZrO_2$ appears as an interesting support because it creates oxygen vacancy ($O_v$) in the indium oxide, which are considered the active sites for the reaction [3]. In this work, the performance of Indium supported catalysts at different In/Zr ratios was analyzed to determine the effect of the interaction between $In_2O_3$ and $ZrO_2$ and the nature of $O_v$ on the methanol and CO formation rates.

**Experimental/methodology.**

$In_2O_3$ catalysts supported on $ZrO_2$ at different In/Zr molar ratios were prepared by wet impregnation method by varying the amount of $In(NO_3)_3{\cdot}xH_2O$. Two pure $In_2O_3$ catalysts were synthesized by precipitation ($In_2O_3$-P) and thermal decomposition ($In_2O_3$-DT) method. The materials were characterized by XRD, $N_2$ sorption at 77 K and $N_2O$-RFC to quantify oxygen vacancies. The catalytic tests were carried out in a fixed bed differential reactor under temperature (220-280ºC) and flow control at 8 bar. The composition of the gases was measured by a gas chromatograph.

**Results and discussion.**

The $ZrO_2$-supported In catalysts showed higher space time yield per gram of Indium than the Cu-Zn-Al catalyst per gram of Cu at T>240ºC (Fig. 1a). Moreover, the selectivity toward $CH_3OH$ of the In-based catalysts resulted significantly higher than that observed for Cu-Zn-Al at all conditions studied (Fig. 1b), being less sensitive to the increase of temperature. The decrease in selectivity at higher temperatures is related to the favoring of RWGS, which is particularly pronounced in the Cu-based catalyst, due to its high difference between the activation energies for CO and $CH_3OH$ formation. This results suggest important differences in terms of mechanism and nature of active sites involved between the In-based catalysts ($O_v$ are proposed) and Cu-based catalysts [2]. Fig 1c shows that the density of $O_v$ per gram of indium measured by $N_2O$-RFC decreases with increasing indium loading, showing higher use of the material. Moreover, the rates of $CH_3OH$ and CO formation per mole of $O_v$ showed different behaviors as a function of In content in the catalyst, indicating a difference in the nature/quality of $O_v$ to form both products. The observed performance of the supported materials, higher activity at lower loading, may be related to the particle distribution as a function of content, which is related to the XRD results on the supported catalysts (17.9 nm for 3:10, 22.4 nm for 5:10 and not measurable for 1:10), suggesting an effect of crystal diameter on the $O_v$ and thus on their activity.

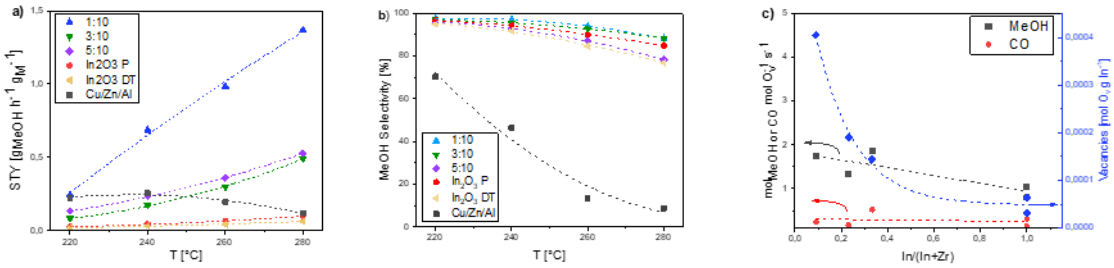

**Figure 1: a) Methanol STY per gram of metal (In or Cu) and b) methanol selectivity as a function of temperature. c) Moles of $CH_3OH$ or CO formed per oxygen vacancy and oxygen vacancy per gram of indium as a function of their molar composition. Reaction conditions: P=8 bar and $H_2/CO_2$=4.**

# A spatially-resolved operando FT-IR analysis on Dual Function Materials (DFMs) for $CO_2$ capture and hydrogenation from flue gases

Alessandro Porta[1], Roberto Matarrese[1], Carlo Giorgio Visconti[1] and Luca Lietti[1]*

[1]*Department of Energy, Politecnico di Milano, Milan, 20156 (Italy)*
** luca.lietti@polimi.it*

**Introduction.** In order to comply with international agreements on the reduction of $CO_2$ emissions, a marked increase in the use of renewable energy and carbon capture and utilization technologies is foreseen. In particular, an appealing solution is represented by the combined capture of $CO_2$ and hydrogenation using green $H_2$ over Dual Function Materials (DFMs) [1, 2]. The idea is to work under cyclyc conditions to capture $CO_2$ from a $CO_2$-containing stream (e.g. combustion flue gases) on the DFM, and then exposing the $CO_2$-saturated DFM to renewable $H_2$ to produce $CH_4$ and regenerate the adsorbent. This is a recently proposed application and the optimal catalyst formulation is still under debate. By combining microreactor experiments and spatially resolved operando FT-IR in this work we provide insights on DFMs performances, reaction mechanism and stability when exposed to different species that are present in combustion flue gases, such as $H_2O$, $O_2$ and $NO_x$.

**Experimental/methodology.** $Al_2O_3$-supported DFM were prepared by sequential impregnation of $Ru(NO)(NO_3)_3$ and Na, K or Ba from the corresponding acetate or carbonate salt [3]. The DFMs were then characterized by $N_2$ physisorption, XRD, SEM-EDX, $CO_2$ TPD, $H_2$ TPR, TGA, $H_2$ and CO chemisorption experiments, in-situ and operando FT-IR spectroscopy. $CO_2$ capture/reduction cycles were performed at constant temperature in the range 250-400°C. Every cycle is composed by an adsorption phase (1% $CO_2$/He) and a reduction phase (4% $H_2$/He), separated by an inert purge. The adsorption phase is progressively enriched with $H_2O$, $O_2$ and NO. The cyclic experiment were performed using both a fixed bed quartz microreactor and an operando FT-IR low dead volume cell (#CSX, AABSPEC) allowing for spatial resolution. In both cases the outlet gases were monitored with a mass spectrometer, a FT-IR gas analyzer and a microGC.

**Results and discussion.** $H_2O$ has an inhibiting effect on the amount of adsorbed $CO_2$ due to a competitive adsorption effect for the same basic sites. Furthermore, spectroscopic evidence demonstrated that the presence of $H_2O$ causes a change in the nature of the adsorbed species, converting the bidentate carbonates to ionic/bulk carbonates, which are more difficult to reduce and tend to accumulate on the DFM surface. $O_2$ causes minor losses in the amount of adsorbed $CO_2$ due to the oxidation of Ru metal sites (which are capable of adsorbing CO in $O_2$-free conditions) but causes a decrease in the $CH_4$ formation rate due to the additional step of Ru-oxide reduction, and in some condition may also induce Ru sintering. When $NO_x$ is present in the adsorption feed, it preferentially adsorbs as nitrate onto the SM resulting in a lower $CO_2$ storage capacity. However, spatially-resolved operando FT-IR indicated that $NO_x$ is adsorbed on the catalyst bed as a moving front (Figure 1), and significant amounts of $CO_2$ can still be adsorbed in presence of small amount of $NO_x$ by calibrating the duration of the adsorption phase.

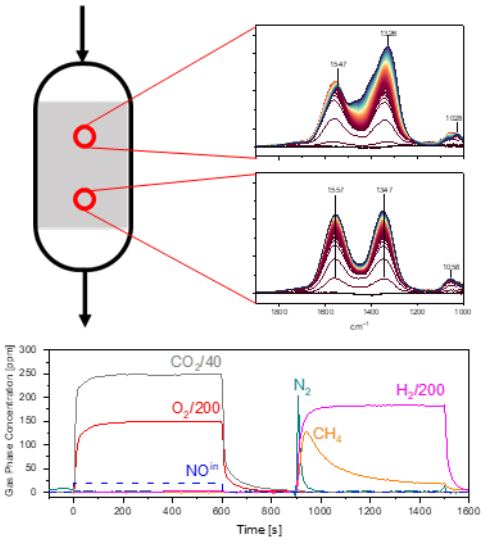

**Figure 1.** Spatially resolved operando FT-IR during $CO_2$ capture in the presence of $NO_x$

**Keywords:** $CO_2$ valorization, $CO_2$ hydrogenation, Operando-FTIR, SSITKA-DRIFTS, KIE

**Introduction.**

The increase in atmospheric $CO_2$ levels has generated negative effects on the climate. Sustainable processes have been promoted to mitigate these effects and reduce the utilization of fossil fuels. The synthesis of clean fuels through the hydrogenation of $CO_x$ to $CH_4$ shows great projection since it requires moderate reaction conditions and can be easily integrated to existing infrastructure. However, the rational design of active, selective and stable catalysts is mandatory and requires knowing in detail the reaction mechanism. In this work, $CO_2$ and CO hydrogenation reactions were studied by kinetic, isotopic (KIE, SSITKA-DRIFTS) and Operando-FTIR measurements in order to understand the mechanistic relationship between the reactions.

**Experimental/methodology.**

Mono and bimetallic 5%wt Ni, Co and Ni-Co supported catalysts were prepared by incipient wet impregnation with varying Co molar composition (Co/(Co+Ni)). The materials were characterized by TEM and XRD. A kinetic and $H_2/D_2$ kinetic isotope effect (KIE) studies were conducted in a fixed bed differential reactor controlling the temperature, $H_2/D_2$ and $CO_x$ feeds. Effluent composition was measured with a gas chromatograph. Operando-FTIR analysis were performed in a differential reaction cell, with a self-supported catalyst wafer. SSITKA/MS-DRIFTS measurements were executed in a low dead volume differential reaction cell by changing the feed from Ar/$^{13}CO_2$/He/$H_2$ to $^{12}CO_2$/He/$H_2$, and the effluents were followed with a mass spectrometer.

**Results and discussion.**

Characterization of the catalysts confirmed similar dispersion (~20%) of the materials ruling out structural sensitivity effects[1,2] on the measured rates. $TOF_{CH4}$ from $CO_2$ hydrogenation showed a negative displacement with respect to metal-weighted activity in $CO_2$ hydrogenation, while from CO showed a slight synergistic effect (Fig1.a). This behavior cannot be explained by the increased of CO* coverage when CO is fed, compared with $CO_2$, as proposed on Rh[3], since higher $TOF_{CH4}$ in the reaction with $CO_2$ would be expected for all catalysts; nevertheless, it is only observed on Ni. Furthermore, Operando-FTIR results show that co-feeding CO leads to higher $CH_4$ formation rates, despite the increase of CO* coverage (Fig 1b,c). The kinetic analysis show apparent reaction orders ~0.5 for $TOF_{CH4}$ with respect to $P_{H2}$ for both reactions, suggesting its participation in the RDS and consistent with the observed inverse KIE (Fig 1,a). Higher $TOF_{ITK-CH4}$ from the $CO_2$ labeled SSITKA/MS-DRIFTS studies on NiCo (0.145 $s^{-1}$) than on Ni (0.042 $s^{-1}$) indicates lower specific reactivity on Ni but a higher density of intermediates was obtained, consistent with IR measurements showing a higher ratio of active multibond CO to $CH_4$[2]. In addition, a greater shift towards CO weakly adsorbed on NiCo is observed, which explains the different behaviors in CO and $CO_2$ hydrogenation.

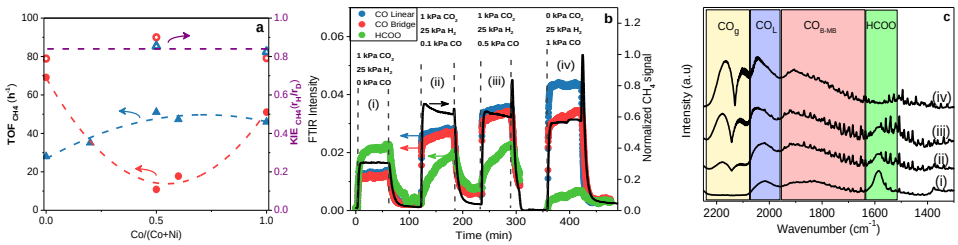

**Figure 1. a) TOF (filled symbols) and kinetic isotope effect, KIE (empty symbols) for $CH_4$ formation in the hydrogenation of CO (▲Δ) and $CO_2$ (●○) at 1 kPa $CO_x$-25 kPa $H_2$ and 280C, as a function of catalyst content. b) In-situ FTIR-MS and c) steady state FTIR for changes from $CO_2$+$H_2$+CO to $H_2$, varying the $P_{CO}$ on the NiCo catalyst at 200°C.**

**Keywords:** Copper oxide, ceria, exsolution, nanoparticles, methanol, $CO_2$ hydrogenation

**Introduction.** With $CO_2$ emission currently having the highest impact on the greenhouse effect, a sustainable and smart approach to reduce such environmental footprint involves the capture and utilization of the emitted $CO_2$ as carbon source for fuels and materials, by recycling it and reusing it in a loop. The $CO_2$ chemical valorisation aims at converting $CO_2$ into a variety of useful products, such as chemicals and fuels. An example is the catalytic conversion of $CO_2$ and $H_2$ into methanol (MeOH), a widely usable component for fuels, plastic, paints, textile chemicals, and a building block for the synthesis of more complex fuels. Although there is also growing interest in the implementation of this research area at industrial level due to its great economic potential, a major challenge related to the process is the low $CO_2$ conversion, triggered by limited catalyst selectivity and deactivation by active metal nanoparticle (NP) sintering. Recently, it has been proposed that the synergistic effect of copper and ceria in the hydrogenation of $CO_2$ to methanol influences the activity, selectivity and stability of these Cu-based catalysts [1]. The present study focuses on the development of different Cu-$CeO_2$ catalysts for the conversion of $CO_2$ and $H_2$ into methanol.

**Experimental/methodology.** Several Cu-$CeO_2$ binary catalysts were synthetised by employing different synthesis techniques (*i.e.*, wet impregnation (WI), solution combustion synthesis (SCS), and gel-oxalate co-precipitation(OX)) and by varying the Cu/Ce atomic ratio. Moreover, due to the Cu high mobility when infiltrated on oxide surfaces often leading to undesidered thermal agglomeration of Cu NPs at operating conditions, exsolution of Cu NPs from monophasic Cu-doped $CeO_2$ particles under high-temperature reducing conditions was also investigated. The samples were tested in a fixed-bed reactor under different reaction conditions. To rationalise their catalytic performance, all the samples (calcined and spent) were characterised with several techniques such as ICP-MS, $N_2$ physisorption, XRD, $H_2$-TPR, $CO_2$-TPD, XPS, Raman spectroscopy, SEM, TEM, and STEM-EDX spectroscopy.

**Results and discussion.** The addition of different amounts of Cu into ceria boosted the catalytic activity of the samples by improving the methanol yield. As illustrated in Figure 1, SCS and OX synthesis techniques lead to smaller particles with an improved interaction between Cu and $CeO_2$ phases. Characterisation results revealed that the specific surface area increased as the average crystallite size of the two phases diminished, rising the point of contacts between the two phases and, hence, the active sites of the reaction. Finally, the exsolution strategy was employed in order to obtain Cu-metal NPs with a strong anchorage of the NPs to the $CeO_2$ support and, due to the strain imposed by the NPs at the interface with the support by their unique "socketing" (*i.e.*, anchorage) [2], to maximise the Cu/$CeO_2$ interaction and stabilise the Cu NPs on the surface of $CeO_2$.

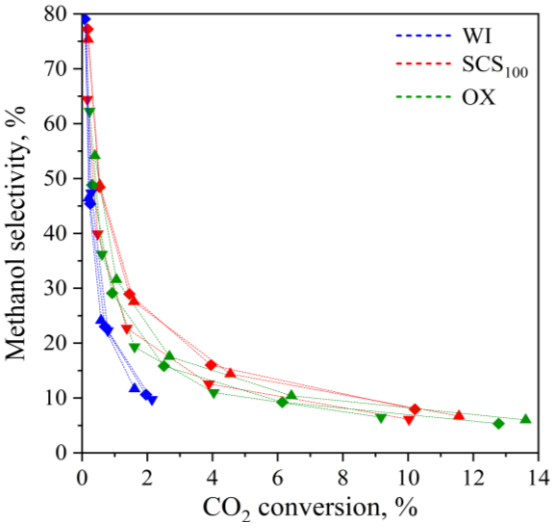

**Figure 1. Conversion-selectivity map of the Cu-$CeO_2$ binary catalysts synthetised with different methods and Cu/Ce ratios (2.5 MPa, 20 NL·$g_{cat}^{-1}$·$h^{-1}$, $H_2/CO_2$ = 3, 200 – 300 °C).**

**Keywords:** $CO_2$ methanation, CNT, composites

**Introduction.** $CO_2$ methanation ($CO_2 + H_2 \leftrightarrow CH_4 + H_2O$) is of great interest since it is the most energetically advantageous reaction to valorise $CO_2$ as carbon source, with respect to thermodynamics. Supported nickel-based catalysts are the most commonly used for this reaction, due to their good combination of activity, selectivity and price [1]. However, these materials are susceptible to thermal sintering aggravated by the formation of hot spots during the reaction, leading to deactivation. In this work, the properties of carbon nanotubes and $ZrO_2$ were combined to obtain a high performing Ni-based $CO_2$ methanation catalyst. Furthermore, the promotion of the catalyst with Fe was evaluated.

**Experimental/methodology.** CNT-$ZrO_2$ composites were prepared with a ball milling procedure, and their composition was optimized. The Ni and NiFe catalysts were prepared by incipient wetness impregnation. The catalysts were characterized and their performance for $CO_2$ methanation reaction was evaluated in terms of $CO_2$ conversion ($X_{CO2}$) and methane selectivity ($S_{CH4}$).

**Results and discussion.** The catalytic results of the optimized catalysts are presented in Figure 1. A ratio of CNT:$ZrO_2$ of 70:30 demonstrated to be optimal to achieve a Ni catalyst with higher $X_{CO2}$ and $S_{CH4}$, outperforming the Ni on CNT catalyst but not the reference Ni on $ZrO_2$. Interestingly, the addition of Fe demonstrated to be beneficial, with the 18:2NiFe/CNT-ZrO2 (70:30) catalyst obtaining $X_{CO2}$ = 85.6% and $S_{CH4}$ = 99.9% at $T$ = 370 °C, a result that compares favourably with those reported in the literature and outperforming the Ni on $ZrO_2$ reference catalyst. The catalyst presented an excellent stability over 70 h of TOS. This systematic study provides evidence that the preparation of carbon:metal-oxides composites could be an interesting approach to achieving high performing catalysts for $CO_2$ methanation reaction.

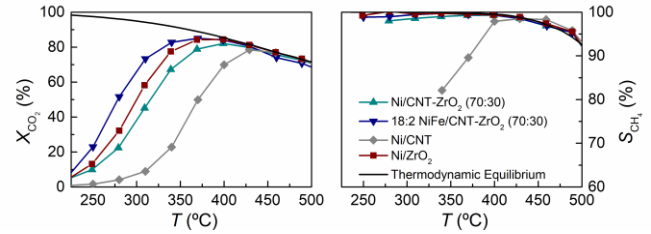

**Figure 1.** Comparison of the catalytic performance, in terms of $X_{CO2}$ (a) and $S_{CH4}$ (b), at different temperatures.

**Keywords:** $CO_2$ methanation, Ceria, Nickel, NAP-XPS, redox active sites

**Introduction.** $Ni/CeO_2$ catalysts are very active and selective for total hydrogenation of $CO_2$ to methane, but the nature of the active sites is still unclear**.** It has been suggested that $Ni/CeO_2$ catalysts combine two types of active sites working together during $CO_2$ hydrogenation to methane [1]. Previously, it was postulated that surface oxygen vacancies located at the $Ni^{2+}$-$CeO_2$ interface are responsible for the chemisorption and dissociation of $CO_2$, while reduced $Ni^0$ sites are more effective for $H_2$ dissociation. Best $Ni/CeO_2$ catalysts are those that combine both types of active sites and distribute the nickel available on the catalyst in an optimum proportion between them. Nonetheless, the behaviour and changes suffered by the different active sites of $Ni/CeO_2$ catalysts under reaction conditions is still unknown. Herein, the surface of a $Ni/CeO_2$ catalyst has been monitored under $CO_2$ methanation conditions by Near Ambient Pressure-XPS (NAP-XPS) using synchrotron radiation.

**Experimental/methodology.** NAP-XPS experiments were performed at the CIRCE beamline at the ALBA Synchrotron Light Source. The catalyst was pretreated in situ and XPS spectra were recorded at different temperatures in steady state under $CO_2$ methanation conditions.

**Results and discussion.** It has been concluded that the species involved in the redox processes taking place during the $CO_2$ methanation mechanism are the $Ni^{2+}$-$CeO_2$/ $Ni^0$ and $Ce^{4+}/Ce^{3+}$ pairs. In addition, a small fraction of nickel is present on the catalyst surface forming NiO and $Ni^{2+}$-carbonates/hydroxyls (around 20% of the total surface nickel), but these species do not participate in the redox processes of the methanation mechanism. Under $CO_2$ methanation conditions the $H_2$ reduction rate of the $Ni^{2+}$-$CeO_2$/Ni0 and $Ce^{4+}/Ce^{3+}$ couples is much faster than their $CO_2$ reoxidation rate (2 times faster, at least, at 300 ºC), but a certain proportion of nickel always remains oxidised under reaction conditions. The high activity of $Ni/CeO_2$ catalysts for $CO_2$ methanation is tentatively attributed to the simultaneous presence of $Ni^{2+}$-$CeO_2$ and Ni0 active sites where $CO_2$ and $H_2$ are expected to be efficiently dissociated, respectively [2].

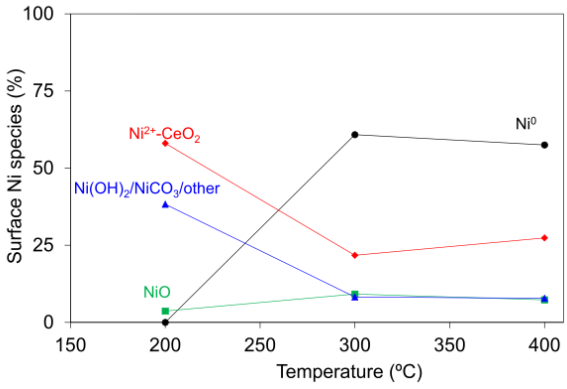

Figure. Evolution of Ni species present on surface during $CO_2$ methanation experiments in NAP-XPS chamber.

**Introduction.** The alarming concerns on the growth of $CO_2$ emissions, and its consequences on the global warming, are the trigger to develop and implement CCUS (Carbon Capture, Use and Storage) strategies for the production of highly valuable molecules [1]. On this regard, a very important process is dry reforming of methane (DRM), where $CO_2$ and $CH_4$( both a part of the GHG) are reacting for producing syngas (mixture of $H_2$ and CO). The use of catalyst in DRM reaction is the key to decrease the reaction temperature and to orient the selectivity. Ni and Co are reported to be used in DRM in different catalytic formulation, nevertheless the deactivation by carbon formation or sintering is still obsserved for the spent catalyst. The conception of the catalyst, is focusing in obtaing an accurate distribution of the active species in DRM in order to reach superior performacies and thermaly stable catalyst.

**Experimental.** We are focusing our attention in this study on the formulation of bimetallic catalyst based on Ni and Co. Our challenge is to control the distribution of the active sites of Ni and Co at the surface of the nanoparticles (NPs) in order to conclude on their impact in the DRM reaction. Thus, we are proposing to prepare catalysts with high loading of 20 wt.% with different ratio of Ni and Co ($Co_xNi_{20-x,}$ where x= 0, 5, 10, 15 and 20 ). We chose to firstly prepare bimetallic phyllosilicate (PS), as precursor for the production of the bimetallic NPs. Our strategy is to use SBA-15 in order to retain high specific surface and to proceed to a slow deposition precipitation process by using urea [2]. In order to evaluate the material characteristics, investigation was made onto calcined, reduced ($H_2$-700 °C) and after DRM test, by situ-XRD, $N_2$ physisorption, TPR, XPS, STEM-EDX-EELS.

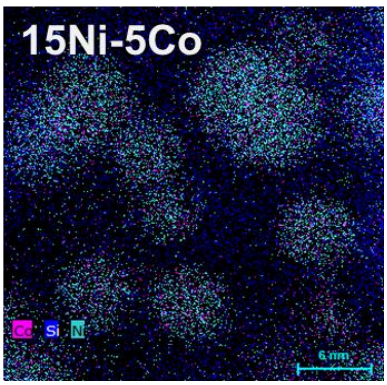

**Fig. 1**: *STEM-EDX* mapping for *Ni (blue)-Co (fuchsia) within bimetallic NPs*

**Results and discussion.** For the calcined phases, the XRD and TEM are revealing the presence of phyllosilicates containing both Ni and Co. We can not distinguish on the type of the phyllosilicate or on distribution of Ni/Co onto the layers of the PS. The reduction of the phyllosilicate, is leading to the formation of small NPs of 2 to 6 nm even if we use high metal loading of 20 wt.%. $H_2$-TPR of NiCo binary materials always occurs below 700 °C, which is > 100 °C lower than for pure 0Ni-20Co sample. The STEM-EDX mapping is showing that the particles rich in Ni have the external layers enriched in Ni, while the core contains both Ni and Co (Fig. 1), although 5Ni-15Co is showing small Co NPs and larger particles with Co rich shells. The materials were tested in the DRM at 700 °C in stoichiometric ratio of $CO_2/CH_4$, and 20 vol.% in Ar. The results are showing the following order 15Ni-5Co > 10Ni-10Co > 15Co-5Ni, and excellent stabilities during 12h are obtained for 15Ni-5Co due to limited carbon formation and absence of NPs sintering. A stability test for 200 hr of reaction confirmed the excellent stability of this 15Ni-5Co catalyst, with constant conversions, no sintering and limited formation of carbon (TGA-MS analysis < 25 wt.% of carbon accumulated). We associate these results to the spacial distribution of the elemnts, thus, the presence of Ni at the surface of the NPs, while the Co core is busting the conversion at 76% $CH_4$ and 81% $CO_2$, leading to a limited formation of coke.

# A Critical View on Direct Syngas to Aromatics over Combined Zinc Oxide on Zirconia and H-ZSM-5 Catalysts

Michael T. Nikolajsen[1*], Niels Christian Schjødt[2], Uffe V. Mentzel[2], Jens Sehested[2], Jakob M. Christensen[1] and Martin Høj[1]

[1]*Department of Chemical Engineering, Technical University of Denmark (DTU), Kgs. Lyngby, Denmark*

[2]*Topsoe A/S, Kgs. Lyngby, Denmark*

**mitni@kt.dtu.dk*

**Keywords:** syngas, aromatics, methanol

**Introduction.** ZnO supported on zirconia ($ZnO/ZrO_2$) catalyses methanol synthesis with high selectivity and stability at temperatures >300 °C. When combined with H-ZSM-5 a $CO_2$ conversion of 14-15 % with an aromatics selectivity of 73-76 % has been reported [1,2]. This work investigates the combination of $ZnO/ZrO_2$ with ZSM-5 of various acid site densities, for the direct conversion of syngas to aromatics. The mixing ratio and operating conditions were optimized to increase the $CO_x$ conversion and aromatics selectivity. This includes fundamental characterization using BET, ICP and XRD and in-depth characterization using in-situ XAS and DRIFTS.

**Experimental/methodology.** The $ZnO/ZrO_2$ was prepared by the incipient wetness impregnation method. H-ZSM-5 materials were obtained from Zeolyst. Activity measurements were conducted in a high-pressure fixed bed flow reactor. DRIFTS was performed in a Harrick Praying Mantis high pressure cell. XAS was performed at Balder, MAX IV (Sweden) and SuperXAS, Swiss Light Source.

**Results and discussion.** As illustrated in Fig. 1(a) increasing the metal oxide to zeolite ratio did not influence the aromatics selectivity but increased the $CO_x$ conversion and olefin selectivity. The higher metal oxide residence time and the observation that olefin selectivity increased with zeolite deactivation, suggest that olefin hydrogenation and aromatization are competing reactions occurring in the zeolite pores. The higher selectivity to olefins by 4:1 mixing ratio enhanced the potential for forming aromatics by olefin cyclization and hydrogen transfer reactions. This potential was utilized by increasing the acid site densities to a Si/Al ratio of 40 of the ZSM-5, illustrated in Fig 1(b). However, the aromatics selectivity decreased when using a Si/Al ratio of 25, due to an increase in the competing olefin hydrogenation activity. To improve the aromatics selectivity to 33 %, the conditions 320 °C and 10 barg were found optimal, far from the ideal $CO_2$ conversion conditions at >50 barg and 340 °C. The hydrocarbon pool dual cycle mechanism, states that olefins act as hydrogen acceptors in hydrogen transfer reactions that produce aromatics, which limits the aromatics selectivity that can be achieved [3]. To achieve >70% aromatic selectivity, dehydrogenation reactions must take place, which creates an alternative reaction path for the formation of aromatics. Cyclohexane dehydrogenation equilibrium calculations showed that this is unlikely below 350 °C and at the high hydrogen concentrations in the syngas. In-situ DRIFTS showed adsorption of carbonate species, followed by two-step reduction to formate and methoxy species and desorption of methanol over $ZnO/ZrO_2$ (Fig. 1(c)).

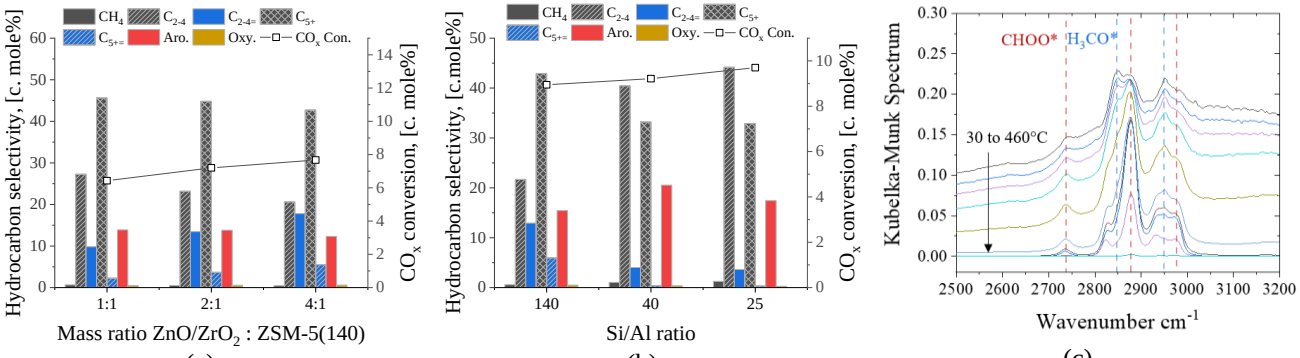

**Fig 1. (a) $CO_x$ conversion and product selectivity after 14 hours on stream with $ZnO/ZrO_2$ and ZSM-5 mixed in different ratios (b) with different Si/Al ratios mixed 4:1. (a,b) Conditions P = 30 bar, $CO_2/CO/H_2/Ar$ = 29/4/64/3, GHSV = 10000 Nml $g^{-1}$ $h^{-1}$. (c) DRIFTS TPD in He flow after catalyst treatment in syngas.**

**Keywords:** RWGS, operando DRIFTS, low-temperature, circurlar economy, $CO_2$ valorisation.

**Introduction.**

The actual economical and envriomental standing makes necessary the research of new process for the obtation of energy and added-value chemicals from different sources. In this scenario, valorisation of $CO_2$ via RWGS for the obtention of syngas is an interesting route to achiebe this aim. The main drawback of this reaction is the need of high temperatures (500-700 $^oC$) for the obtention of reasonable of catalytic results because $CO_2$ methanation competes at low temperatures [1]. In order to gain insights of the mechanism of this process to get closer to an active low-temeprature catalyst, Catalytic activity test, operando DRIFTS study and transient experiments have been done over two catalytic systems: $Pt/TiO_2$ and $PtCs/TiO_2$. Furthermore, the effect of Cs has been also elucidated for this reaction.

**Experimental/methodology.** $Pt/TiO_2$ and $PtCs/TiO_2$ catalysts were synthesied by sequential wet impregnation and calcinated at 550 $^oC$ for 3 h (10 $^oC$/min). The catalytic activity test was perfomed over a quartz bed reactor, adding 200 mg of catalyst. Firstly, catalysts were activated at 550 $^oC$ under $H_2/N_2$ flow. Then, the reaction was carried out at three different temperatures for 24 h (300, 400 and 500 $^oC$) and mataining a $H_2/CO_2$ ratio of 4/1. Finally, for the Operando DRIFTS measurements, catalysts were activated at 400 $^oC$ under $H_2/N_2$ flow and then reaction was carreid out at five different temperatures (150, 200, 250, 300 and 350 $^oC$) mataining the $H_2/CO_2$ ratio of 4/1. Transient experiments were carried out by using pulses of both reactants $H_2$/Ar and $CO_2$/Ar, altered during periods of 5 min each one at 250 $^oC$.

**Results and discussion.** Reasonable $CO_2$ conversiond were achived at low-temepature range. Furthermore, addition of Cs promotes a seletivity of 100% towards CO at 300 and 400 $^oC$, and 95% at 500 $^oC$ (figure 1). The results obtained from Operando DRIFTS measurements indicated that $Pt/TiO_2$ follow a redox mechanism for the synthesis of CO, while in the $Pt\text{-}Cs/TiO_2$ catalyst this mechanism is not possible because of the neutralization of -OH surface species due to the presence of Cs. Furthermore, a new intermediate for this reaction could be seen in the IR spectra of $Pt\text{-}Cs/TiO_2$ (-CHO species). For the better comprehension of the mechanics and the intermediates formed, transient studies were also carried out. The results (**Figure 1**) confirmed the previous hypothesis. Overall, our study demonstrates that Cs is an excellent promoter for the RWGS enabling high selectivity in the low-temperature range, opening new mechanistic pathways for gas-phase $CO_2$ upgrading.

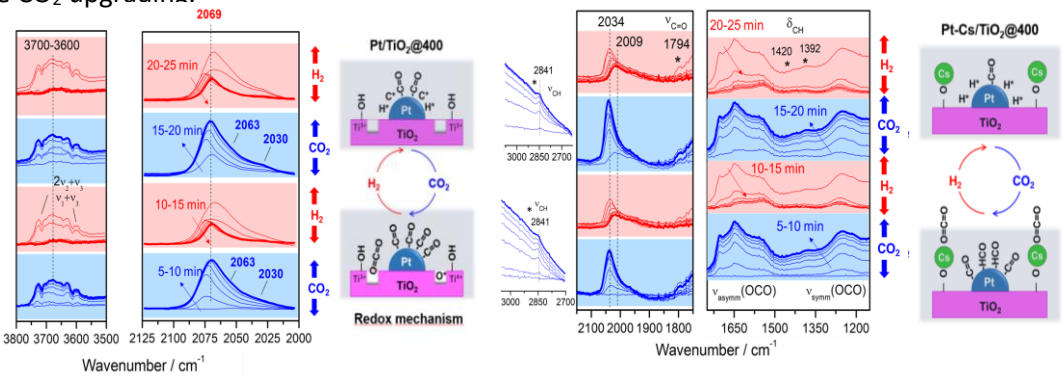

**Figure 1.** Transient experiment for $Pt/TiO_2$ (left) and $PtCs/TiO_2$ (right) with alternated pulses of $H_2$/Ar and $CO_2$/Ar at 250 $^oC$

# Pore size effects in porous Ag electrodes for electrochemical $CO_2$ reduction

Maaike E.T. van Ittersum[1]*, Claudia J. Keijzer[1], Karen van den Akker[1], Peter Ngene[1] and Petra E. de Jongh[1]

[1]*Materials Chemistry & Catalysis, Debye Institue of Nanomaterials Utrecht, The Netherlands*

**m.e.t.vanittersum@uu.nl*

## Introduction

Electrochemical $CO_2$ reduction is promising to close the carbon cycle. Good catalysts converting $CO_2$ at high current densities (**>**10 mA/cm$^2$**)** are required for industrial application [1]. Porous metal electrodes are promising to achieve this, because of their high surface area and good electronic conductivity [2]. Unfortunately, they are also more prone to diffusion limitations. Also, the often complex pore structures make it hard to disentangle the effect of different parameters. Hence, porous model catalysts -made by use of ordered templates- are useful to fundamentally understand the processes taking place. Previous research showed the influence of the mesostructure of template-based porous Ag made on gold coated glass-slides on the selectivity [3]. To our knowledge, no one has tried to make these catalysts on commonly used substrates (such as carbon paper for GDEs) or discussed the presence and effect of diffusion limitations. Therefore, we discuss that template-based porous Ag can be prepared with PMMA sphere templates on different substrates and we discuss the effect of pore size.

## Experimental

PMMA template spheres were prepared as previously described in literature [4], slightly changing the reaction conditions to obtain different sphere sizes. Porous Ag electrodes were prepared by firstly drying a dispersion of PMMA spheres on top of a substrate (carbon paper, Ag foil). After drying, 2.2 mg/cm$^2$ of Ag was deposited at -0.2 V vs Ag/AgCl using a solution described in literature[5][6]. Subsequently, the PMMA template was dissolved in acetone. Electrochemical measurements were performed in a H-type cell using a Pt counter electrode, a Ag/AgCl reference electrode and a Nafion membrane. In both the cathodic and anodic compartment (18 mL), 15 mL 0.1 M $KHCO_3$ was used as electrolyte and a flow of 10 mL $CO_2$/min was applied in the cathodic compartment. During catalysis, the gas products were analyzed with a GC.

## Results and Discussion

After the syntheses of PMMA spheres, their average particle diameters were determined based on SEM images (e.g. Figure 1A) and were found to be 87, 115, 123, 203, 308 and 372 nm. Using these PMMA sphere templates, inverse porous structures (e.g. Figure 1B) were obtained successfully on different substrates (carbon paper, Ag foil). To investigate diffusion limitations in catalysis, the partial current densities for the porous Ag samples with different pore diameters were compared. Figure 1C shows that at more negative potentials, the pore diameter becomes more important for the partial current density. At a potential of -1.4V vs RHE, an optimum in CO current density was found around 200 nm pore diameter. At this pore size, the current density is more than 1.5 times higher. This is an indication that, especially at more cathodic potentials, diffusion in and out the pores becomes an important factor to take into account.

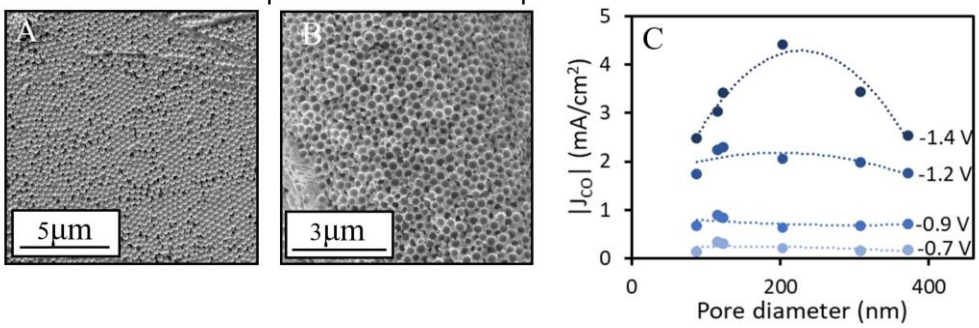

**Figure 1. A) PMMA spheres with an average particle diameter of 308 nm; B) Porous Ag made by deposition of Ag in the holes of a 308 nm PMMA spheres template on C paper and subsequent removal of the PMMA spheres; C) Partial CO current density at -0.7, -0.9, -1.2 and -1.4 V vs RHE for porous Ag with different pore diameters.**

**Keywords:** sorption-enhanced, chemical looping, super-dry reforming

**Introduction.** Over the past decades, the interest in sorption-enhanced catalytic and chemical looping processes has tremendously increased, owing to their advantages with respect to (1) thermodynamic equilbrium limitations through Le Chatelier's principle and (2) inherent $CO_2$ capture and utilization at limited additional cost[1,2]. To upscale these processes, it is crucial to develop multifunctional materials, carrying a combination of $CO_2$ sorption, catalytic and/or redox properties. This work provides new insights into the design of low-cost "multifunctional materials" aided by rational active component distribution.

**Experimental/methodology.** In this work, multifunctional materials based on Fe and Ca were synthesized through 3 different methods. First, a benchmark of $CaO/Al_2O_3$ ($CO_2$ sorbent) and $Fe_2O_3/MgAl_2O_4$ (oxygen storage material) was prepared by physical mixing[3]. Secondly, a set materials was synthesized by sol-gel autocombustion (SGAC) using citric acid and calcium, magnesium, aluminum and iron nitrates as precursors (CFMA-SGAC). Finally, a wet physical mixing (WPM) method was applied using $CaO/Al_2O_3$ with $Fe(NO_3)_3.9H_2O$ (FCA-WPM) and $Fe_2O_3/MgAl_2O_4$ with $Ca(NO_3)_2.6H_2O$ precursor, respectively (CFMA-WPM). All materials were characterized through X-ray diffraction (XRD), synchrotron-based in situ X-ray Absorption and Raman Spectroscopy (XAS, XRS) and temperature-programmed reactions (TPRe) such as carbonation-decarbonation, reduction by $H_2$ and oxidation by $CO_2$.

**Results and discussion.** Detailed characterization by means of XRD and TPRe indicates that the CFMA-SGAC materials exhibit a clear loss of sorption functionality compared with the benchmark physical mixture (Figure 1), owing to mixed oxides containing Ca. Since this Ca is less readily available for $CaCO_3$ formation, the formation of such phases jeopardizes the $CO_2$ sorption capacity. Even when comparing samples with an increased nominal Ca content, hardly any $CO_2$ sorption functionality is observed, indicating that oxides of Fe, Mg and/or Al immobilize Ca through mixed phases in CFMA-SGAC materials. Nevertheless, some of these materials showed excellent oxygen storage and $CO_2$ conversion capacity, albeit at temperatures above 1123 K. For the materials synthesized through wet physical mixing, CFMA-WPM proves far superior to FCA-WPM in terms of $CO_2$ sorption capacity (Figure 1). Although the latter has a very high redox capacity, more than twice that of the benchmark material, it is solely available at temperatures exceeding 1173 K. Similar as for CFMA-SGAC materials this is attributed to the effect of Ca-containing mixed oxides, again leading to strongly diminished $CO_2$ sorption capacity. As for CFMA-WPM, on top of its promising $CO_2$ sorption capacity, ample redox capacity is observed at intermediate and high temperature, outperforming the benchmark physical mixture with ca. 85% in $CO_2$ sorption and ca. 30 % in oxygen storage capacity. Based on this performance, the material makes a true candidate for Ni addition and use in the chemical looping super-dry reforming process[3].

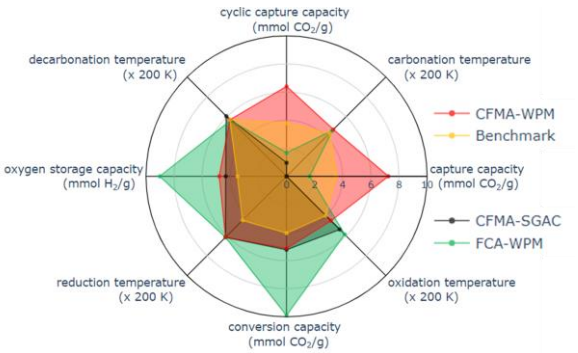

**Figure 1. Result summary of $CO_2$ sorption behaviour, $H_2$ and $CO_2$ conversion capacity.**

# Reverse Microemulsion Synthesis Promotes the Formation of Iron Carbide in Direct Hydrogenation of $CO_2$ to Light Hydrocarbons

Y. Yu, D.S.A. Simakov*

*University of Waterloo, Waterloo, Ontario, Canada*
**dsimakov@uwaterloo.ca*

**Keywords:** reverse microemulsion, $CO_2$ conversion, iron carbide, light hydrocarbons

**Introduction.** $CO_2$ utilization has recently attracted significant interest as an alternative approach to $CO_2$ storage [1]. Converting $CO_2$ into synthetic fuels is an attractive pathway to decrease $CO_2$ emissions and to reduce our dependence on fossil fuels. Thermocatalytic hydrogenation provides advantages of fast reaction rates and high conversion efficiencies, thus allowing for compact, high-throughput operation. The required $H_2$ can be generated via water electrolysis using renewable electricity (hydro, wind, solar), surplus electricity, or nuclear power.

In the study presented herein, reverse microemulsion (RME) method was implemented aiming for smaller nanoparticle size and narrower size distribution [2, 3]. In the RME system, small water droplets containing desired reactants are surrounded by surfactant molecules and dispersed in a continuous oil phase. RME method is favored by the advantages of the high specific surface area of the synthesized nanoparticles, since the nanodroplets act as microreactors, restraining the amounts of reactants and limiting the nanoparticle size.

**Experimental/methodology.** K-Fe/$\gamma$-$Al_2O_3$ catalyst was synthesized by the RME method [2, 3], alongside two reference samples fabricated by wet impregnation on the RME-synthesized $\gamma$-$Al_2O_3$ and commercial $\gamma$-$Al_2O_3$. The RME synthesis resulted in the highest specific surface area (239 $m^2/g$), consisting of well dispersed iron oxide nanoparticles (5-10 nm). The prepared catalysts were evaluated for their catalytic performance in $CO_2$ hydrogenation to lower olefins and paraffins (C2-C6). Fresh (calcined) and spent (post reaction) catalysts were characterized by a number of analytical techniques (XRD, TPR, TPD, STEM-EDS, TGA-FTIR, XPS).

**Results and discussion.** The RME-synthesized K-Fe/$\gamma$-$Al_2O_3$ catalyst showed excellent catalytic performance at a moderately elevated pressure (10 bar), with the C2-C6 selectivity of 52% and $CO_2$ conversion of ca. 55% at 375 °C and $H_2/CO_2$ = 4. Reference (wet impregnation) samples showed significantly lower $CO_2$ conversion and higher selectivity to CO and $CH_4$ formation. The RME method resulted in a superior catalytic performance, ascribed to the enhanced specific surface area, reinforced reducibility, and facile formation of the iron carbide ($\chi$-$Fe_5C_2$) phase.

The maximum obtained $CO_2$ conversion and selectivity to C2+ hydrocarbons exceeded 50% over the RME-synthesized K-Fe/$\gamma$-$Al_2O_3$, attaining 7.4 mmol $g^{-1}$ $h^{-1}$ space time yield (STY) at 10 bar and 375°C. STEM-EDS analysis revealed the formation of both $\chi$-$Fe_5C_2$ and $Fe_3O_4$ phases under reaction conditions.

Direct $CO_2$ hydrogenation to light hydrocarbons can provide an alternative route to conventional oil cracking, which is energy- and carbon-intensive. However, achieving high $CO_2$ conversion and high selectivity to C2+ hydrocarbons at the same time is very challenging. Elevated temperatures result in high $CO_2$ conversion but also lead to increasing formation of CO and $CH_4$. Our study provides important insights into the synthesis of Fe-based catalysts for $CO_2$ hydrogenation to light hydrocarbons.

# Structure sensitivity of methanol synthesis from $CO_2$ on $Cu/ZrO_2$ catalysts

Rodrigo Pallacán[1], Tomás Vergara[1], María F. Guevara[1], Romel Jiménez[1], Alejandro Karelovic[1]*
[1]*Carbon and Catalysis Laboratory (CarboCat), Department of Chemical Engineering, Concepción, Chile*

**Keywords:** Methanol, $CO_2$ hydrogenation, *operando*-DRIFTS, $ZrO_2$

**Introduction.** Copper catalysts are the most studied for the methanol synthesis via $CO_2$ hydrogenation. An appropriate support for copper nanoparticles should be capable of enhancing the desired reaction and also avoid deactivation of the catalyst. Zirconium oxide has been shown to greatly increase the methanol formation rates compared to inert supports, like silica, probably via the formation of new interfacial Cu-$ZrO_2$ active sites. In this work, we assess the effect of Cu particle size on the kinetics of the process.

**Experimental/methodology.** $Cu/ZrO_2$ catalysts were prepared by wet impregnation varying the Cu content from 0.1 to 10 wt.%. Catalysts were characterized by TEM, XRD, $H_2$-TPR and $N_2O$-decomposition. Kinetic studies were performed in a fixed bed reactor in differential operation, without mass transfer limitations. Kinetic isotopic effect (KIE) experiments ($H_2/D_2$) as well as $H_2$ and $CO_2$ partial pressure variations were carried out in the same system. *Operando*-DRIFTS experiments were performed in a low dead volume cell connected to a mass spectrometer for on-line product measurement. Steady State Isotopic Transient Kinetic Analyses (SSITKA) coupled with *operando*-DRIFTS were also carried out.

**Results and discussion.** Kinetic experiments showed an asymptotic behavior of the methanol formation rate with increasing copper content (particle size)(Fig. 1-a). Apparent activation energies ($E_{app}$) are different for CO and $CH_3OH$ formation. For methanol, the $E_{app}$ increases significantly for catalysts with low particle size (Fig. 1-a). Fig. 1-a shows that, for methanol formation, the apparent reaction order with respect to hydrogen partial pressure does not depend on the particle size, which agrees with hydrogen activation occurring on Cu and that this phenomenon is not affected by the size of copper particles. On the other hand, the order with respect to $CO_2$ increases from ca. 0.2 to 0.43 when particle size decreases, showing that $CO_2$ activation and further reaction is occurring on sites affected by the decrease in particle size, probably on the interphase between Cu and $ZrO_2$. The change in the KIE with particle size also points out to a change in the nature of the active sites. The variation of methanol synthesis TOF with particle size for $Cu/ZrO_2$ shows a different behavior compared to $Cu/SiO_2$ [1], with increasing rates for lower particle sizes, which are correlated with higher interfacial length. *Operando*-DRIFTS experiments allowed the identification of bidentate formates and methoxy groups on the surface, in accordance to other studies [2]. Formate species at 2848 $cm^{-1}$ were identified as active intermediates since the rate of their disappearance under transient conditions is similar to that of methanol formation. These species are nearly absent on the catalyst with lower particle size (0.1% $Cu/ZrO_2$, Fig. 1-b). This could be attributed to a change in the nature of the active site when Cu particle size is too low (< 2 nm) in which the interphase is no longer able to locate reactive intermediates.

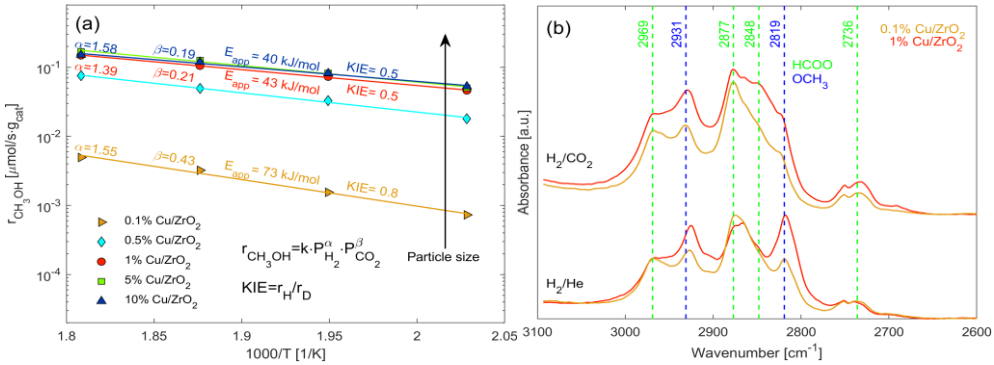

**Fig. 1**. (a) Arrhenius plot and kinetic parameters as a function of Cu content. (b) Operando-DRIFTS at steady state $H_2/CO_2$=3/1, 25 mL/min, 6 bar and 240°C.

# $CO_2$ hydrogenation to methanol on an ordered mesoporous $InCu/Al_2O_3$ catalysts: effect of indium promoter

Faisal Zafar[1], Mansoor Ali[1], Jong Wook Bae[1*]

[1]*School of Chemical Engineering, Sungkyunkwan University (SKKU), Suwon, Gyeonggi-do, Republic of Korea*

**Keywords:** $CO_2$ hydrogenation, Methanol, Indium, copper, catalyst, oxygenates.

**Introduction.** Carbon dioxide ($CO_2$) is by far the most emitted greenhouse gas, its utilization by $CO_2$ hydrogenation to methanol is considered a practical approach to mitigate its negative effects [1]. Copper (Cu) based methanol synthesis catalysts (e.g. Cu-ZnO-$Al_2O_3$) are less active for the selective methanol formation and are prone deactivatation due to the sintering and agglomeration of Cu and ZnO nanoparticles [2]. To enhance the thermal stability of Cu nanoparticles with reduced RWGS reaction and increased oxygenate formation rate, herein, we investigated the effects of $In_2O_3$ (In) promoter by varying In/Cu ratios on the mesoporous $Cu/Al_2O_3$.

**Experimental/methodology.** The highly ordered mesoporous γ-$Al_2O_3$ (mAl) support was synthesized by the well-known evaporation-induced self-assembly method (EISA) with slight modification from our previous work [3]. The CuO was impregnated first on the mAl support by incipient wetness impregnation method with subsequent calcination at 350 °C and further indium was successively impregnated with its different weight loadings (0 – 0.5 wt%). The $CO_2$ hydrogenation activity of the pre-reduced catalyst was performed at 250 °C and 5.0 MPa for 40 h in a fixed bed reactor using mixed gas with $H_2/CO_2$ molar ratio of 3. The effluent products were analyzed by an *in-situ* GC equipped with TCD and FID analyzer.

**Results and discussion.** The thermally stable spinal-type $CuAl_2O_4$ phase formations on the highly ordered mAl were confirmed by XAFS analysis (**Figure 1(A)**), and the $CuAl_2O_4$ phases were found to accelerate the CO formation rate by the RWGS reaction on the monometallic Cu/mAl catalyst (**Figure 1(B)**). Whereas, the loading of the optimum amount of $In_2O_3$ promoter (0.1 wt%) on the Cu/mAl suppresses the CO formation due to the newly formed Cu-$In_2O_{3-x}$ interaction and larger oxygen vacant sites. $CO_2$ conversion was found to be higher on the InCu/mAl(1) with 7.4% compared to other InCu/mAl in the range of 3.9 – 7.4% as well as $In_2O_3$ itself (0.8% conversion with 55.0% selectivity to methanol) with their stable activity for 40 h (**Figure 1(B)**). Higher loading of $In_2O_3$ resulted in lower $CO_2$ conversion due to the decreased active sites and oxygen vacancies on the catalyst surfaces. Interestingly, product distributions were significantly altered according to $In_2O_3$ content on the InCu/mAl, and the main CO byproduct formed by RWGS reaction was steadily decreased with an increase of In/Cu ratio from 79.9% on the Cu/mAl to 29.7% on the InCu/mAl(5). That suppressed CO formation rate corresponds to the steady increases of $CH_3OH$ selectivity from 18.8 to 62.5%, which was inversely related to the amount of metal oxides including less active $CuAl_2O_4$ phase. It is worth to note that the significant product shifts from CO to $CH_3OH$ on the $In_2O_3$-promoted InCu/mAl were attributed to the suppressed RWGS activity as well as increased surface formate intermediates (**Figure 1(C)**).

# Utilization of $CO_2$ and $H_2$ for Arene Methyl-, Ethyl-, and Propylation

Jiachang Zuo, Youzhu Yuan*

*State Key Laboratory of Physical Chemistry of Solid Surfaces, College of Chemistry and Chemical Engineering, Xiamen University, Xiamen, P. R. China*
**E-mail: yzyuan@xmu.edu.cn*

**Keywords:** $CO_2$ hydrogenation, arene alkylation, modified zeolite, multifunctional catalyst

**Introduction.** Considering the trend of carbon neutrality, the involvement of $CO_2$ in preparing value-added bulk chemicals, such as para-xylene and other alkyl arenes, is feasible in terms of both economic and environmental benefits. Developing the catalyst for arene methyl-, ethyl-, and propylation reactions using $CO_2$ as a building block in a one-pot method will provide new routes for the regulation of arene components. Due to the difference in arene ring C($sp^2$) and side chain C($sp^3$), methylation in arene ring is prefered compared with alkylation (chain growth) in side chains of arene.[1] We reported a bifunctional catalyst for toluene methylation to para-xylene using $CO_2$ and $H_2$. The closer active sites between $CO_2$ hydrogenation and alkylation, the better catalytic performance.[2] However, in benzene ethyl- and propylation reactions by the same strategy, the two active sites must be separated because the high energy barrier $CO_2$ coupling reaction needs to be conducted preferentially. Here, we further report the in-depth results of this topic.

**Experimental/methodology.** Catalytic performance was evaluated on a high-pressure fixed-bed reactor. For the methylation reacion, $ZnZrO_x$ (ZZO) and Si-modified H-ZSM-5 (Z5) were mixed as bifunctional catalyst and used to conduct $CO_2$ hydrogenation and arene methylation, respectively. For the ethyl- and propylation, an additional SAPO-34 (S34) was used for $CO_2$ coupling to ethyl- and propylene. P-modified Z5 was used to regulate the ethyl- and propylbenzene products. In this case, ZZO and P-modified Z5 were separated by a dual-bed system or ZZO@S34 core–shell catalyst.

**Results and discussion.** ZZO solid-solution catalyst with excellent methanol selectivity at above 320 °C was used to perform $CO_2$ hydrogenation reaction, to match the high reaction temperature above 350 °C of arene alkylation. Compared with the industrial methylating reagent methanol, $CO_2$ can generate $CH_3O$* intermediate for the methylation at 360 °C via the hydrogenation route, while the methanol dehydrogenation route requires 420–480 °C. Thus, methanol to olefin side-reaction can be avoided and the usage of carbon source is improved. For the benzene ethyl- and propylation reaction using $CO_2$, S34 was used for the $CO_2$ to ethyl- and propylene reactions. The Gibbs free energy barrier for $CH_3O$* to undergo C($sp^3$)–C($sp^3$) coupling to form ethylene is 146 kJ $mol^{-1}$, which is higher than that of 96 kJ $mol^{-1}$ for C($sp^2$)–C($sp^3$) benzene ring alkylation with $CH_3O$*. Therefore, the active site of $CO_2$ hydrogenation (ZZO) needs to be separated from that of alkylation (Z5), otherwise the product is polymethylbenzene. The selectivity of ethylbenzene in aromatics can reach up to 84% by using a dual-bed system. In addition, regulating the acidity of Z5 by P can modulate the product distribution toward propylbenzene up to 65%.

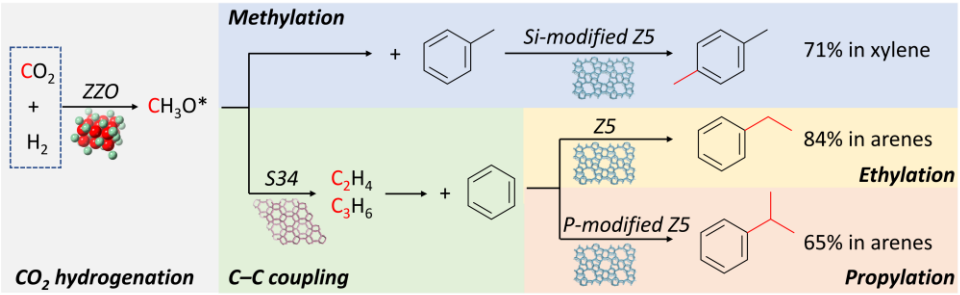

**Figure 1. Reaction routes of arene methyl-, ethyl-, and propylation using $CO_2$ and $H_2$.**

# Catalytic Conversion of Amine Carbamates into Organic Urea Derivatives by $CeO_2$ Catalyst in Corresponding Amine Solvents

M. Yabushita[1], J. Peng[1], Y. Li[1], R. Fujii[1,2], M. Tamura[3], Y. Nakagawa[1], K. Tomishige[1,4*]

**Keywords:** $CO_2$ capture and utilization (CCU), non-reductive conversion, $CeO_2$, acid-base bifunctionality

**Introduction.** Non-reductive conversion of $CO_2$ with amines to orgnic urea derivatives is an attractive approach as a CCU technology and also alternative to the current harmful production process of urea derivatives relying on phosgene. We recently found that ethylenediamine carbamate (EDA-CA), whose production is easy via the chemical absorption of $CO_2$ in ethylenediamine (EDA), was transformed into 2-imidazolidinone (so-called ethyleneurea, EU) over $CeO_2$ catalyst without pressurized $CO_2$ (Fig. 1), where 2-propanol was the reaction solvent [1]. 2-Propanol suppressed the undesired thermal decomposition of EDA-CA to EDA and $CO_2$ to some extent, but not completely. Another drawback of this system is the insolubility of EDA-CA in 2-propanol at room temperature, making the handling of this system quite difficult. This paper introduces our recent achivements of the development of new efficient catalytic system for EDA-CA conversion into EU by using EDA as a solvent [2], which can dissolve EDA-CA even at room temperature.

**Experimental.** The white powder of pure EDA-CA was prepared by pressurizing $CO_2$ at 5 MPa in a 190 mL high-pressure reactor containing EDA. For typical reactions, 20 mmol of EDA-CA, 2.0 mmol of $CeO_2$ (Daiichi Kigenso Kagaku Kogyo, calcined at 873 K for 3 h), and 100 mmol of EDA were charged into the reactor. After being filled with Ar 1 MPa, the reactor was heated to a designated temperature. The time when the inner temperature of the reactor reached the target one was defined as 0 h of reaction time. The products and unreacted substrate were quantified by GC-FID and $^1$H NMR.

**Results and discussion.** Our catalyst screening test demonstrated only $CeO_2$ to exhibit the high catalyic performance for this reaction. Fig. 2 shows the time course of EDA-CA transformation in EDA solvent at 413 K. EU was the sole reaction product at 0 h, while another urea derivative *N*,*N*'-bis(2-aminoethyl)urea (LU) was also produced due to the subsequent reaction of EU with EDA in the liquid phase. The turnover frequency for the EDA-CA conversion was elucidated from the initial slope of this time course to be 3.7 $h^{-1}$. This value was at least 6-fold higher than those in reported works regardless of the lower reaction temperature (0.60 h-1 by $CeO_2$ catalyst in 2-propanol at 413 K [1]; 0.47 $h^{-1}$ by $Cp_2Ti(OTf)_2$ in *N*,*N*'-dimethyl-2-imidazolidinone at 433 K [3]). Also, the monitoring test for inner pressure of the reactor indicated that the thermal degradation of EDA-CA was suppressed apparently completely. These data clearly demonstrated the great advantages of EDA as a reaction solvent compared to previously used ones. This catalytic system using $CeO_2$ catalyst and corresponding amine solvent was also found to be reusable and also applicable to the conversion of other amine carbamates into organic urea derivatives.

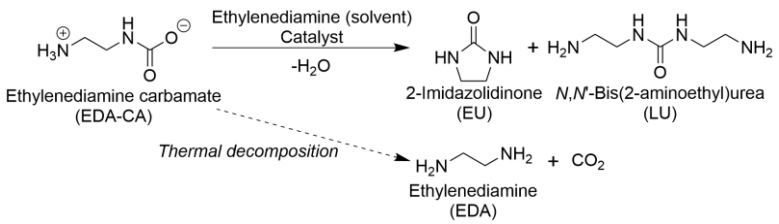

**Fig. 1** Conversion of ethylenediamine carbamate (EDA-CA).

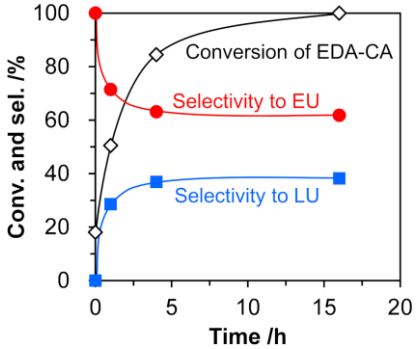

**Fig. 2** Time course of EDA-CA conversion. Conditions: EDA-CA 20 mmol; $CeO_2$ 2.0 mmol; EDA 100 mmol; Ar 1 MPa (r.t.); 413 K.

# Leaching in Specific Facets of ZIF-67 and ZIF-L Zeolitic Imidazolate Frameworks During the $CO_2$ Cycloaddition with Epichlorohydrin

Jose J. Delgado-Marín[1], Alejandra Rendón-Patiño[2], Vijay Kumar Velisoju[2], Gadde Sathish Kumar[2], Naydu Zambrano[2], Magnus Rueping[2], Jorge Gascón[2], Pedro Castaño[2], Javier Narciso[1] and Enrique V. Ramos-Fernández[1,*]

**Keywords:** Crystals, Carbon dioxide, Epichlorohydrin, ZIFs, Catalysts

## Introduction

Catalytic coupling of $CO_2$ with epoxides to form cyclic carbonates is one of the most efficient methods for $CO_2$ fixation. This reaction is catalysed by Lewis acid sites with the help of nucleophilic (co-catalyst). ZIF-8 and ZIF-67 are MOF very active as catalysts in this reaction although they do not have coordinative unsaturated sites or catalytically active functional groups. In addition, the pore opening of the structure is around 0.3 nm, which makes it difficult the diffusion. The scientific community generally ascribes the origin of this catalytic activity to defects in the ZIF crystals on the outer surface. So in this study, we decided to prepare crystals that ended up with different facets, to see which one was more active and thus be able to design better catalysts. What we found was that the crystals were easily degraded by the {100} facet and the leached species are the true origin of the catalytic activity.

## Experimental/methodology

Four types of ZIF-67 have been synthesized: nanocubes (ZIF-67-NC), truncated rhombic dodecahedrons (ZIF-67-TRD), rhombic dodecahedrons (ZIF-67-RD) and ZIF-L. The catalysts have been tested in the cycloaddition of $CO_2$ with epichlorohydrin, at 15 bar of $CO_2$ and 120$^0$C. The stability of the catalyst in the reaction was studied by hot filtering test, analyzing results of ICP-MS, FTIR and microscopy before and after reaction.

## Results and discussion

Figure 1 shows the conversion of epichlorohydrin in the cycloaddition of $CO_2$, with ZIF-L and ZIF-67-NC being the most active catalysts. The diffraction patterns of the used samples do not change with respect to the freshly prepared ones. This may be a false proof of stability. If we look at the SEM images (Figure 2), we see that the ZIF-67-NC sample, which ends in the {100} facet, degrades considerably. When we analyse the reaction mixture (ICP-MS) we also see that there is a considerable amount of Co in the reaction mixture. The same is true for the other samples. In all cases the samples were degraded by the {100} facet.

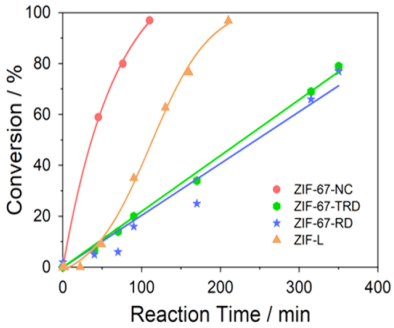

**Figure 1. Cycloaddition of $CO_2$.**

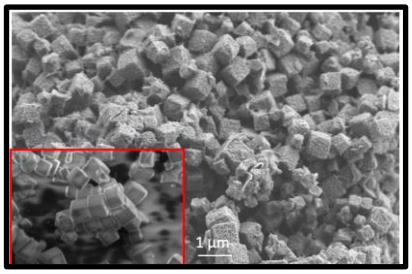

**Figure 2. SEM image of ZIF-67-NC.**

Thus, it can be concluded that leaching of some constituents of the MOF results in the formation of species in solution that are much more active than the MOF itself. In addition, the exposed facets on the MOF crystal play a large role, with the {100} facet degrading much faster (Figure 3).

# Biogas methanation in an industrial-scale plate-type methanation reactor: interplay of reactor and catalyst optimization

E. Moioli[1*]

[1]*Hitachi Zosen Inova AG, Zürich, Switzerland*

**Keywords:** Biogas methanation, Reactor design, Heat transfer

**Introduction**

$CO_2$ methanation is an effective way to convert this greenhouse gas into a valuable product. The reaction is spontaneous, highly exothermic ($\Delta H^R_0$ = -165 kJ/mol) and controlled by the thermodynamic equilibrium at high temperature. Hence, the scale up of the reaction is challenging, because a large heat exchange is required to achieve high conversion without running into heat transfer limitation problems [1]. We selected the plate-type fixed bed reactor operated with a $Ni/ZrO_2$ catalyst to obtain a large heat transfer, with the simplicity of a standard fixed bed reactor operating with a transition state catalyst. $Ni/ZrO_2$ is selected as catalyst because lab tests previously performed showed that this material shows an exceptional performance, offering catalytic activity already at 230 °C and preventing coking in the standard conditions for $CO_2$ methanation.

**Experimental/methodology**

The reactor is composed of thin plates, separated by 1,5 cm large chambers where the catalyst is filled. In the plates, boiling water is circulated, so that large heat transfer can be achieved and the temperature of the cooling medium can be controlled with precision. After the unavoidable (but limited) hotspot, the temperature is controlled by keeping the boiling water at the target temperature of maximum reaction yield (approximately 230 °C). The steam produced is collected in a steam drum on top of the reactor. Water is circulated from the steam drum in a descending pipe that feeds back the water to the bottom of the reactor. The maximum steam content in the cooling plates is kept below 5%, to maintain the circulation via natural draft. The catalyst employed is based on $Ni/ZrO_2$ [2]. It was observed that the optimal temperature for the $CO_2$ methanation over this catalyst is between 230-250 °C.

**Results and discussion.**

The reactor was operated for several hundred hours in the biogas methanation. Thanks to the large heat exchange and the precise temperature control, the reactor produced grid-compliant synthetic natural gas (SNG) over more than 1000 hours of operation. This was accomplished without exceeding the maximum temperature allowed by the catalyst (ca. 580 °C). A characteristic temperature profile is shown in figure 1b. The heat transfer limited region in the reactor is limited to the hotspot, as visible in the change of slope in the temperature profile after approximately after 0.8 m of reactor. The reactor was targeting a GHSV of 1000 $h^{-1}$, but the experiments showed the possibility to higher the space velocity to 2000 $h^{-1}$. Additionally, it was possible to operate the reactor in partial load without problems and still producing grid compliant SNG. In this presentation, we will show several characteristic results of the reactor operation, demonstrating how this reactor type is particularly suitable for the $CO_2$ methanation reaction.

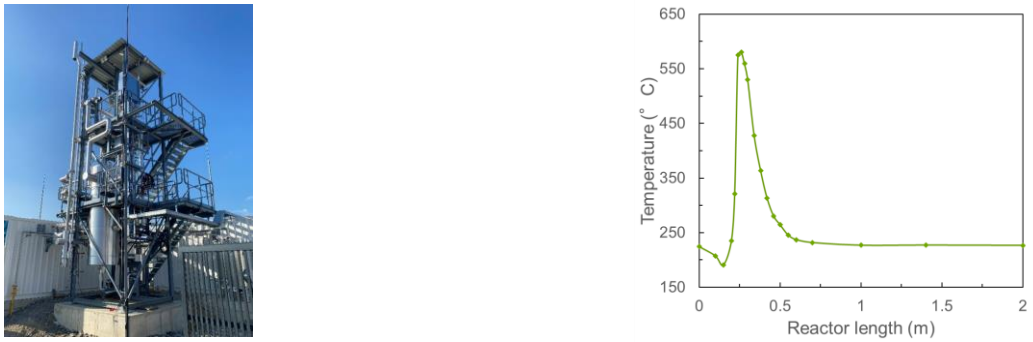

**Figure 1.** A) Image of the plate-type fixed bed reactor operating the $CO_2$ methanation B) The characteristic temperature profile of the plate-type methanation reactor.

# Lewis acid zeolites activate dihydrogen in N-formylation reaction

Jan Přech[1*], Martin Hulla[2]

[1]*Dept. of Physical and Macromolecular Chemistry, Faculty of Science, Charles University, Albertov 6, Prague 2, Czech Republic*
[2] *Dept. of Inorganic Chemistry, Faculty of Science, Charles University, Albertov 6, Prague 2, Czech Republic*
**corresponding author: jan.prech@natur.cuni.cz*

**Keywords:** Lewis acid, zeolite, N-formylation, $CO_2$ hydrogenation, frustrated Lewis pairs

**Introduction.**

Pairs of sterically hindered Lewis acids and bases, which cannot form classical acid-base adducts, are called frustrated Lewis pairs (FLPs). Their unquenched Lewis acidity and basicity are available to accept and donate electron density to $H_2$ molecules, which results in their heterolytic cleavage. Homogeneous FLPs are thus established hydrogenation catalysts [1]. On the contrary, examples of heterogeneous FLPs are scarce. Zeolites are crystalline microporous silicates with acidic properties. Lewis acidic sites are generated, i.a., by isomorphous substitution of tetravalent hetero-ions such as $Sn^{4+}$, $Zr^{4+}$ or $Ti^{4+}$, which contain empty d-orbitals and can extend their coordination [2]. In the present study, we demonstrate that Sn- and Zr-substituted beta zeolites catalyse N-formylation of morpholine with $CO_2$ and molecular hydrogen and investigate whether the reaction occurs via a mechanism similar to that of FLP homogenous catalysts.

**Experimental/methodology.**

Sn-beta and Zr-beta zeolites were synthesized by seed assisted direct hydrothermal synthesis. Titanium silicalite-1 (TS-1, MFI structure) was kindly provided by Zeolyst Int. Concentration of the present Lewis sites was determined by infrared analysis using deuterated acetonitrile and CO adsorbed on the respective sites. N-formylation of morpholine was performed with $CO_2$ (6 bar) and $H_2$ (94 bar) at 190°C in sulfolane.

**Results and discussion.**

Table 1 lists representative results of the reactions performed over the Lewis acidic zeolites together with their basic characterization. Experiments without hydrogen or the catalyst gave no N-formyl morpholine (N-FM). The observed turn-over-frequencies (TOF) over all of the zeolite catalysts outperform tricyclohexyl tin (IV) triflate : collidine (1.2 $h^{-1}$), which is a state-of-the-art homogeneous FLP catalyst [3]. Morpholine is a base small enough to penetrate the zeolite beta micropores. Therefore, it is expected to coordinate to the acidic sites or stay in their close vicinity. Due to the confined space in the zeolite, such adduct can act as FLP activating molecular hydrogen, which subsequently hydrogenates $CO_2$ to formic acid. Formic acid then reacts with morpholine yielding N-FM, which is less basic than morpholine and thus can be replaced by another morpholine molecule on the acidic site. To our knowledge, this is the first time a sole Lewis acid zeolite has been observed to activate molecular hydrogen.

Table 1: Si/M molar ratio (determined by ICP-MS), concentration of the Lewis acid sites (determined by $CD_3CN$ probe), and TOF of the morpholine formylation over the Lewis acid zeolites.

**Keywords:** $CO_2$ hydrogenation, Mg Promoter, Higher hydrocarbons, Deactivation behavior.

**Introduction:** $CO_2$ can be considered an alternative feedstock to fossil resources for producing fuels and chemicals [1], which can contribute not only to reduce the high concentration in the atmosphere, but also to provide a sustainable solution to depleting fossil fuel reserves. Several studies have successfully converted $CO_2$ into $C_1$ chemicals (e.g., methanol, methane, formic acid, and carbon monoxide) [2]. The inherently high thermodynamic stability and inertness of $CO_2$ make its hydrogenation very challenging towards C–C coupling reaction; as a result, the $CO_2$ hydrogenation products have high H/C ratios because of rapid methane formation [3]. To overcome these limitations, sodium-promoted iron-magnesium oxide (Na-FeMgO$_x$) catalyst was proposed with high $C_{5+}$ selectivity and low methane selectivity. Furthermore, the deactivation behavior of Na-FeMgO$_x$ catalysts was studied with several characterization techniques.

**Experimental/methodology:** The Na-FeMgO$_x$ catalysts were prepared by the co-precipitation method. Iron and magnesium nitrate were mixed and then sodium carbonate was used as a precipitant. Precipitates were filtered, dried, and calcined to synthesize the calcined catalyst.

**Results and discussion:** The $CO_2$ hydrogenation reactions were conducted over Na-FeMgO$_x$ at 330 ℃, 3.5 MPa, $H_2/CO_2$ ratio of 1:1 at a gas hourly space velocity (GHSV) of 2000 mL $g^{-1}$ $h^{-1}$, which exhibit high $C_{5+}$ liquid hydrocarbon selectivity of 66.5% (excluding CO) at a $CO_2$ conversion of 19.6%, while the selectivity of $CH_4$ (6.7%) was suppressed. The Na-FeMgO$_x$ shows effective performance for a high $C_{5+}$ yield of 25.1% with a conversion of 49.1% at 360 ℃, 3.5 MPa, $H_2/CO_2$ ratio of 3:1 at a gas hourly space velocity (GHSV) of 4000 mL $g^{-1}$ $h^{-1}$. The deactivation behavior of Na–FeMgO$_x$ catalyst was studied which shows the re-oxidation of the χ-$Fe_5C_2$ phase to the highly pulverized Fe oxide phases, and subsequent "wetting" of the pulverized Fe oxides on the surface of $MgCO_3$ as shown in Fig. 1.

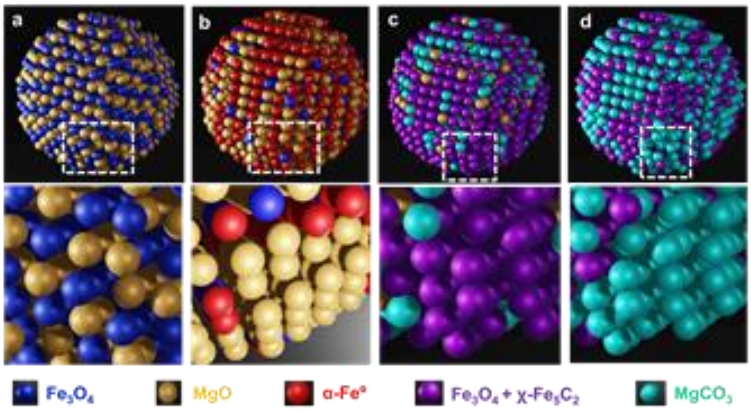

Fig. 1: Schematics of deactivation behavior of Na-FeMgO$_x$ (a) calcined Na-FeMgO$_x$, (b) reduced Na-FeMgO$_x$, (c) spent Na-FeMgO$_x$ (100h), and (d) spent Na-FeMgO$_x$ (670h).

# Fabrication of Cu-Zn coated structured foam catalysts for $CO_2$ hydrogenation to methanol in a fixed-bed reactor

Aakash Bhardwaj*, Rohit Sahu, Kamal Kishore Pant, Sreedevi Upadhyayula

*Indian Institute of Technology Delhi, New Delhi, India*

**Keywords:** Methanol, Ceramic Foams, Sintering, Hotspot formation.

**Introduction.** The conversion of anthropogenic $CO_2$ into value-added chemicals is key to begin the energy transition of chemical industries. This $CO_2$ hydrogenation to methanol reaction released a massive amount of heat due to its exothermicity ($CO_2 + 3H_2 \leftrightarrow CH_3OH + H_2O$, $\triangle H_{298K}$ = -49.79 kJmol$^{-1}$). Hence, this released heat directly affects the catalyst properties due to the catalyst deactivation by sintering and hotspot formation [1]. Ceramic foams are superior to pellet ones owing to their attractive properties, such as high porosity, thermal resistivity, and high mechanical durability. These foam-based catalysts improve the hydrodynamics, heat and mass transfer properties, which helps enhance the catalytic performance [2]. In this work, we studied the effect of catalyst-loaded ceramic foams on the catalytic performance of methanol synthesis.

**Experimental/methodology.** The catalyst, slurry, and foam preparation were done in three steps: The Cu and Zn hydroxy carbonate precursors were mechano-chemically prepared in a ball mill, which subsequently dried and calcined to attain a catalyst denoted as CZ-BM-C. The as-prepared catalyst was then used for slurry preparation using polyvinyl alcohol (PVA), water, and glycerol in a fixed ratio [3], which was then dip-coated on corroded ceramic foams to attain the final structured foam catalyst. The catalyst characterization was done using XRD, FESEM, and HRTEM analysis. The catalytic activity tests were performed in a high-pressure fixed-bed tubular reactor connected with gas chromatography for product analysis.

**Results and discussion.** The FESEM images show the surface morphology of the ceramic foam, catalyst, and loaded foam (Figure 1 (a-e)). The effect of the foam combination on activity is given in Figure 1 (f). As depicted in the figure, we can see that the highest catalytic performance (conversion, selectivity, and space-time yield) was achieved in N (Zr-Zr) combination due to its low thermal conductivity. Further, the effect of temperature was studied (Figure 1 (g)) over the N$^{th}$ combination at P = 40 bar and WHSV= 2600 ml/$g_{cat}$.hr, and it was observed that at T = 240 $^oC$, P = 40 bar, and W =2600 ml/$g_{cat}$.hr highest catalytic performance was achieved and which follows the reaction thermodynamics.

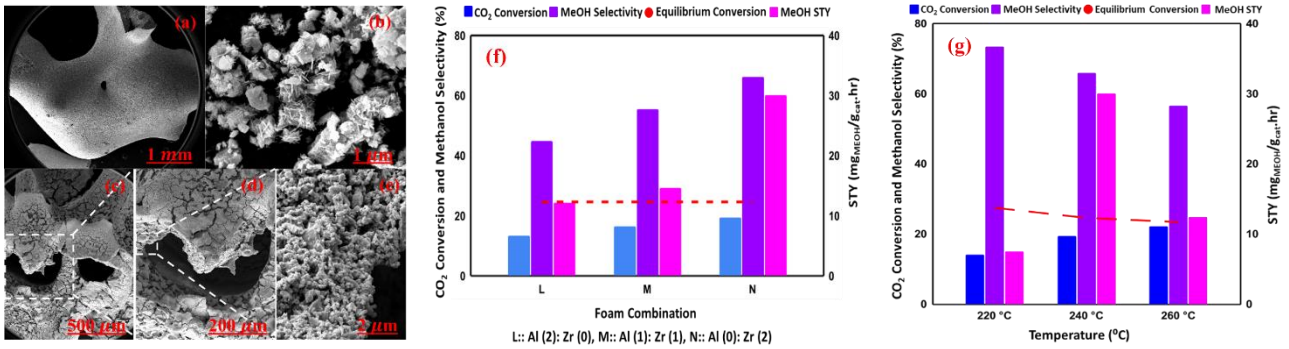

**Figure 1. Fesem images of (a) Zr foam (b) Calcined catalyst (c, d, e) magnified view of the catalyst loaded Zr foam, (f) Effect of catalyst loaded foam combination on catalytic performance, (g) Effect of temperature on the catalytic performance at P= 40 bar and WHSV= 2600 ml/$g_{cat}$.hr.**

## Introduction

Hydrogenation of carbon dioxide ($CO_2$) to formate ($HCOO^-$) is a promising application of carbon capture and utilization for the production of formic acid (FA), an important feedstock chemical with increasing potential as an energy carrier. $CO_2$ hydrogenation to FA is normally carried out in liquid phase since the reaction is thermodynamically unfavorable in the gas phase. Often, FA is stabilized in the form of formate adducts by reaction with a base[1].

While homogeneous catalysts have industrially high activity and product selectivity at low temperature[2], their heterogeneous counterparts are preferred due to their well-established application in continuous flow and low dependence on solvents. Single-site catalysts have active sites with an uniform structure and a well-defined geometry characteristic of homogeneous catalysts, and the desired stability and easier handling of heterogeneous catalysts.

Solid Micellar (SOMIC) catalysts are an example of this new frontier[3, 4]. In this work, we report the potential of a solid micellar catalyst for $CO_2$ hydrogenation to formate both in batch and continuous flow.

## Experimental/methodology

Our research approach includes catalyst synthesis, characterization (STEM-HAADF, EXAFS, XRD), and catalyst testing in combination with DFT modeling.

## Results and discussion

The first SOMIC material, $Ru^{(III)}$@MCM-41 (**Figure 1a**), consists of $Ru^{(III)}$ sites incorporated in the walls of MCM-41 and stabilized by $CTA^+$ surfactant molecules in the pores. $Ru^{(III)}$@MCM was thoroughly tested in a 40 mL batch reactor and showed outstanding productivity of 0.9 g $HCOO^-g^{-1}h^{-1}$ in the presence of a tertiary ethyl amine (TEA) at 90 °C.

To make this catalyst industrially relevant and by using a multiphase continuous flow Robinson-Mahoney reactor, we recently demonstrated that $Ru^{(III)}$@MCM efficiently catalyzes $CO_2$ hydrogenation to formate in flow (**Figure 1b**), reaching a productivity of 0.3 g $HCOO^-g^{-1}h^{-1}$ at 70°C.

DFT modeling indicates that the unique activity and selectivity of this catalyst results from the heterolytic $H_2$ activation over Ru-OSi active sites.

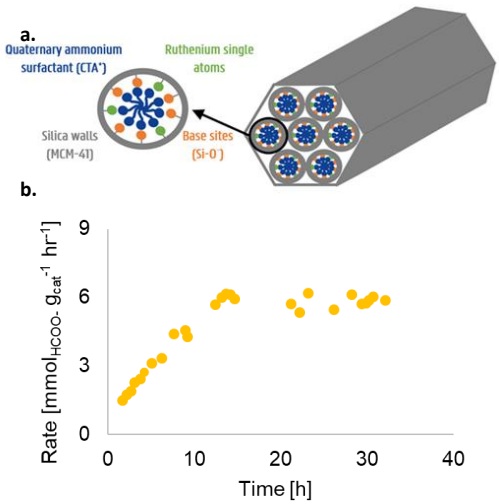

**Figure 1. (a)** Schematic representation of the $Ru^{(III)}$@MCM catalyst; **(b)** $CO_2$ hydrogenation to formate reaction rate over $Ru^{(III)}$@MCM in a continuous-flow experiment. Conditions: 2 g cat., 70°C, $C_{TEA}$= 1.3 M,$F_{H2}$/ $F_{CO2}$=0.4/0.4 mol/h.

**Keywords:** CCUS, Sustainable energy, Hydrogenation

**Introduction.** Many efforts have been made for long years to reduce $CO_2$ emissions which is one of the origins of global warming. Recently, $CO_2$ utilization have attracted attention as a hopeful way to contribute to the negative $CO_2$ emission. Conversion of $CO_2$ with $H_2$ to $CH_4$ is a potential route in the utilization of $CO_2$ [1]. $CO_2$ methanation is a significant exothermic reaction, and the equilibrium yield of $CH_4$ decreases with increasing reaction temperature. Therefore, to obtain a high yield of $CH_4$, the reaction should be carried out at a low temperature and the catalyst that shows high activity at such temperature is strongly demanded. Supported Ru catalyst is one of the candidate for $CO_2$ methanation due to superior $CH_4$ selectivity and high activity for a wide temperature range. We have previously reported that $ZrO_2$ calcined at low temperature with tetragonal type structure is potential support for Ru catalysts [2]. In this contribution, we have investigated the physicochemical properties of the highly avtive $Ru/ZrO_2$ catalysts and the reaction mechanism over the catalysts.

**Experimental/methodology.** The precursor of the $ZrO_2$ support was prepared by wet precipitation method using $ZrO(NO_3)$. Obtained precursor was calcined at 300, 500, and 800 ºC in static air. Hereafter, these are denoted $ZrO_2(300)$, $ZrO_2(500)$, and $ZrO_2(800)$. 5wt% Ru was supported on the $ZrO_2$ by the wet impregnation and followed by heating under Ar stream. The loading of Ru is set to 5 wt% of the weight of the catalyst. $CO_2$ methanation activity of the $Ru/ZrO_2$ catalysts were measured with a conventional flow system under atmospheric pressure.

**Results and discussion.** The calcination temperature of the $ZrO_2$ support influenced the catalytic activity of the $Ru/ZrO_2$ catalysts (Fig. 1). $Ru/ZrO_2(300)$ was the most active among tested catalysts. X-ray diffraction patterns elucidated that a significant part of $ZrO_2(300)$ is a tetragonal-type structure. With an increase in calcination temperature, the crystallite structure of $ZrO_2$ changed to monoclinic-type from tetragonal-type. This indicates that tetragonal-type $ZrO_2$ is the origin of the high $CO_2$ methanation activity of $RuZrO_2(300)$. To elucidate the influence of the crystallite structure of $ZrO_2$ for $CO_2$ activation step, the state of adsorbed $CO_2$ species was investigated by DRIFT analysis. A large amount of formate and bicarbonate species were absorbed on the surface of $ZrO_2(300)$. In contrast, the amount of adsorbed $CO_2$ species over the other two catalysts were small. It was reported that formate species are more easily hydrogenated to methane than other adsorbed species [3]. We surmise that tetragonal type $ZrO_2$ is suitable for the adsorption of $CO_2$ as formate species, and such character contributes to high $CO_2$ methanation activity at low temperatures.

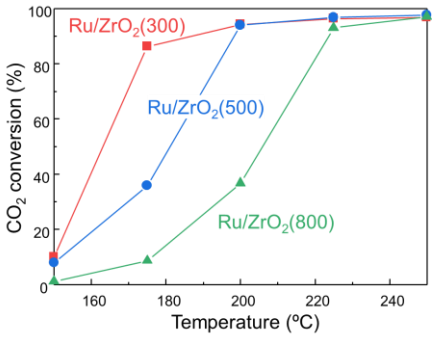

Fig. 1. Temperature dependence of $CO_2$ methanation activity over supported $Ru/ZrO_2$ catalysts.

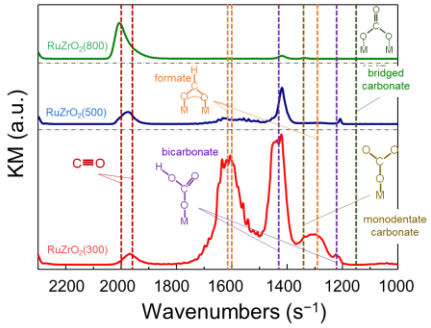

Fig. 2. DRIFT spectra for adsorbed $CO_2$ species over $Ru/ZrO_2$ catalysts..

**Keywords:** Reverse water gas shift (RWGS) reaction, perovskite-type oxide catalysts, metal loading effect

**Introduction.**

The conversion of $CO_2$ to fuels via catalytic reactions has attracted attention as a way of achieving carbon neutrality. In particular, the process for synthesizing liquid fuels by sequential catalytic reaction of reverse water-gas shift (RWGS) reaction followed by Fischer-Tropsch synthesis (FTS) using renewable $H_2$ and atmospheric $CO_2$ is expected as a promising technology. The former reaction produces CO from $CO_2$, and the latter affords hydrocarbons from CO. However, the challenge with this process is the divergence of the appropriate reaction temperatures (RWGS: >800 °C, FTS: 200-350 °C). Although the $CO_2$ conversion on RWGS reaction becomes lower as temperature decreases theoretically, the most important factor in this process is CO selectivity since the FTS can proceed even if the feed gas contains $CO_2$.[1] In this study, we considered the effective temperature for RWGS to be 500 °C, at which the RWGS reaction progresses up to 50%. Then, we investigated the effect of active metal addition on $BaZrO_3$-based perovskite-type oxide which was a high-temperature RWGS catalyst.[2]

**Experimental/methodology.**

The perovskite-type oxide containing $Ba^{2+}$, $Zr^{4+}$, and $Y^{3+}$ ($BaZr_{0.9}Y_{0.1}O_{3-\delta}$; BZY10) was prepared by coprecipitation method from barium nitrate, zirconyl nitrate dihydrate, and yttrium nitrate hexahydrate, and then resulting solid was calcined at 1000 °C. The metal loading onto BZY10 was carried out by evaporation-drying method using metal nitrate aqueous solutions. The resulting catalysts were defined as M/BZY10 (M = Pt, Ru, Rh, Ir, Pd, Ni, or Co). The catalytic activity was evaluated using a fixed bed flow reactor at 0.1 MPa. 0.10 g of catalyst was packed into the center of the reactor tube and the temperature was increased to 700 °C under $N_2$ gas flow of 40 mL $min^{-1}$. After that, the catalyst was exposed to reactant gas ($H_2/CO_2/N_2$=3/1/1) at the flow rate of 40 mL $min^{-1}$. The outlet gas was analyzed using a gas chromatograph. The catalytic activities were evaluated by decreasing the reaction temperature from 700 °C to 300 °C.

**Results and discussion.**

Fig. 1 shows the $CO_2$ conversion and product selectivity on the RWGS reaction over BZY10 and 0.1wt%M/BZY10 at 500 °C. BZY10 showed 100% of CO selectivity, but the conversion was only 2%. When Pt, Ru, and Rh were added, significant increases in $CO_2$ conversion were observed, while only slight enhancements of the catalytic activity for RWGS reaction were revealed in the case of M = Ir, Pd, Ni, and Co. Although, the $CO_2$ conversions on Ru/BZY10 and Rh/BZY10 were higher than the that of Pt/BZY10, a large amounts of $CH_4$ was produced. In contrast, Pt/BZY10 showed high $CO_2$ conversion and 100% of CO selectivity. Therefore, Pt had the best active metal for the RWGS.

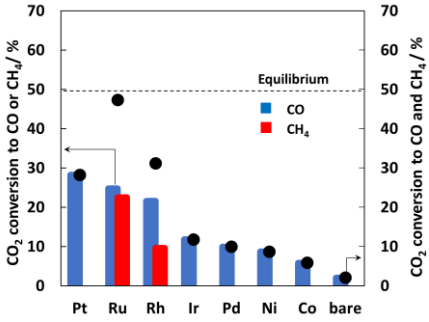

**Fig. 1 $CO_2$ conversion and product selectivity on 0.1wt%M/BZY10 (M = Pt, Ru, Rh, Ir, Pd, Ni, and Co) at 500°C**

**Keywords:** $CO_2$ capture and utilization, carbamate, $CeO_2$ catalyst

**Introduction.** Utilization of $CO_2$ as a cheap and non-toxic C1 resource has been desired to reduce its emission. In this view, synthesis of carbamates from $CO_2$ is a promising method because they are widely used for pharmaceuticals and dyes. Recently, catalytic conversion of $CO_2$-captured amines, which are easily synthesized from amines and $CO_2$ by chemical absorption, into urea derivatives was reported without high-pressure $CO_2$.[1-3] Yet, there is no report that has applied such substrates to catalytic production of carbamates. Here, we tackled carbamate synthesis from $CO_2$-captured benzylamine (BZA-CA) and methanol over $CeO_2$ (Scheme 1).

**Scheme 1**: Carbamate synthesis from BZA-CA.

**Experimental.** $CO_2$-captured benzylamine (BZA-CA) was synthesized from benzylamine (BZA) and $CO_2$.[2b] BZA-CA (10 mmol), $CeO_2$ (2 mmol), BZA (100 mmol), and methanol (1500 mmol) were put into an autoclave (190 mL) with a magnetic spinner. Reactants were heated at appropriate temperature, and then cooled to room temperature. Reaction solution was collected with methanol and analyzed by $^1$H NMR and GC-FID by using *tert*-butyl alcohol as an internal standard.

**Results and discussion.** The time courses of the BZA-CA conversion were investigated at four different temperatures. The low reaction temperatures such as 393 K and 403 K gave low reaction rate and thus required long reaction times to obtain moderate yields of the desired product. On the contrary, the yield and selectivity of carbamate was decreased at 423 K due to undesired side reactions. Therefore, the moderate reaction temperature of 413 K was optimum. Fig. 1 shows the time course at 413 K. The amount of target product (red circles) was rapidly increased until 12 h and then gradually decreased. At longer reaction times, the produced carbamate successively reacted with benzylamine to form dibenzylurea and *N*-methylbenzylamine, the latter of which was formed via the thermal reaction of the produced carbamate. The highest yield of the target product was 64% in 12 h at 413 K. The larger amount of methanol provided the higher carbamate yield, and 1500 mmol of methanol was the optimum amount. The $CeO_2$ catalyst was confirmed to be reusable for this reaction at least four runs. This catalytic system was also demonstrated to be applicable to the transformation of various $CO_2$-captured amines with methanol to corresponding carbamates in good yield and selectivity.

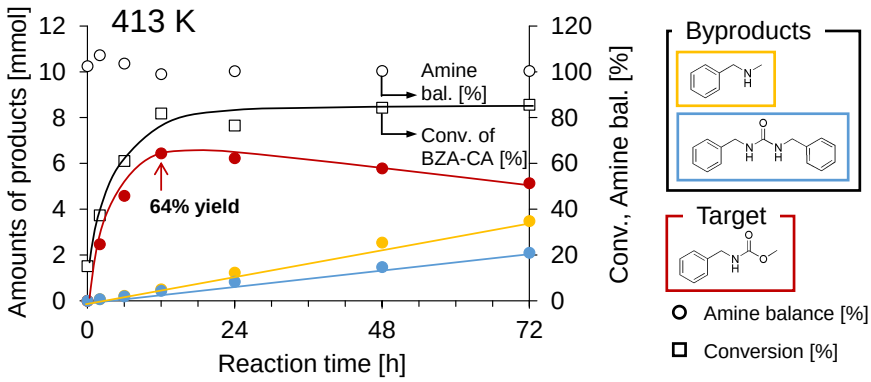

**Fig. 1**: Time course of carbamate synthesis from BZA-CA at 413 K. Conditions: BZA-CA 10 mmol, $CeO_2$ 2 mmol, BZA 100 mmol, MeOH 1500 mmol, Ar 1 MPa (at r.t.), 413 K, 0-72 h.

# Realistic conditions for Sabatier reaction: a promising alternative for cement industry decarbonization

D.Spataru[1,2*], A. Quindimil[1], C. Bacariza[2], J. Lopes[2], C. Henriques[2]

*[1]c[5]Lab - Sustainable Construction Materials Association, Linda-a-Velha, Portugal*

**Keywords:** Decarbonization, Cement, $CO_2$ valorization.

**Introduction.** Nowadays, reducing greenhouse gases (GHG) emissions, namely $CO_2$, is mandatory in order to reach the ambitious goal of zero net emissions, i.e., climate-neutrality by 2050. One of the sectors that has a greater impact on $CO_2$ emissions is the cement industry, responsible for 8-11% of the $CO_2$ global emissions. $CO_2$ conversion into synthetic fuels, integrated with renewable energy pathways and efficient catalytic systems, became both a challenge and an opportunity to decarbonize several industrial (e.g., cement) and energy sectors. Indeed, $CO_2$ hydrogenation using green hydrogen, produced via water electrolysis with renewable energy (Power-to-Gas), is one of the most promising $CO_2$ utilization routes. More specifically, the $CO_2$ hydrogenation to $CH_4$, which is a clean energy vector with high calorific value, is considered an effective solution to store the excess of renewable electricity in the natural gas grid. Therefore, the $CO_2$ methanation reveals high potential for the future towards a circular economy and low carbon society [1].

$CO_2$ methanation, also known as Sabatier reaction, requires the use of catalysts due to the stability of carbon dioxide molecules. Thus, active metals such as Ni, Ru or Rh and supports such as $Al_2O_3$, $SiO_2$, zeolites, hydrotalcites, $ZrO_2$, $CeO_2$, SBA-15 etc. have been widely analysed in the literature. Among them, the utilization of zeolite-based catalysts has been gaining attention, mainly due to their easily tuneable properties [2].

One of the main components of flue gases from cement industries is oxygen (10-15 vol. %), which cannot be 100 % removed in the previous capture/pre-treatment step. Therefore its influence on $CO_2$ methanation reaction was evaluated.

**Experimental/methodology.** In the present work, three materials (Ni/Zeolite, Ru/Zeolite and a Commercial methanation catalyst) were used as catalysts for $CO_2$ methanation. Several characterization techniques (XRD, TGA, $H_2$-TPR, $N_2$ adsorption) were employed before and after reaction. Additionally, catalytic tests (2.5 bar and 250-450 $^oC$) with and without $O_2$ (~4 vol. %) in the feed were performed.

**Results and discussion.** Results indicate that the nature of the active metal influences the resistance towards the presence of $O_2$. Ru exhibited a higher resistance towards oxidation, in accordance with literature, while the commercial sample presented the highest deactivation.

**Keywords:** $CO_2$ conversion, Nickel catalysts, Silica doping

**Introduction.** Nowadays, environmental pollution represents one of the main environmental problems. In this context, $CO_2$ emissions achieved the remarkable value of 36.3 Gt in 2021, increasing greenhouse gases concentration and correlated global warming [1]. A possible strategy to mitigate this environmental concern is the conversion of $CO_2$ into methane by the socalled Sabatier reaction using hydrogen arising from renewables. Conventional catalysts for this application are based on Ru- and Ni- [2-4]. Ni-based catalysts thanks to the Ni low cost and remarkable natural abundance, their high activity and robustness, represent a suitable choice for $CO_2$ hydrogenation reaction. Several supports have been investigated to enhance the catalytic performances. Among them $Al_2O_3$, $SiO_2$ [5], $TiO_2$, zeolites [6] are the most invesigated. However, Ni-based catalysts present several issues that need to be solved: *i*) low activity at low temperature, *ii*) low dispersion of the active phase and, *iii*) high deactivation manly due to particles sintering or coking. For these reasons and to make nickel-based catalysts suitable candidates at industrial scale, more efficient and competitive than noble metals-based catalysts more effort need to be done.

**Experimental/methodology.** In this work [7], we prepared a series of $Ni/Al_2O_3$ catalysts, with a Ni loading from 1 to 33 NiO wt.%, and we investigated the influence of the addition of $SiO_2$ (1 and 20 wt.%) both from the material and catalytic performances point of view. Catalysts were prepared by incipient wetness impregnation and both fresh end exhaust materials were characterized by means of BET, XRD, FE-SEM, EDXS, TPR, FT-IR, and UV-vis-NIR. Catalysts were tested in a tubular quartz reactor in diluted conditions and with a $H_2/CO_2$ ratio of 5. Reaction temperature has been varied in-between 523 to 773 K with 50 K temperature and backward to evaluate eventual short-term deactivation.

**Results and discussion.** Characterization results showed that $SiO_2$ support displayed a low Ni dispersion ability producing segregated NiO particles and a small amount of dispersed $Ni^{2+}$. While, increasing the Ni loading on the Si-doped alumina support a “surface spinel monolayer phase” is produced, and NiO is formed only when the support surface is completely covered by the spinel phase. Low loading Ni catalysts supported on $SiO_2$ showed moderate activity for rWGS (reverse Water Gas Shift) reaction and high CO selectivity, mainly due to nickel species dispersed in silica exchange sites. High Ni loading on the same support showed both rWGS and methanation activity but high short-term catalyst deactivation for methanation due to a coverage by a carbon veil on the large and segregated Ni metal particles. Ni dispersion, in the form of surface spinel phase, was higher on Ni-based alumina -rich carriers. These catalysts showed high metanation activity and selectivity to methane and short-term catalyst stability. The high methanation activity was attributed to small Ni clusters or metal particles interacting with alumina formed under reaction conditions. The 16 wt.% NiO supported on 1 wt.% of $SiO_2/Al_2O_3$ resulted to be the best catalyst by achieving a methane yield of 73% and a selectivity to methane around 100% at 673 K at atmospheric pressure and at a GHSV of 55000 $h^{-1}$.

**Keywords:** $CO_2$ utlization, Fe catalyst, inductive heating, reverse water-gas shift

**Introduction.**
$CO_2$ utilization to produce CO via the reverse water gas shift (rWGS) reaction has gathered increasing attention in recent years. Fe-based catalysts are an attractive option because of their high thermal stability and high oxygen mobility,[1] in addition to their abundance and low cost. The ferromagnetic properties of Fe and Fe oxide nanoparticles in a relatively large temperature range enable their use as inductive heaters, via hysteresis losses when placed under an alternating magnetic field. The approach of using Fe nanoparticles both for catalysis and heating is expected to bring advantages such as the elimination of heat transfer limitations, fast response and the possibility of using electricity from renewable sources [2].
This work studies the magnetic and catalytic properties of Co-doped Fe nanoparticles as potential bifunctional materials for the catalysis of rWGS reaction using induction.

**Experimental**
Fe-Co materials were synthesized by wet impregnation of commercial $SiO_2$ and γ-$Al_2O_3$ supports with a total metal loading of 20% wt. and different Fe:Co ratios. The metallic loading is adjusted to ensure that the material can reach self-heating properties up to the temperatures necessary for rWGS.
Structure and redox properties of the catalysts were studied by in-situ XRD and $H_2$ temperature-programmed reduction. The magnetic heating capability was measured by the hysteresis loop area after applying a magnetic field in a vibrating sample magnetometer (VSM) at temperatures relevant for the catalytic reaction. Activity measurements were carried out in a tube reactor (3 mm internal diameter) in the temperature range of 250 – 350 °C. Prior to the reaction, the catalysts were activated in flowing $H_2$ at two different temperatures (350 and 500 °C).

**Results and discussion.**
Doping Fe catalysts with Co was found to increase the rWGS activity while maintaining high CO selectivity (>90%). In addition, the high Curie temperature of Co aids the inductive heating properties of the FeCo-catalysts, as it is confirmed by magnetic hysteresis cycles measured at 500 °C. The temperature of activation in $H_2$ of Fe catalysts has a significant impact on both the catalytic activity and the heating capability of the material. This is attributed to the different particle size and metal/metal oxide phases present in the material after reduction. It was found that $SiO_2$ supported Fe particles are more reducible than those supported in $Al_2O_3$. Among the tested materials, FeCo supported on $SiO_2$ and reduced at 500°C, shows the highest heating potential, based on the large area of the hysteresis loop [3]. However, development of large Fe or FeCo particles (20 nm) results in low activity in rWGS. Conversely, γ-$Al_2O_3$ supported materials yielded smaller Fe particles (ca. 12 nm) after reduction at 500 °C, due to stronger metal-support interactions. Overall, Fe and Fe-Co particles supported on $Al_2O_3$ exhibit a good compromise between catalytic performance and magnetic heating capability, showing promise for their use as multifunctional materials for the heating and catalysis of $CO_2$ utilization via rWGS.

# Cobalt carbide catalyst development for $CO_2$ methanation: synthesis and characterization

S. Suman[1], A. Banerjee[1], L. Lefferts[1*]

[1]*University of Twente, Enschede, Netherlands*
[*]*Corresponding Author's E-mail address: l.lefferts@utwente.nl*

**Keywords:** $CO_2$ reduction, Transition metal carbides, Cobalt carbide, Heterogeneous catalysis

**Introduction.** The major energy demand of the world population is fulfilled by non-renewable resources of energy. These non-renewable resources cause pollution, global warming and lead to depletion of our natural resources [1]. So, there is a big need to find a solution to the pollutants that are emitted on burning of non-renewable resources. One of the major pollutants is $CO_2$ (a greenhouse gas) and there is a growing interest in the utilization of $CO_2$, as an abundant C1 source, to synthesize value-added chemicals and fuel ($CH_4$) by means of catalysis. Transition-metal carbides (TMCs) have a lot of potential in the field of catalysis, due to their exceptional electronic conductivity, remarkable chemical stability, and abundance of surface-active sites [2].

**Experimental/methodology.** Traditional synthesis techniques like carburization [3], the polyol method [4], ball milling [4] etc., are reported for $Co_2C$ synthesis. These kinds of methods often cause the carbon species, which are concentrated more on the particle surface than in the bulk, to form coke and polymerize at high temperatures, significantly obstructing the catalyst's active sites. Here, we present an efficient and reasonably straightforward method for synthesizing carbides using melamine as carbon source. $Co_3O_4$-$Al_2O_3$ was synthesized by incipient wet impregnation method and then reduced and carbonized in a tube furnace at 500 °C for 1 h in a $N_2$ atmosphere. By carbonizing Co-oxide/$Al_2O_3$ catalysts using melamine under various reaction conditions, a series of $Co_2C/Al_2O_3$ catalysts were synthesized.

**Results and discussion.** It is seen that due to a strong thermodynamic driving force Co-oxides transform into carbides, thermodynamically driven by formation of stable CO and $H_2O$ as by-products. Characterization results obtained with scanning electron microscopy (SEM), X-ray diffraction (XRD), X-ray photoelectron spectroscopy (XPS), and Raman analysis, were used to examine the catalysts' physicochemical features. Changes in the carbonization temperature led to the creation of cobalt phases with varying composition. The influence on the catalytic performance in $CO_2$ reduction will be reported and the structure-performance relationship will be discussed

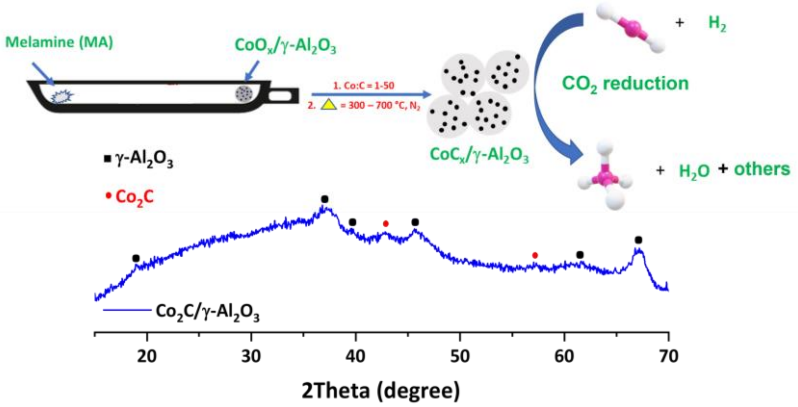

**Figure 1. Graphical representation of $Co_2C/\gamma$-$Al_2O_3$ synthesis for $CO_2$ reduction to methane**

**Keywords:** Dry reforming of methane (DRM), dealuminated Beta, coke deposition

**Introduction.** Global warming and climate change caused by greenhouse gas emissions from human activities have become serious issues. Effective utilization of $CO_2$, the largest emission of greenhouse gases, has been the focus of much attention in recent years. One promising method is dry reforming of methane (DRM), a catalytic process that converts $CH_4$ and $CO_2$ into valuable syngas (CO and $H_2$) with a $CO/H_2$ molar ratio of 1:1. The syngas can be converted into a variety of feedstock chemicals used in the petrochemical industry. However, since this reaction is endothermic, operating conditions at high temperatures (700-1000 $^oC$) are required to achieve a high conversion efficiency of $CH_4$ and $CO_2$ [1]. Ni-based catalysts are considered the most promising for DRM reactions because they exhibit high DRM activity even at low reaction temperatures, are abundant in resources, and are relatively inexpensive. However, a major drawback of Ni-based catalysts is a coke deposition on the catalysts, which leads to catalyst deactivation. As a solution, we paid attention to Cr species interacting with zeolites because our previous work revealed that the Cr species improved the coke deposition resistance [2]. Herein, we impregnated Ni and Cr on a dealuminated Beta zeolite and investigated the effect of Cr on the amount of coke deposition after DRM reactions.

**Experimental/methodology.** The dealumination process was achieved by treating commercial Beta with 35 wt% nitric acid (the mass ratio of nitric acid and zeolite was 10:1) at 393 K for 24 h. The resultant powder was washed with deionized water. After drying at 363 K, the powder was calcined at static under air at 823 K for 5 h. The dealuminated Beta was impregnated with an aqueous solution of $Cr(CH_3COO)_3$, containing the amount of chromium needed to obtain the desired chromium content in the samples (Cr(x)/deAl-Beta), where x means the mass content of $Cr_2O_3$. After impregnation, the samples were dried at 363 K and calcined under air at 823 K for 5 h. The Cr(x)/deAl-Beta was impregnated with an aqueous solution of $Ni(NO_3)_2 \cdot 6H_2O$ similarly with the impregnation of Cr. The obtained samples were donated as Ni/Cr(x)/deAl-Beta. As a comparison, the only Ni-loaded sample without Cr (Ni/deAl-Beta) was prepared by a similar impregnation method using dealuminated Beta and an aqueous solution of $Ni(NO_3)_2 \cdot 6H_2O$. DRM reactions were carried out at 873 K for 5 h under the mixed gases flow of $CO_2$ and $CH_4$ (v : v =1 : 1) with a total flow rate of 40 sccm using 0.05 g of catalysts. The amounts of carbon deposition for spent catalysts were analyzed by TGA.

**Results and discussion.** No significant decrease in CO yield was observed by adding Cr. We summarized the amount of coke deposition for spent catalysts in Fig. 1. The spent Ni/deAl-Beta catalyst has the highest coke deposition (286 %). In contrast, coke deposition was lower for the Cr-doped samples. Furthermore, in the Ni/Cr(2.0)/deAl-Beta, the smallest amount of deposited coke was observed (1.1 %). XRD measurements confirmed the *BEA-type derived peaks in all synthesized samples. These samples showed a shift in the peaks which are characteristic of *BEA-type zeolite compared to the commercial beta. From UV-vis spectra, peaks derived from Cr (VI) were detected in all Cr-doped samples. These results suggest that Cr (VI) in the framework of dealuminated Beta contributed to the suppression of coke deposition in the DRM reaction.

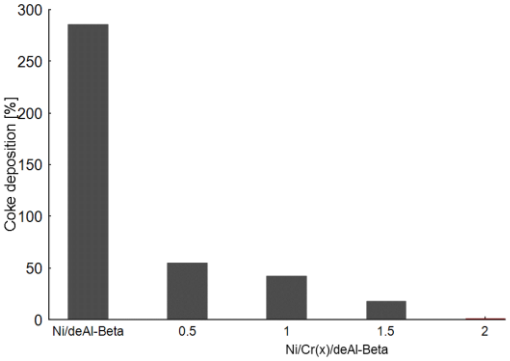

**Fig. 1** The amount of coke deposition for spent catalysts.

**Keywords:** $CO_2$ conversion, Photo-Electrocatalysis, Layered Double Hydroxides, solar fuels

**Introduction**

Photoelectrochemical $CO_2$ valorization is a sustainable and promising way to reduce carbon dioxide concentration in atmosphere through its capture and conversion into fuels and chemicals. Tremendous efforts have been already made to identify the best materials and device configuration for efficient $CO_2$ reduction reaction ($CO_2$RR) in Photoelectrochemical Cell devices (PEC) [1]. Layered Double Hydroxides (LDHs) anionic clays represent an appealing option for such application thanks to their good affinity for $CO_2$ and tunable chemical composition [2]. This aspect allows to modify morphological, physical-chemical, and electrochemical properties of the material to provide good catalytic activity.

**Experimental/methodology**

Ni, Cu and Fe containing LDHs films supported on a conductive glassy substrate (FTO) were produced through screen printing deposition of LDH powder-based ink. Bulk LDHs have been synthetized by coprecipitation method as described in a previous work of our group [3]. The photoelectrodes have been characterized with different techniques (XRD, SEM, UV-Vis, cyclic voltammetry (CV), Linear Sweep Voltammetry (LSV), Electrochemical Impedance Spectroscopy (EIS) and Mott-Schottky analysis. Photoelectrocatalytic $CO_2$ reduction tests were performed in a three-electrodes PEC cell equipped with a quartz window.

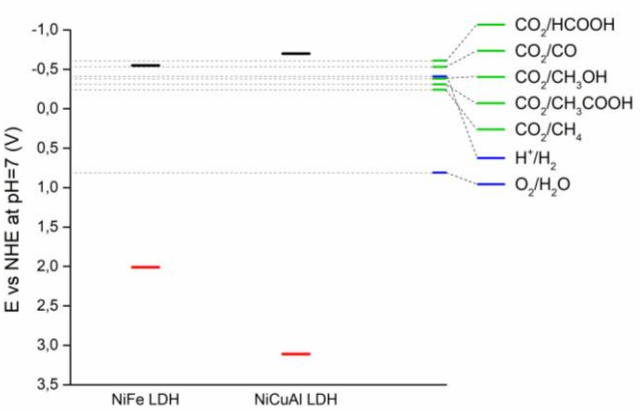

**Figure 1** - Band-edge positions of samples based on LDHs relative to standard potential of $CO_2$RR of interest for solar fuels production.

**Results and discussion**

XRD and SEM analysis underlined the morphological homogeneity of the samples, both powder and films, as well as the presence of the desired LDH phase. Band gap and electronic energy levels' position of the samples have been defined and confirmed compatible with standard potentials of $CO_2$RR thanks to UV-vis DRS and Mott-Schottky tests respectively (Figure 1). The characterization of the electron transfer ability, charge accumulation capability, and materials conductivity of the LDHs by CV, EIS and LSV showed that both NiFe 3:1 LDH and NiCuAl 3:1 LDHs provided an appreciable cathodic current density starting at -1.25 V vs Ag/AgCl, resulting promising materials for PEC electrodes. Furthermore, the film based on NiCuAl LDH showed a good adherence to the substrate and fast charge mobility as well as a lower resistance towards charge transfer at the electrode/electrolyte interface.

These properties were linked to the photoelectrocatalytic activity. Indeed Ni, Cu, Fe containing LDHs demonstrated to be active in photoelectrochemical $CO_2$RR with higher selectivity for C-containing products i.e., formic and acetic acid, over hydrogen evolution at relatively low potential of – 0.8 V vs NHE (pH=7), while $H_2$ production was the favored when higher potential was applied i.e., – 1.3 V vs NHE (pH=7).

**Introduction.** Methanol as an energy vector has experienced increasing interest due to the possibility to produce $CO_2$-neutral methanol from captured $CO_2$ and $H_2$ generated from electrolysis using sustainable electricity. This way it is possible to reduce $CO_2$ emissions related to conventional methanol production based on fossil feedstocks.
For Cu-catalyzed hydrogenation of $CO_2$ to methanol, the reaction rate and the Cu surface area are linearly correlated [1], which indicates that the reaction occurs on the Cu surface. However, the industrially applied ZnO-support raises the turnover frequency per Cu surface atom by an order of magnitude and this essential metal-support synergy is not fully understood. Kuld et al. [2] found that $H_2$ pre-treatment of a $Cu/ZnO/Al_2O_3$ catalyst accelerated the reaction rate and suggested Zn-Cu surface alloy formation as the cause of this effect. This proposal seems to be at odds with the observation that metallic Zn is found to be oxidized in $CO_2$-containing reaction gas [3-4]. The aim of this work is to enhance the understanding of the active site of the industrial $Cu/ZnO/Al_2O_3$ catalyst by investigating how the catalyst is affected by pre-treatments with CO or $H_2$.

**Experimental/methodology.** The $Cu/ZnO/Al_2O_3$ catalyst was prepared by co-precipitation from metal nitrate precursors and sodium carbonate as the precipitating agent at T = 65 °C and pH = 6.5, followed by drying overnight at around 50 °C and calcination at 330 °C. The catalyst is loaded in a flow reactor setup described elsewhere [5]. The catalyst was then subjected to pre-reduction (with either 5 % $H_2/N_2$ or 10% CO/Ar) followed by a pre-treatment in different $H_2$ partial pressures. Raney Cu (referred to as pure Cu without support) was tested similarly to study the effect without support interactions. The pre-treated catalyst was tested in methanol synthesis using a synthesis gas flow rate of 200 NmL/min with a composition of $H_2/CO_2$ = 80/20 at 135 °C and a pressure of 1 atm. Additionally, TPD experiments, $N_2O$ adosprtion and infrared spectroscopy were conducted to determine the amount of adsorbed $H_2$, Cu surface area and to study how the catalysts and adsorbates are affected by the pre-treatment, respectively.

**Results and discussion.** Figure 1 illustrates that the pre-reduction atmosphere has a major impact on the catalytic activity. Pre-treatment of the reduced catalyst with varying $H_2$ pressures prior to catalytic tests show a beneficial effect on the methanol reaction rate. However, this effect is not primarily due to a reduction of the support, since pre-reduction in a more reducing gas (CO vs $H_2$) leads to an inferior catalytic performance (see Figure 1). The reasons behind these effects are elucidated from catalytic and spectroscopic investigations.

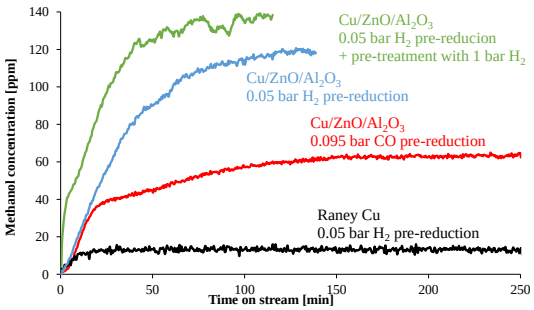

**Figure 11 The methanol effluent concentration as a function of time on stream at $H_2/CO_2$ = 4/1, 135 °C, 1 atm for differently pre-treated catalysts.**

**Keywords:** machine learning, $CO_2$ hydrogenation, reverse water-gas shift, catalysis informatics

**Introduction.**

Recent revolution in data science could significantly accelerate the pace of new catalyst development and greatly impact the on-going catalysis research.[1] Machine learning (ML), a sub-field of data science, would play a central role in this paradigm shift. Despite having already seen proof-of-concept examples that artificial intelligence (AI) can reduce the time and costs involved in catalyst development, most research has been directed toward the resolution of benchmark problems, but truly novel compounds and materials have rarely been discovered. This is due to one of the most common limitations of ML—an assumed inability for models to extrapolate, i.e. to identify extraordinary materials beyond those present in the training data set. In materials and catalysis informatics, we often desire to use ML models to find entirely new classes of materials and catalysts, with heretofore-unseen combinations of elements.

In this context, our group has developed a new ML approach that uses elemental features as the input representations, rather than inputting the catalyst compositions directly.[2-4] In our method, the elemental composition ratios are multiplied by elemental descriptors such as electronegativity and atomic radius, which are unique for each element. This ML method has the potential to guide catalyst design and discovery in areas where limited catalyst composition overlap exists, even for elements previously unseen in the given dataset. This will enable us to make extrapolative prediction beyond the training data.

**Results and discussion.**

In this study, we have applied this ML approach to develop multi-elemental catalysts based on supported Pt as an active metal and $TiO_2$ as a support for the reverse water-gas shift (RWGS) reaction.[5] Our ML model efficiently spot active catalyst candidates with high predictive accuracy and identified multi-elemental catalysts which exhibited the best CO formation rates compared to any reported RWGS performances at $T \leq 250$ °C with 100% CO selectivity. The composition of the most optimal catalyst discovered by this approach was Pt(3)/Rb-Ba-Mo-Nb/$TiO_2$. Notably, Nb was not included in the original dataset, and the catalyst composition identified would be hardly predictable even by human experts.

**Keywords:** Non-thermal plasma, Plasma catalysis, $CO_2$ hydrogenation

**Introduction**

$CO_2$ hydrogenation to CO, also called the reverse water gas shift (RWGS) reaction, has received increasing interest recently, especially in conjunction with the Fischer-Tropsch process to produce hydrocarbon fuels. However, RWGS is endothermic and thus is thermodynamically favorable at higher temperatures. Non-thermal plasma (NTP) is an emerging technology for $CO_2$ valorization under mild conditions [1-3]. In addition, coupling NTP with catalysis (plasma catalysis), has great potential to create a synergistic effect due to plasma-catalyst interactions [4], offering an effective way for the selective production of chemicals and fuels from $CO_2$. However, plasma-catalytic chemical reactions (*e.g.*, $CO_2$ hydrogenation) are a complex chemical process. The exact reaction pathways in the plasma-catalytic $CO_2$ hydrogenation have not been fully explored, particularly the plasma-assisted reactions on surface of the catalyst. In this work, the plasma-catalytic hydrogenation of $CO_2$ over ZnO and Pd/ZnO was investigated using *In situ* plasma/FTIR combined with online MS and OES analysis to understannd plasma-assisted gas-phase and surface reactions.

**Experimental/methodology**

Plasma-catalytic $CO_2$ hydrogenation was conducted in a dielectric barrier discharge (DBD) plasma reactor. A mixture of $H_2$ and $CO_2$ with an $H_2/CO_2$ ratio of 3:1 was used. The catalyst (0.5 g) was packed into the entire discharge gap and was reduced by $H_2$/Ar mixed gas ($H_2$/Ar = 1:9) at 400 $^oC$ for 4 h before the reaction. All the electrical signals were recorded using an oscilloscope (Tektronix DPO 3034).

**Results and discussion**

The conversion of $CO_2$ and $H_2$ was 21.3% and 9.3%, respectively, in the plasma reaction with no packing. However, placing ZnO in the DBD did not enhance the conversion of $CO_2$ (20.2%) and $H_2$ (8.4%). In contrast, the combination of DBD with 2 wt.% Pd/ZnO notably improved the conversion of $CO_2$ and $H_2$ to 36.7% and 16.9%, respectively. Moreover, in comparison to the plasma only system, the incorporation of plasma with ZnO or Pd/ZnO showed a similar CO selectivity (93.2-96.6%). *In situ* spectroscopy techniques including *in situ* FTIR, online MS and OES diagnostics combined with catalyst characterization and kinetic analysis were used to understand the role of Pd/ZnO in the plasma-catalytic $CO_2$ hydrogenation. In the plasma-catalytic reaction using Pd/ZnO, the hydrogenation of adsorbed $CO_2$ on Pd/ZnO significantly contributes to the enhanced $CO_2$ conversion, which can be attributed to the formation of a $ZnO_x$ overlay as a consequence of the SMSI between ZnO and Pd, and the presence of abundant H species (evidenced by plasma-assisted $H_2$-TPD analysis) on the Pd/ZnO surface due to $H_2$ activation by Pd NPs. However, without Pd loading, the hydrogenation of surface adsorbed $CO_2$ on the ZnO surface was limited due to the absence of the SMSI and the lack of active H species formed on the ZnO surface. The splitting of $CO_2$ to CO is believed to make major contributions to the conversion of $CO_2$, in both the gas phase and on the ZnO surface during the plasma-catalytic $CO_2$ hydrogenation over ZnO. This work provides new insights into the reaction pathways for plasma-catalytic chemical reactions, particularly plasma-assisted surface reactions.

**Keywords:** $CO_2$ capture, modified mesoporous silicas, DOPO derivative

**Introduction.** The large amounts of carbon dioxide released into the atmosphere by human activities (greenhouse effect) is considered one of the great challenges of the twenty-first century [1]. Therefore, the $CO_2$ controlling emission, capture, and recycling attract worldwide attention, which reveals a strong prospect for greenhouse level decrease. The adsorption approach is one of the most promising methods due to its high selectivity and low energy penalties [2]. The mesoporous silica materials are widely studied sorbents. They possess a large number of silanol groups, which is a key precondition for suitable functionalization with different organic molecules, which improve silica's performance in $CO_2$ adsorption. Mesoporous silicas are extensively used for amine immobilization by covalent bonds [3] or hydrogen bonds [4] and used for $CO_2$ capture and separation due to the large pore volume, and high specific surface area.

**In this study,** mesoporous KIT-6, SBA-15, and SBA-16 silicas modified with DOPO derivative (DAPTES)-were developed and studied as efficient adsorbents of $CO_2$.

**Experimental/methodology.** KIT-6, SBA-15, and SBA-16 were prepared by hydrothermal synthesis. The post-synthesis procedure for DAPTES-modified mesoporous KIT-6, SBA-15, and SBA-16 silicas was developed. The materials were characterized by NMR spectroscopy, ATR-FTIR spectroscopy, $N_2$ physisorption. $CO_2$ adsorption experiments were performed in dynamic and equilibrium conditions.

**Results and discussion.** The DAPTES-modified mesoporous silicas with different pore structures, 2D SBA-15 and 3D SBA-16, and KIT-6, were successfully synthesized by a simple two-step post-synthesis procedure. The preservation of mesoporous structure during the modification procedure was detected for the obtained new mesoporous materials. Higher capacity for $CO_2$ adsorption was determined for all modified materials depending on the structural peculiarities of the supports used in comparison to the initial ones. The higher $CO_2$ adsorption capacities were detected for DAPTES-modified silicas in the experiments with 3 vol.% $CO_2$ plus 1 vol.% water vapor due to the facilitated formation of chemisorbed $CO_2$ in the form of a bicarbonate ion (HO-COO-) in the presence of water as well as the presence of physisorbed $CO_2$. The chemisorption of $CO_2$ for DAPTES-modified silicas was assumed based on the calculated heats of adsorption for the studied materials. The DAPTES-modified mesoporous SBA-15 silica showed the highest adsorption capacity for $CO_2$ (3.9 mmol/g). The total $CO_2$ desorption from the modified materials was achieved at 80°C.

**Keywords:** Methanol, $CO_2$ hydrogenation, *operando* - DRIFTS, SSITKA, $CeO_2$

**Introduction.** At present, there is no consensus about the reaction mechanism for the formation of methanol from $CO_2$ on Cu catalysts promoted by $CeO_2$. On one hand, there are authors who propose that the interfacial site between Cu and Ce is able to adsorb $CO_2$ and make it react towards methanol at a high rate [1]. A second group claims that $CeO_2$ would have no effect and that $Cu/CeO_2$ catalysts are kinetically equivalent to $Cu/SiO_2$ [2]. This study focuses on elucidating the reaction mechanism of the $CO_2$ hydrogenation on Cu-based catalysts promoted by $CeO_2$, as well as the structural and kinetic effect of $TiO_2$.

**Experimental/methodology.** $CuCeO_x/TiO_2$ and $CuCeO_x/SiO_2$ (6% wt. Cu) catalysts were synthesized by wetness impregnation with different Ce/(Cu + Ce) molar ratios. The catalytic activity was measured in a fixed bed reactor at 8, 30 and 50 bar. Catalysts were characterized through XRD, *quasi-in situ* XPS, TEM, CO adsorption and $H_2$-TPR. *Operando* – DRIFTS, $H_2/D_2$ isotopic exchange, product feeding, KIE ($D_2/H_2$) and DRIFTS/MS – SSITKA ($^{12}CO_2/^{13}CO_2$) analyzes were carried out.

**Results and discussion.** The characterizations showed that $TiO_2$ improves the dispersion of Cu and evidenced a SMSI between Cu and $TiO_2$. $CeO_2$ promotes methanol synthesis, which is important for low $CeO_2$ concentrations and shows an asymptotic behavior in terms of the apparent activation energy (figure 1-a) and other parameters ($CH_3OH$ rate, conversion, apparent reaction order). This behavior occurred regardless of the support and pressure, and it is attributed to the generation of a new interfacial active site between Cu and $CeO_2$ and the formation of a greater number of sites for higher promoter concentrations. It was evidenced that the production of CO is sensitive to the catalyst support while $CH_3OH$ is independent of it (figure 1-a). Indeed, $TiO_2$ increases methanol selectivity by inhibiting the formation of CO. Consistently, it is suggested that the active site for CO would be the copper surface and, due to the SMSI, these sites would be affected by $TiO_2$. The spectroscopic and DRIFTS/MS – SSITKA studies allowed to clarify that (i) formates are the main intermediates in the methanol pathway (figure 1-b), (ii) there are formates adsorbed on copper (spectators) and interfacial sites (active) (figure 1-b) and (iii) CO would be synthetized assisted by hydrogen, likely via carboxyl. From this, a consistent macrokinetic model was derived.

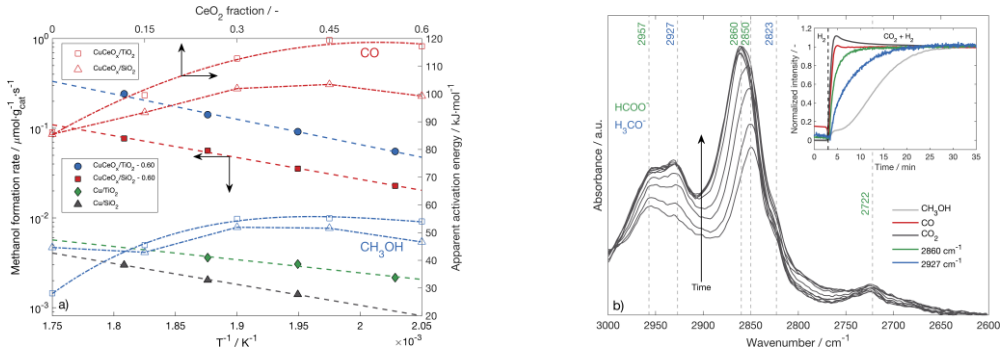

**Figure 1.** a) Arrhenius plot for 4 different catalysts (P = 8 bar, 20 mL/min) and apparent activation energy as a function of $CeO_2$ content and support. b) *operando* – DRIFTS over $CuCeO_x/TiO_2$ – 0.60 following the switch 20%$CO_2$/60%$H_2$ →20%He/60%$H_2$, P = 6 bar, T = 240°C, 25 mL/min.

# Supported metal oxide materials for plasma-catalytic dry reforming of methane

Valeria Vermile[1*], Sander Bossier[1], Bram Seynnaeve[2], Jeroen Lauwaert[2], An Verberckmoes[2], Vera Meynen[1]

[1]*University of Antwerp, Wilrijk, Belgium*

**Keywords:** plasma catalysis, dry reforming of methane, $CO_2$ conversion, dielectric barrier discharge.

Plasma catalysis is gaining increasing interest for various gas conversion applications, such as $CO_2$ conversion into value-added chemicals and fuels, $CH_4$ activation into hydrogen, higher hydrocarbons or oxygenates, and $NH_3$ synthesis [1]. Plasma is an electrical energy driven process, important for the worldwide transition to renewable energy. Its highly energetic, collision-rich environment, is able to activate relatively stable compounds at milder and more convenient conditions (ambient pressure and near ambient temperature) than for classical thermal processes [2]. However, plasma catalysts currently have the drawback of not being selective and still requiring progress in energy efficiency. The interactions between plasma and catalyst are complex as the chemical and physical properties of both can be modified by the presence of each other. The catalyst influences the plasma characteristics in a physical way (e.g., through changes in electric field, discharge, sorption processes), and this has an impact not only on selectivity, but also on conversion [3]. The key challenge is then to design cost-effective, highly active, selective and stable catalysts tailored to the plasma environment.

In this context, we evaluate the impact of different spherical γ-alumina packing materials activated with different metal oxides (10%) on dry reforming of methane (DRM) to understand the influence of the metal oxide deposited on selectivity and conversion. The reaction was performed in a packed bed DBD (dielectric barrier discharge) plasma reactor with a 4.44 mm discharge gap size, setting the experimental conditions at 15 W, 3 kHz and a residence time of 40 s. All catalysts were synthesized using a dry impregnation procedure [4]. γ-$Al_2O_3$ microspheres with a diameter of 1.8 mm were used as support and different metal oxides were selected as active elements. The catalysts were dried by removing water overnight under vacuum at 150°C. The $CO_2$, $CH_4$ and total conversion are clearly influenced by the presence of metal oxides on the γ-$Al_2O_3$ surface. Interesting results have been obtained regarding the selectivity of the different materials.

**Keywords:** Solution combustion synthesis, reverse water-gas shift, Fischer-Tropsch

**Introduction.** In a hope to contain the negative effects of the climate change several technologies are being developed to capture carbon dioxide and use it as a feedstock for synthethic fuels and other useful value added chemicals [1]. One of the key reactions in CO2 activation is reverse water-gas shift reaction (RWGS). This reaction can be utilized effectively to convert carbon carbon dioxide to synthesis gas, which is a key feedstock for the Fischer-Tropsch (FT) process for hydrocarbon production [2].

In this study solution combustion synthesis (SCS) will be used to produce catalysts for RWGS reaction. Laboratory scale tests will be conducted with the SCS catalysts to determine if there is an advantage in SCS catalysts versus traditional conformated active metal catalysts in activity, adsorption, resistance to deactivation or applicability for interesting reactor geometries such as microchannels or metallic substrates. The SCS method is energy and time efficient way to produce porous nano powders that do not suffer from non-uniformity as the self sustaining exothermic reaction produces thermodynamically favourable shapes [2].

**Experimental/methodology.** The SCS method is based on self-sustained exothermic reactions that produce highly porous materials [2]. The method utilizes a fuel, usually an organic such as glycine or urea, and an oxidizer in the form of metallic nitrates [2], that in our case also contain the active metals of the catalyst that is produced. The fuel and the oxidizer are heated in an aqueous solution to 100-200 $^{o}$C until the water has evaporated and the dry reactants heat further and start the reaction [3]. The SCS catalyst is tested with RWGS reaction in powdered form as well as coated on substrates. The results of the powdered SCS catalysts made at CSIC are compared to conformated catalysts made at VTT.

Catalyst testing is done with bottled reactant gases (CO2 and H2) that are fed into a reactor heated with an oven. Reaction products and the unreacted gases are analyzed with gas chromatographs and online gas analyzers in order to calculate the mass balances and conversion.

**Results and discussion.** The experiments are ongoing so the results will be released at the Europacat2023 seminar. The results of this work will deepen the understanding of the effect of the highly porous structure of the SCS catalyst powder on the RWGS reaction. The data will be used for scaling a pilot sized RWGS reactor coupled to a FT unit called mobile synthesis unit (MOBSU).

**Keywords:** non-thermal plasma, $CO_2$ hydrogenation, methanol

**Introduction.** $CO_2$ hydrogenation to methanol is a promising process for $CO_2$ utilization for a sustainable carbon recycling process. Conventional thermocatalytic conditions for this process are energy intensive, requiring high temperatures (200-300 °C), and high pressures (30-100 bar) to form methanol [1]. In contrast, non-thermal plasma can activate $CO_2$ effectively under mild conditions (e.g., room temperature and atmospheric pressure) [2]. However, the synergistic effects between plasma and catalysts, the nature of the active species and the mechanistic understanding of $CO_2$ hydrogenation in plasma catalysis are still lacking. In this work, we focus on $CO_2$ hydrogenation into methanol at room temperature and atmospheric pressure by using plasma catalysis over ZSM-5 zeolite supported Cu and CuZn catalysts. we have shown that comparing Cu catalyst, CuZn-based catalysts have a promoting effect on the methanol formation under plasma conditions.

**Experimental/methodology.** The catalytic activity, selectivity and stability of the developed catalysts were assessed in a dielectric barrier discharge flow reactor. Aluminium foil was wrapped around outside of the quartz tube was used as the high voltage electrode, while a stainless-steel rod placed in the centre of the quartz tube was used as the ground electrode. The outlet gas composition was analysed by a two-channel on-line gas chromatography.

**Results and discussion.** For Cu/ZSM-5 catalyst, highest $CO_2$ conversion of 12% with a 18% methanol selectivity was achieved at NTP power of 2.5W. This demonstrated that NTP catalysis can form methanol at atmospheric pressure and room temperature. Comparatively, the NTP system using the packing of CuZn catalysts showed the higher $CO_2$ conversions and selectivity to methanol regardless of plasma energy, indicating that Zn addition promoted $CO_2$ conversions to methanol. For example, the CuZn/ZSM-5 (Cu/Zn=1) catalyst showed the higher activity with the highest $CO_2$ conversion of 14.5% and selectivity of methanol of 36% achieved at power of 2.5 W. $H_2$-TPR and $CO_2$-TPD showed that Zn addition improved the reductivity of Cu and affect the $CO_2$-Cu interactions, which may affect the catalytic performance for $CO_2$ hydrogenation. Additionally, in situ DRIFTS for $CO_2$ hydrogenation over Cu/ZSM-5 and CuZn/ZSM-5 catalysts shows similar active intermediates for methanol, indicating that Zn addition did not affect the pathway for $CO_2$ hydrogenation to methanol.

# Analysis of photocatalytic $CO_2$ reduction by machine learning

Dilara Saadetnejad, Burcu Oral, Elif Can, Ramazan Yıldırım*

*Boğaziçi Univeristy, Istanbul, Turkey*
**yildirra@boun.edu.tr*

**Keywords:** Photocatalytic $CO_2$ reduction, Band gap prediction, Machine learning

**Introduction.**

Methane and $CO_2$ are considered as effective greenhouse gases causing global warming. It is important to reduce the $CO_2$ emission or to utilize $CO_2$ more effectively to decrease the adverse effects on climate. Reducing $CO_2$ by photocatalysis is a cost-effective way to convert $CO_2$ into valuable products since it uses solar energy. Methanol, methane, carbon monoxide, and hydrogen are the main products in $CO_2$ photoreduction, whereas formic acid, formaldehyde, ethanol, acetic acid, acetaldehyde, ethylene, and ethane may also be produced. This work analyses gas and liquid-phase photocatalytic $CO_2$ reduction using machine learning. The band gap of the photocatalysts and the total gas production rate were predicted using random forest and decision tree algorithms.

**Experimental/methodology.**

The dataset for liquid and gas phase $CO_2$ reduction was collected from 80 articles that were published between 1993-2019. There were 549 data points of which 268 cases were for the gas phase and 281 cases for liquid phase processes. The collected input variables (total of 21) included details about the semiconductor, co-catalyst, their preparation methods, and operation conditions. Train-test split ratio of 80-20% was determined to be optimum and hyperparameter tuning of algorithms was done using five-fold cross-validation. Random forest algorithm was used to predict band gap values of missing cases. The minimum number of instances in a terminal node (*nodesize*) and the number of trees (*ntree*) were used as hyperparameters, and the optimum values were found to be 5 and 75 respectively. Decision tree clasification was used to predict the conditions leading low and high gas production rates. *Minsplit* and *complexity parameter* were chosen as hyperparameters and optimum values were found to be seven and 0.01 respectively.

**Results and discussion.**

The descriptive analysis of the dataset showed that the main products of the gas phase are $H_2$, CO, and $CH_4$ while $CH_3OH$ production is more dominant in the liquid phase. The hydrogen production in the gas phase is higher under visible light and also CO production is favored. The most commonly used semiconductor is $TiO_2$ followed by $C_3N_4$ and CdS; the most frequently used co-catalysts are Cu, Ag and Pt. The random forest model for band gap prediction had high prediction power with RMSE of 0.12 and 0.15 for train and test sets respectively. [Figure 1) Decision tree models for the total gas production rates were also successful; 80% and 79% accuracies were achieved for training and testing respectively for the gas phase process.

# Analysis of Catalytic $CO_2$ Methanation by Machine Learning

B. Yılmaz, B. Oral, R. Yıldırım*

*Boğaziçi University, Department of Chemical Engineering, Istanbul, Türkiye*
**yildirra@boun.edu.tr*

**Keywords:** Catalytic $CO_2$ methanation, Machine learning, Random forest, $CO_2$ conversion prediction

**Introduction.** Carbon dioxide is a major greenhouse gas that causes global warming. Great efforts have been made to diminish $CO_2$ emissions generated by industry [1]. Catalytic $CO_2$ methanation process is one of the promising solutions which constitute a route to eliminate $CO_2$ release into atmosphere by converting it to valuable energy carrier $CH_4$ [2]. Methanation, discovered by Sabatier in 1902, includes the following catalytic reactions in the presence of excess $H_2$[3].

$$CO_2 + 4H_2 \leftrightarrow CH_4 + 2H_2O \qquad \Delta H_{298K} = -165\ \text{kJ mol}^{-1} \qquad (1)$$

$$CO + 3H_2 \leftrightarrow CH_4 + H_2O \qquad \Delta H_{298K} = -206\ \text{kJ mol}^{-1} \qquad (2)$$

$CO_2$ is a highly stable compound which needs high temperatures to be activated although the Sabatier reactions are favored in ambient conditions [4]. Hence, the challenge of methanation process is to identify optimum operating conditions and proper catalysts for high yield and selectivity for methane [5]. In this context, numerous studies have been performed to design catalysts with high activity at optimum conditions. As a result, a good deal of experimental data has been accumulated in methanation literature, which can be analyzed by machine learning tools to find a reliable pathway that leads to high $CO_2$ conversion to methane.

The aim of this work is to extract knowledge on the catalytic $CO_2$ methanation from published articles in literature and to predict the $CO_2$ conversion. The significant variables were identified by Boruta analysis and the predictive model for $CO_2$ conversion was developed using random forest algorithm.

**Experimental/methodology.** $CO_2$ methanation dataset, consists of 4051 data points from 527 distinct experiments, was created using 100 papers that were published between 2011-2022. There were 23 descriptors related to catalyst contents, preparation methods, and reaction conditions. The data was split into training (80%) and testing (20%). The 5-fold cross validation procedure was used for hyperparameter optimization. Random forest algorithm was used to predict $CO_2$ conversion, and Boruta analysis was performed to determine the significant variables. The optimum values for the number of trees (ntree) and the minimum number of instances in a terminal node (nodesize) were found to be 220 and 5 respectively.

**Results and discussion.** The random forest model successfully predicted the $CO_2$ conversion with the training and testing root mean square error (RMSE) of 6.4 and 12.7 respectively; $R^2$ was 0.95 for training and 0.87 for testing (Figure 1). The validation procedure was also performed succesfully by employing the model to obtain $CO_2$ conversion values with respect to operating temperatures for each experiment in test data and comparing them with the experimental data reported in publications. Reaction temperature was identified as the most significant variable in $CO_2$ conversion prediction, while the catalyst properties such as support type, preparation method, metal loading, and metal base type were also important in $CO_2$ conversion.

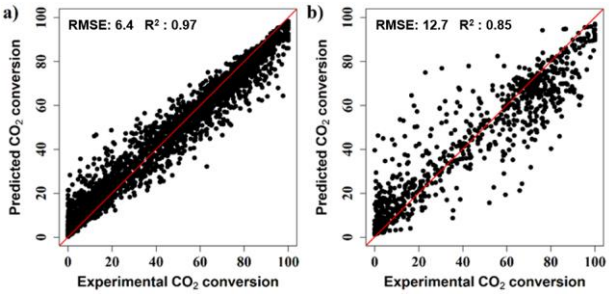

**Figure 1. Predicted vs real conversion results from random forest model for a) training b) testing sets.**

# Template-free synthesis of mesoporous amine-bridged organosilicas for $CO_2$ valorization into cyclic carbonates

T. Q. Bui*, Z. Moravec, P. Machac, A. Styskalik

*Department of Chemistry, Faculty of Science, Masaryk University, Brno, Czech Republic*
**Corresponding Author: 247831@mail.muni.cz*

**Keywords:** mesoporous amine-bridged organosilica, non-hydrolytic sol-gel, $CO_2$ utilization, cyclic carbonate

**Introduction.**

Synthesis of cyclic carbonates from $CO_2$ and epoxides using heterogeneous catalysts is one of the most promising routes for chemical fixation of $CO_2$ on industrial scale due to 100% atom economy and ease of product separation. Mesoporous amine-functionalized silicas could act as potential catalytic materials for this reaction as they are low-cost and enable high accessibility of active Lewis basic N-sites for $CO_2$ activation [1]. In addition, these solid amines are well-known in $CO_2$ capture and utilization studies due to their high $CO_2$ selectivity and uptake even at low $CO_2$ concentration as in ambient air [2,3].

**Experimental/methodology.**

Herein, we report a template-free, one-pot preparation of mesoporous amine-bridged organosilicas via non-hydrolytic sol-gel reactions between 2 silicon precursors ($SiCl_4$, $Si(OAc)_4$) and 4 aminosilane precursors (3-aminopropyl)trimethoxysilane, bis[3-(trimethoxysilyl)propyl]amine, bis[3-(trimethoxysilyl)propyl]-N-methylamine, tris[3-(trimethoxysilyl)propyl]amine (denoted as N1, N2, N3-methyl and N3, respectively) in dry $CH_2Cl_2$/THF/toluene at 140-180 °C for 4 days. The obtained gels were dried under vacuum at 120 °C overnight. The structure and surface chemistry of these xerogels were characterized mostly by means of solid-state NMR spectroscopy and XPS. The textural properties were characterized by $N_2$ sorption at 77 K while the $CO_2$ uptakes and the heat of adsorptions were characterized by $CO_2$ sorptions at 273 K and 298 K. The catalytic reactions between $CO_2$ and epoxides (epichlorohydrin, 1,2-butylene oxide, styrene oxide) were performed in batch reactor under solvent-free and co-catalyst-free conditions at 120 °C and 10 bar of initial $CO_2$. Reaction mixtures were analyzed by NMR (in $CDCl_3$) and GC-MS. Reusability tests of catalysts were also performed. The spent catalysts were also characterized and discussed.

**Results and discussion.**

The obtained N-containing xerogels are mostly mesoporous with large specific surface areas and pore volumes (Table 1). Xerogels obtained from combinations between bridged aminosilanes and $Si(OAc)_4$ in toluene achieve excellent porosity and structural integrity (i.e., no side reactions during condensation, only expected signals in MAS NMR spectra). The catalytic performance of prepared highly porous materials depends mostly on the structure of amine sites with tertiary and non-sterically-congested amine site being the most active (Table 1).

**Table 1. Preliminary results of xerogels obtained from combinations between aminosilanes and $Si(OAc)_4$ in toluene at 180 °C for 4 days**

# Direct air capture and conversion of carbon dioxide into cyclic carbonate

Marcileia Zanatta,[1*] Eduardo García-Verdugo,[2] Victor Sans[1]

[1] *Institute of Advanced Materials (INAM), Univesitat Jaume I, Avda Sos Baynat s/n, 12071, Castellón, Spain*

**Keywords:** atmospheric air • $CO_2$ conversion • ionic liquids

**Abstract**

Direct air capture (DAC) is a very attractive strategy to reduce $CO_2$ concentration in the atmosphere. However, the existing capturing processes are technologically challenging due to the costs of the processes and the low concentration of $CO_2$ to be employed as feedstock. Thus, chemisorbent materials (e.g. amines or hydroxides) have proven to be much more effective for DAC processes. This renders thermodynamically stable adducts (e.g. carbamates and carbonates), which require large amounts of energy to recover the $CO_2$ or low added value products (e.g. $CaCO_3$). The efficient valorisation of the $CO_2$ captured from extremely diluted sources could help overcome many techno-economic limitations.[1]

In previous work we demonstrated that ILs with basic and hygroscopic anions (e.g. acetate, imidazolate, hydroxide), can capture $CO_2$ from concentrated sources, forming $HCO_3^-$.[2]

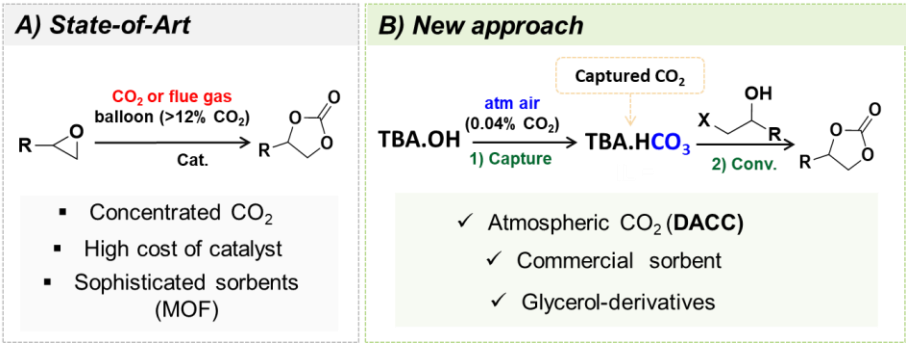

Figure 1. General approach of this work.

Here we present a novel methodology for direct air capture and conversion (DACC), able to efficiently convert $CO_2$ from the air into cyclic carbonates (Figure 1) . The new approach employs commercially available basic organic salts, works under mild reaction conditions without the need for sophisticated and expensive co-catalysts or sorbents. Two hypothesis have been demonstrated: (i) a solution of organic hydroxide salts can be able to capture de $CO_2$ directly from the air forming $HCO_3^-$; and (ii) the captured $CO_2$ ($HCO_3^-$) can be employed as a source of $CO_2$ to achieve a sequential transformation, reducing the energetic cost compared to a carbamate. Besides, the use of halohydrines derived from glycerol is advantageous from a sustainable chemistry perspective, since it derives from biomass processing waste and it avoids the use of less safe epoxides. The reaction mechanism was evaluated and the $CO_2$ sorbent demonstrated activity even after 3 cycles.

**Keywords:** Red Mud, $CO_2$ conversion, Hydrocarbons, Metal catalyst, Fixed bed reaction

**Introduction**

Greenhouse gas such as carbon dioxide ($CO_2$), methane ($CH_4$), nitrous oxide ($N_2O$) and fluorinated gases are being emitted to the atmosphere and it become a major concern for industries across the globe. Conversion of $CO_2$ to useful chemicals can reduces their release to atmosphere and simulatanesouly result in economic benefits as well. The process of hydrogenation of $CO_2$ to hydrocarbons, syngas, oxygenates and aromatics has got huge response from the scientific community as these molecules are important raw materials for plastics and polymers, fine chemicals and petrochemicals. Larget number of studies are reported on developing and effective utilization of different materials as catalysts, viz. $CO_2$ valorization [1], ketonization [2], adsorption [3]. $CO_2$ hydrogenation [4] is also reported to an effective process to convert $CO_2$ into hydrocarbons.

**Experimental/methodology.**

In this work, metal oxide based by product material, namely red mud and its modified versions are utilized as catalysts (containing Fe & Al oxides in major). These mixed metal oxides mixed with zeolites to get hybrid dual function catalysts. They were characterized using X-ray diffraction (XRD), temperature program reduction using $H_2$ ($H_2$-TPR) and $N_2$ adsorption/desorption method etc. The catalyst samples are named as RM-1, RM-2 and RM-3. All the prepared samples were tested and their performance for $CO_2$ hydrogenation application was demonstrated using a fixed bed test reactor at 350°C and 40 bar pressure in down-flow mode using the feed containing $CO_2$ and $H_2$ at 1:3 ratio. The basicity and acidity of the catalysts are analyzed using temperature program desorption using carbon dioxide ($CO_2$-TPD) and ammonia ($NH_3$-TPD), respectively. Attempts have been done to understand the chemistry and mechanism of the reaction after carefully interpreting the characterization results

**Results and discussion**

The characterization results of the prepared samples results are showed in Table 1. RM-1 catalyst showed 11.98% $CO_2$ conversion whereas RM-2 and RM-3 showed 14.20 and 13.85% $CO_2$ conversion, respectively as shown in Table 2 and Figure 1. CO is a significant product in RM-1, whereas methane is produced in equal amounts over RM-2 and RM-3.

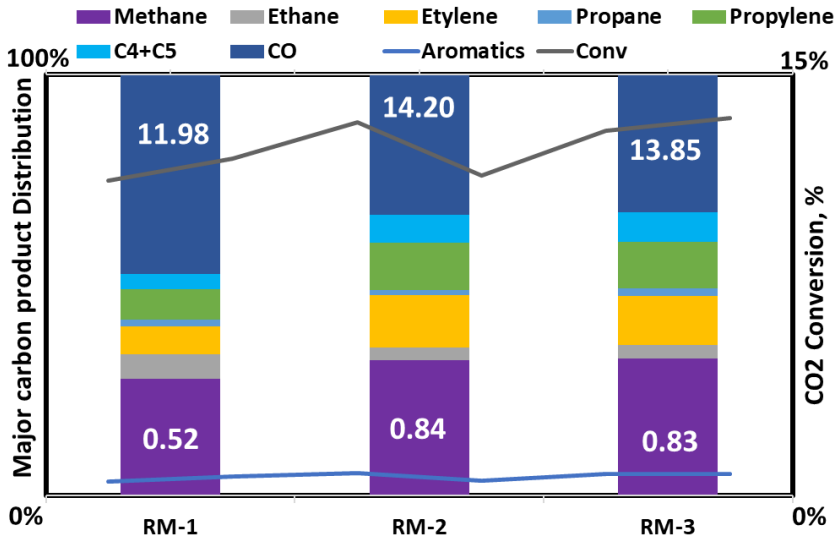

Figure 1. Catalytic performance results of some of the prepared samples for $CO_2$ hydrogenation

Upon modifying with the promoter, RM-3 samples showed significant improvement in olefin formation which is also reflected in its affinity towards $NH_3$ and $CO_2$. Acidity values reduced and Basicity value increased, which may enhance the $CO_2$ adsorption and further its reaction with $H_2$ to produce desired products. The difference in surface and basicity of different samples, as given in Table 1 are discussed and correlated to the performace. The presence of zeolites contribute the dehydration of the intermediate products to produce more olefins.

Table 1. Characterization results of some of the prepare samples

| **Sample** | **RM-1** | **RM-2** | **RM-3** |
|---|---|---|---|
| **BET Surface Area ($m^2/g$)** | 15.9 | 31.5 | 57 |
| **Pore volume ($cm^3/g$)** | 0.034 | 0.043 | 0.068 |
| **$H_2$-TPR (mmol/g)** | 2.71 | 3.87 | 1.35 |
| **$NH_3$-TPD (mmol/g)** | 0.003 | 0.004 | 0.014 |
| **$CO_2$-TPD (mmol/g)** | 0.036 | 0.07 | 0.295 |

In the similar way, aromatics formation is also enhanced over RM-2 and RM-3 as compared. Even though the aromatics production is marginal in quantity, being a high value commodity produced over a cheap catalyst using $CO_2$, one of the environmentally harmful gas which need immediate solutions to utilize effectively. The study includes modification and synthesis of hybrid catalysts using red mud and zeolites, characterization and catalytic evaluation of selected hybrid duab function catalysts for the hydrogenation of $CO_2$ to valuable hydrocarbons and chemicals

Table 2. Catalytic performance data of some of the prepared samples

| **Sample Name/Product(wt%)** | **C1** | **C2** | **C2=** | **C3** | **C3=** | **$C4^+$** | **Arom** | **CO** | **Conv** |
|---|---|---|---|---|---|---|---|---|---|
| **RM-1** | 27.51 | 5.77 | 6.71 | 1.61 | 7.17 | 3.6 | 0.54 | 47.09 | 11.98 |
| **RM-1** | 31.88 | 2.92 | 12.31 | 1.32 | 11.18 | 0.09 | 0.83 | 33.02 | 14.20 |
| **RM-1** | 32.28 | 3.19 | 11.62 | 1.62 | 10.95 | 0.11 | 0.82 | 32.49 | 13.85 |

The cheap catalytic material utilized in this study offer significant value in terms of carbon footprint achievements and utilization of industrial waste as well. The interpretation and understanding of the results will be presented.

**Introduction**

Using $CO_2$ as a raw material to generate light olefins can not only mitigate global warming, but also provide an alternative option to replace depleting fossil fuels [1]. Fe based catalysts have been extensively studied in $CO_2$ hydrogenation, which typically demonstrate unsatisfactory selectivity towards lower olefins [2].

**Experimental**

The ionic exchange method was used to produce Fe-ZSM-5 with Co and the $CO_2$ hydrogenation was conducted on continuous flow reactor.

***Results and discussion***

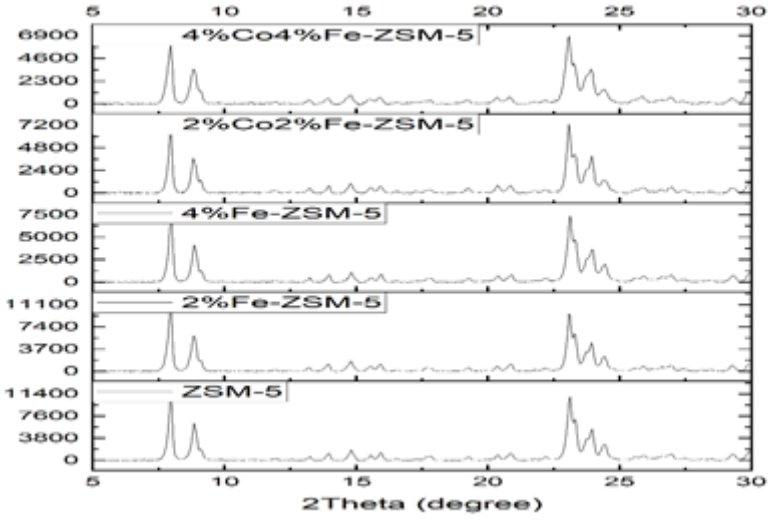

*Figure 1: XRD patterns of ZSM-5 and metal modified catalysts.*

**Conclusion**

The synthesized Fe-based catalysts were active in the $CO_2$ hydrogenation into hydrocarbons.

**Keywords:** Dry reforming, Ni-based catalyst, syngas and catalyst regeneration

**Introduction.**

Methane dry reforming (DRM) is an innovative process that uses heat and a catalyst to convert methane and carbon dioxide into useful products like syngas (a mixture of $H_2$ and CO). This process can help reduce greenhouse gas emissions and create environmentally sustainable fuels [1]. However, the DRM reaction is accompanied by several side reactions, such as methane decomposition, the Boudouard reaction and CO reduction, which can lead to deactivation of the catalyst due to the accumulation of carbon deposits [2]. For this reason and for the economic viability of the reforming processes, the regeneration of catalysts has attracted great attention. Therefore, it is crucial to design catalysts and related supports that do not undergo deactivation by coke and that can be regenerated after poisoning [3][4]. Nickel-based catalysts are often used in DRM due to their low cost, high availability, and good catalytic performance. However, they can be affected by sintering and coke deposition at high temperatures [5]. To increase the effectiveness of these catalysts, the use of different preparation conditions of the support material can affect and improve the characteristics, phase composition and distribution of the nickel phases. The aim of this study is to evaluate how the support preparation conditions influence the catalytic performance of Ni-$La_2O_3$ catalysts in DRM reaction. Additionally, the catalysts stability and regeneration from coke poisoning was investigated.

**Experimental/methodology.**

Ni-$La_2O_3$ catalysts were synthesized by one pot hydrothermal method (HT) and precipitation assisted by microwave irradiation (MW). The so prepared samples were compared to Ni/$La_2O_3$ where Ni was deposited by wetness impregnation over $La_2O_3$ oxides obtained by HT and MW methods. DRM reaction was carried out in a fixed-bed reactor by feeding a gas mixture of $CH_4$ and $CO_2$ (ratio 1:1) diluted in He. The physiochemical properties, redox stability and regeneration capacity of the catalysts, before and after reaction, were characterized by XRD, $N_2$-physisorption, $H_2$–TPR, $O_2$-TPO, TGA and XPS.

**Results and discussion.**

The comparison between Ni-$La_2O_3$ catalysts synthesized using different methods showed that the support and Ni phases composition played a crucial role in determining the nature of active sites and their dispersion. As a result, the DRM activity, redox stability and ability to regenerate from coke poisoning were strongly influenced by the catalyst preparation methods.

# Thermochemical catalysis for carbon dioxide splitting

S. Costa[1*], A. Glisenti[1]

[1]*Università degli studi di Padova, Padova, Italia*
[*]*simone.costa.2@studenti.unipd.it*

**Keywords:** carbon dioxide, splitting, iron spinel, thermochemical cycle.

**Introduction.** To prevent climate change from becoming irreversible big efforts are carried out to decrease the concentration and the emission of $CO_2$. A thermochemical cycle for the splitting of $CO_2$ can be a very good way to exploit this gas, because the catalyst, after a pre-reduction step at 1400°C and in an inert atmosphere can take the oxygen of carbon dioxide and water reducing these gases in CO and $H_2$[1,2,3], that is the composition of the syngas, useful for producing synthetic fuels by Fischer-Tropsch reaction. After this oxidation, the catalyst is regenerated and it can afford another cycle. The best materials for this thermochemical cycle result to be ceria[1] ($CeO_2$) and iron spinel[2] ($Fe_3O_4$) and studies on these two oxides focus on the attempt to increase stability by means of doping them and/or by supporting them with refractory materials, like $ZrO_2$[3]. In particular, $Ni_{0.9}Mg_{0.1}Fe_2O_4$ seems to be the catalyst that gives the best performances and stability[2]. A possibility is to investigate the use of support that can act as "co-catalysts" to allow the reduction at lower temperature with respect to $Fe_3O_4$. The best materials turn out to be nickel oxide and cupric oxide.

**Experimental/methodology.** The $Ni_{0.9}Mg_{0.1}Fe_2O_4$ iron spinel is synthetized using the citrate method[4], mixed with CuO, NiO or $ZrO_2$ (at 20% and 50% in weight) by wet ball milling method, then all of these compounds are characterized using XRD, SEM, EDX and XPS. To study the maximum oxygen released and successively reabsorbed by all of the materials, $H_2$-TPR (5% of hydrogen in helium) and $O_2$-TPO (5% of oxygen in helium) up to 900°C both are carried out. Also, $CH_4$-TPR and $CO_2$-TPO are carried out in order to study the reduction temperatures of materials, up to 900°C and with a concentration of active gases of 10%. The catalytic tests are performed in a dynamic bed reactor, flowing 100 sccm of 5% $H_2$, raising the temperature from room to 580 °C with a ramp rate of 10°C/min, flowing helium to 1000°C with the same ramp, and then 100 sccm of 10% $CO_2$ for 30 min at 1000°C (the gas complement is helium). Other catalytic tests are carried out, at 1000°C, flowing 100 sccm of 10% $CH_4$ for 30 min and then 10% $CO_2$ (also in this case the complement is helium). During these catalytic tests, IR and mass spectrometry are used to quantitate and observe the gases flowed and produced in the reactor.

**Results and discussion.** By $H_2$-TPR and $O_2$-TPO it is observed that all of the compounds released almost all of the oxygen, then reabsorb the same quantity; a different behaviour is observed for the samples mixed with zirconium oxide because this type of support is a refractory and inert material. $CH_4$-TPR show that NiO greatly favours the reduction of the material in methane, in fact the reduction temperature is lowered. All of the $CO_2$-TPO occurs immediately, at 600°C, demonstrating that the reduced phase of the iron spinel is very active for the splitting of carbon dioxide also at a low temperature, and that the reduction step of the thermochemical cycle is the one at highest temperature. Mass spectrometry showed that all of the compounds produce syngas after the reduction in methane and CO during the splitting of $CO_2$, and it is noticed that $Ni_{0.9}Mg_{0.1}Fe_2O_4$ mixed with NiO at 20% in weight is the material with best performances and stability, both using $H_2$ or $CH_4$ as reductant atmosphere. After two thermochemical steps, SEM images showed the very high sintering of samples with copper oxide due to his low melting temperature and no sintering on the sample supported by $ZrO_2$.

**Keywords:** silica mesoporous materials, Ni catalysts, $CO_2$ methanation

**Introduction.**

In the actual context of global warming the economic and the scientific community are compelled to search for better strategies for sustainable resources. The transformation of greenhouse gas $CO_2$ into valuable chemicals might prove one solution to this problem. A known and potential feasible technology is the $CO_2$ methanation consisting in hydrogen reduction of $CO_2$, thus transforming the $CO_2$ into synthetic methane. Although this technology has been investigated on large variety of metal catalyst like Ni, Ru, Rh [1] improvements can be done in order to enhance catalytic activity and stability of the catalytic material. Thus, highly accessible silica supports (SBA-15, FDU-12) with high surface areas and stability might improve the dispersion of the active metal nanoparticles species, which may lead to a better catalytic performance.

**Experimental/methodology.**

**Catalyst synthesis**

The support of the catalyst has been prepared following Zhao [2] method and the Ni metal nanoparticles were deposited on the support via different techniques : **wet impregnation (IMP)** which consists in adding the nickel nitrate hexahydrate precursor dissolved in water to the mesoporous silica support, followed by a heat treatment step and **melting infiltration (MI)** a method based on grinding together the mesoporous support and the nickel nitrate hexahydrate, subsequently subjected to a heat treatment step.

**Catalyst Characterization**

From the $N_2$ adsorption−desorption isotherms it was determined the specific surface area and pore structure of the catalysts. The crystalline phases and the dimension of Ni crystallites were determined through X-ray diffraction. Transmission electron microscopy measurements and thermogravimetry analyses completed the structural characterization. The used catalysts were also subjected to all these characterizations.

**Evaluation of Catalyst activity**

The performance of catalysts was assessed in a fix bed reactor under atmospheric pressure. The catalyst was reduced in hydrogen prior to testing. The evaluation of the catalyst was performed at different temperatures (100-500°C). The outcome composition of the effluent gas was analyzed by gas chromatography.

**Results and discussion.**

From the characterization methods we can conclude that the prepared catalytic materials present a uniform dispersion of the metallic Ni nanoparticles. For catalysts prepared by MI the NiNPs were found mainly inside the pores of the mesoporous silica support. Regarding the catalytic activity it has been observed that even at low temperature the catalytic material is able to convert the $CO_2$. The major components obtained in the reaction are $CH_4$ and $H_2O$, but also small amounts of CO were detected. The catalysts prepared by MI method are more active and stable than those prepared by IMP, in accordance to their better structural properties and higher capacity to adsorb and activate hydrogen. As a conclusion, the attained results might present a significant contribution in developing highly active and stable catalysts for $CO_2$ methanation.

# Effects of zeolite acidity on catalytic performance and coking behavior for $CO_2$ to light olefins using bifunctional composite catalysts

Wei Di[1], Abdenour Achour[1], Phuoc Hoang Ho[1], Oleg Pajalic[2], Lars Josefsson[3], Louise Olsson[1] and Derek Creaser[1 *]

**Keywords:** $CO_2$ hydrogenation, light olefins, bifunctional catalysts, SSZ-13 zeolite, acidity

**Introduction.** Effectively converting waste $CO_2$ into basic chemical feedstocks opens up a sustainable way to produce green chemicals in the future. Over an oxide-zeolite catalyst with the bifunctional active sites for $CO_2$ hydrogenation and C−C bond formation, $CO_2$ can be converted via the intermediate methanol into a mixture of short-chain olefins [1]. Previously, few investigations have been devoted to studying the low-temperature performance of bifunctional catalysts in $CO_2$ hydrogenation since the quick deactivation caused by coking. Inspired by the fact that the hydrogenation catalyzed by Brønsted acid sites (BAS) can inhibit coke deposition during the MTO reaction [2-3], here the effect of zeolite acidity on both olefin distribution and coke deposition is explored during low-temperature $CO_2$ hydrogenation with the aim to boost the selectivity for light olefins. This is done with $In_2O_3$/SSZ-13 bifunctional catalysts synthesized with varying BAS density.

**Experimental/Methodology.** The Na-SSZ-13 zeolite with varied Brønsted acid sites was post-synthesized by exchanging the proton-type of SSZ-13 (Si/Al=15) zeolite with a sodium nitrate solution, the obtained Na-SSZ-13 zeolites were mixed with $In_2O_3$ oxides to get the bifunctional catalysts. The fresh catalysts and individual ingredients were characterized by XRF, XRD, BET, $NH_3$-TPD, and SEM, and the spent catalysts were analyzed by using TPO, TG, and GC-MS. The $CO_2$ hydrogenation experiments were performed in a flow reactor with 1g total of bifunctional catalysts under 1 MPa, 325℃, 6400 $h^{-1}$ of GHSV with $H_2$: $CO_2$ molar feed ratios at 6:1. Products were analyzed by online GC.

**Results and discussion**. Exchanging from proton to sodium ions can significantly reduce the BAS density of the SSZ-13 zeolite and the BAS density of SSZ-13 zeolite influences the performance of the bifunctional catalyst during the $CO_2$ hydrogenation process. At the beginning of the reaction, it affects the initial transient behavior. Specifically, the catalyst with low BAS density shows a low methanol conversion rate, where unreacted methanol appears in the effluent at the beginning. Methanol gradually decreases to zero when the organic co-catalytic centers (Hydrocarbon pool species, HPC) are established. At the same time, the accumulation of methanol also causes a higher CO selectivity during the initial stage. With higher conversion of methanol, the selectivity to CO also decreases to its steady-state value as the reaction proceeds. The BAS density of the catalyst also strongly impacts the hydrogenation of olefins, and the formation of aromatics and coke precursors. The lower the BAS density of the catalyst, the slower rate of hydrogenation, which gives higher selectivity for light olefins in the product. However, the weakened hydrogenation will also promote the proliferation of coking precursors. The characterization of spent catalysts showed that the catalysts with low BAS density experienced a rapid coke deposition rate. In particular, compared with polycyclic aromatics, adamantanes are abundant on the deactivated catalysts. Their formation was strongly correlated with emissions of unreacted methanol during the initial stage of reaction, which may be one of the most important reasons for catalyst deactivation. It is necessary to avoid harmful coke formation while adjusting BAS to increase the yield of olefins.

# Advancement of design of Ni/$Ce_{0.8}Ti_{0.2}O_{2-\delta}$ for the dry reforming of methane using transient and isotopic techniques

**Keywords:** dry reforming of methane, syngas, doped ceria, supported Ni catalysts, coking.

**Introduction**

The discovery of several Natural Gas reservoirs rich in $CO_2$, and the progress in biogas production and $CO_2$ capture emissions, has attracted resurgent interest in the dry reforming of methane reaction (DRM: $CH_4+CO_2 \leftrightarrow 2CO+2H_2$). Supported Ni catalysts are mainly explored but they suffer from severe carbon deposition and deactivation. To face this problem, there is a need of knowing the fundamental kinetics of carbon deposition (via $CH_4$ decomposition and Boudouard reaction) and removal steps (via support's lattice oxygen, $O_L$) in the DRM (**Fig. 1A**), and this was the aim of the present work [1].

**Experimental/methodology**

x wt% Ni/$Ce_{0.8}Ti_{0.2}O_{2-\delta}$ (x = 3-10) were synthesized aiming to investigate the effect of Ni particle size (ca. $d_{Ni}$ = 22-45 nm) on important kinetic and mechanistic parameters of carbon paths in the DRM reaction. The influence of $d_{Ni}$ (nm) on the surface coverage (θ), mean residence time (τ), rate constant of RDS ($k_{eff}$) of *active* carbon-containing species, and oxidation of carbon by the support's lattice oxygen were investigated by SSITKA (use of $^{13}CO_2$ and $^{13}CH_4$) and other protocols of using transient $^{18}O_2$ isotopic experiments.

**Results and discussion**

The amount ($N_C$, μmol $g^{-1}$) and mean residence time (τ, s) of *active* C-containing intermediates formed in the *$CO_2$ activation route* (SSITKA switch: $^{12}CO_2/^{13}CO_2$) were found to increase with increasing TOS (0.5 to 16 h) and $d_{Ni}$ (22-45 nm). Similarly, the concentration ($N_{CO2}$) of *inactive* reversibly adsorbed $CO_2$ (carbonate-type species) that potentially influence the mobility and concentration of *active* $O_L$ species, likely affecting the oxidation rate of C, were found to increase. An *active* -$CH_x$ of $\theta_C \sim 1$ was formed via dissociation of $CH_4$ on Ni, and this was probed for the first time by SSITKA ($^{12}CH_4/^{13}CH_4$ switch). A small amount of active $O_s$ and/or $O_L$ participates in the formation of $CO_2$ via oxidation of C derived from $CH_4$. The $\theta_C$ and $\tau_C$ were found to increase with increasing $d_{Ni}$ and TOS. Also, $\tau_C$ was an order of magnitude larger than that related to the $CO_2$ activation route. This implies that the RDS in the C-path of $CH_4$ activation is slower compared to that in the $CO_2$ activation path. The small Ni particles ($d_{Ni}$ = 22 nm) was found to accumulate lower amounts of carbon (~ 300 times) compared with the larger ones (32-45 nm) after 100 h DRM (20%$CH_4$, $CH_4/CO_2$=1; 750 °C). **Fig. 1B** depicts the dynamic rate evolution of $C^{18}O(g)$ and $C^{16}O(g)$ formation (normalized to the number of Ni particles/$g_{cat}$) obtained during DRM following $^{16}O/^{18}O$ exchange at 750°C [1]. The $C^{18}O(g)$ is due to the oxidation of C (derived from $CH_4$) by lattice $^{18}O_L$, while $C^{16}O(g)$ is due to the oxidation of C by $^{16}O$-s (s: Ni) derived from $CO_2$ [1]. The R($C^{18}O$) at the initial stage of the transient was described by: R($C^{18}O$) = $k_{app}$ $C_{O\text{-}L}$ $C_C$ ($C_{O\text{-}L}$ is the concentration of lattice $^{18}O$, and $C_C$ that of carbon nearby the Ni-support interface). The small Ni particles present the lowest R($C^{18}O$) (**Fig. 1C**) but possess the largest $k_{app}$ compared to those for $d_{Ni}$ = 32-45 nm. Thus, small Ni particles become more active towards carbon oxidation by $O_L$, and this agrees with the lowest amount of carbon accumulated per gram of catalyst for the small Ni particles.

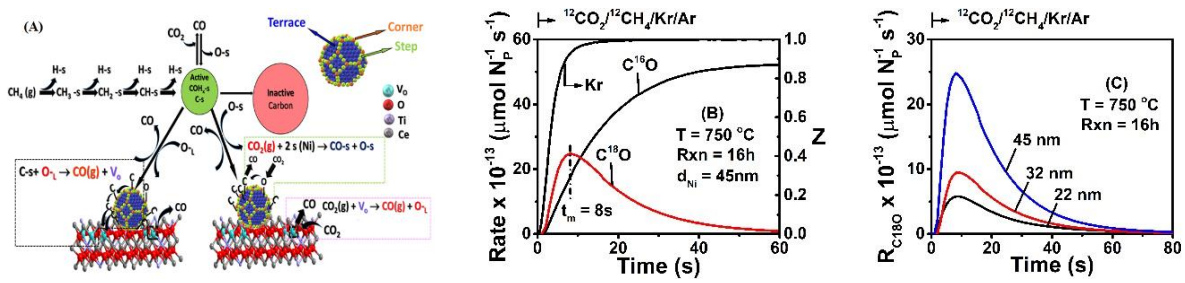

**Figure 1: (A) Reaction network of catalytic DRM on Ni/$Ce_{0.8}Ti_{0.2}O_{2-\delta}$; (B)-(C) Transient rates of $C^{16}O$ and $C^{18}O$ formation obtained during DRM following $^{16}O/^{18}O$ exchange at 750 °C, as a function of $d_{Ni}$ (nm).**

**Keywords:** Power-to-gas, $CO_2$ Methanation, Ni-supported catalyst, Pr-doped $CeO_2$.

**Introduction.** The increasing $CO_2$ concentration in the atmosphere is one of the major concerns of the 21st century due to the adverse environmental effects associated with it [1]. This has led to intensive research efforts in $CO_2$ mitigation technologies. Recently, power-to-gas technologies have been gaining ground proving their reliability in providing green $H_2$ for $CO_2$ reduction to value-added chemicals such as $CH_4$, $C_2H_4$, or $CH_3OH$. In this study, efficient Ni catalysts supported on Pr-doped ceria are designed and the interfaces involved are investigated for $CO_2$ methanation reaction.

**Experimental/methodology.** Pr-doped ceria (CP) modifier and Ni metal (10 wt.%) are both incorporated into porous alumina with different textural properties (i.e., low-porosity (LA), and high-porosity (HA)). The physicochemical properties of both calcined and reduced catalysts are investigated via different techniques. The catalytic activity/stability tests are obtained in a fixed-bed tubular microreactor from 200-500°C. Kinetics studies and DFT computations are carried out to obtain activation energies and configuration geometries for the $CO_2/H_2$ co-adsorption, respectively. Catalysts are coded as NCP-HA, NCP-LA, and NCP (bare, no alumina).

**Results and discussion.** The highest conversion is obtained at 350°C reaching a value of 75% for the best performing catalyst with an accompanied selectivity to $CH_4$ of >98%. Different spectroscopy and microscopy tools are used to unveil the intrinsic characteristics of the catalysts due to the perplex structure of the latter. Ni K-edge Synchrotron EXAFS demonstrates difference in local structure among the NCP-HA, NCP and NCP-LA catalysts. Ce $L_3$ edge analysis shows that the presence of $Al_2O_3$ as dispersion medium impacts the Pr oxidation state (more metallic Pr in the absence of $Al_2O_3$). Additionally, Ni dispersion ($H_2$-TPD) is found in the 18-37% range with a strong effect of $Al_2O_3$ textural features; good agreement with the HRTEM $Ni^0$ particle size (7-15 nm) is found. RGB (STEM-HAADF) shows the well dispersion of all elements on the high-porosity $Al_2O_3$ support. Structural studies, as implemented through Raman spectroscopy, along with the Ce 3d XPS spectra confirms oxygen vacancy presence and deficiency, in the bulk and surface, respectively. The apparent activation energy ($E_a$) of the $CO_2$ methanation over the here in investigated catalysts is around 53.7-68.8 kJ/mol; these values are much lower than that reported in the open literature for similar composition catalytic systems, such as $Ni/Al_2O_3$ ($E_a$ = 80 kJ/mol) [3], and Ni/Pr10Ce (93 kJ/mol) [4]. For the DFT calculations, $Ni_{13}$/Pr-$CeO_2$ surface is used; the DFT calculations prove the bifunctional character of the catalyst, where $H_2$ adsorbs/dissociates on $Ni^0$, and $CO_2$ is simultaneously bonded to both $Pr^{4+}$ and $Ce^{3+}$ atoms (bridged site) as the most favorable site with the strongest binding energy of -1.25 eV.

**sofiaess@uma.es, luijo@uma.es*

**Keywords:** $CO_2$-capture, $CO_2$-SR technology, greenhouse gasses valorization, hybrid catalysts.

**Introduction.**

In the past decades, global warming resulting from the emission of greenhouse gases, consisting mainly of carbon dioxide and methane, has become one of society's main concerns. In this context, there has been a growing interest in developing technologies that allow the capture and storage of $CO_2$ in an economical and sustainable way. The application of a heterogeneous bimetallic nickel-barium catalyst as a dual material has been studied for its use in the $CO_2$ regeneration cyclic process [1]. The present work shows the data corresponding to the substitution of Ba by Ca or Sr and K as a bimetallic catalytic systems to analyse the structural and physicochemical properties and the effect on $CO_2$ storage capacity.

**Experimental/methodology.**

The catalysts were synthesised by an ultrasonic assisted coprecipitation of the heterometallic mixed precursors employing an atomic ratio Ni:Me = 1:1 using colloidal silica as surface area promoting agent, and calcined at 800 °C in air for 4 h.

X-ray diffraction (XRD), KBr-FTIR infrared, Raman spectroscopy and nitrogen adsorption-desorption were employed for the characterisation. The $CO_2$ adsorption capacity was analysed at low temperature and at high reaction temperature.

**Results and discussion.**

The influence of the incorporation of the metal in combination with nickel has been studied and it has been found that, even at high temperature, it maintains a cubic structure with a surface area higher than 80 $m^2 \cdot g^{-1}$. The crystal size of bivalent or monovalent cation was not affected by the modification of the catalytic formulation. There is a correlation between $CO_2$ adsorption capacitity and the electronegativity of the second metal incorporated to the nickel structure as shown in Figure 1.

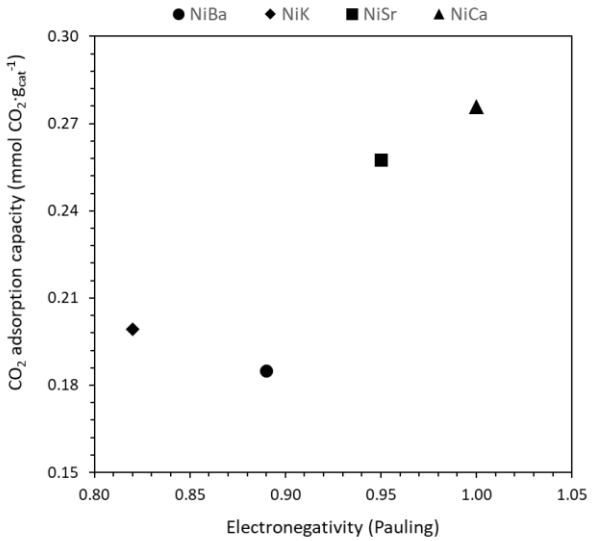

**Figure 1. $CO_2$ adsorption capacity of the catalysts at 25°C versus the electronegativity of the metal incorporated.**

[*]*corinna.fauth@uni-ulm.de*

**Keywords:** $CO_2$ reduction, active oxygen deposition, Ru/$Al_2O_3$ catalyst, temporal analysis of products (TAP)

**Introduction.** Ruthenium nanoparticles (NPs) supported on inorganic oxides act as highly active catalysts for several reactions, including the methanation of CO or $CO_2$ [1], the oxidation of CO [2], the Fischer-Tropsch reaction [3], or the reverse water-gas shift (RWGS) reaction [4]. In all these reactions, the interaction of $CO_2$ with the catalyst plays an important role. Thereby the reaction may occur in an associative or dissociative way, which possibly involves changes in the oxidation state of Ru. Aiming at a detailed picture of the interaction of $CO_2$ with Ru or supported Ru catalysts we investigated the dynamic reduction and oxidation of Ru/$Al_2O_3$, exploring the reversible replenishment of active oxygen by interaction with $CO_2$ by temporal analysis of products (TAP) reactor measurements under well-defined reaction conditions. In these multi-pulse experiments, we compared the oxidation strength of $O_2$ and $CO_2$ pulses and further investigated the interaction of isotope marked $C^{18}O_2$ with the catalyst and adsorbed species present on the catalyst.

**Experimental/methodology.** We used a commercial 5.0 wt.% Ru/$\gamma$-$Al_2O_3$ catalyst (100 $m^2$ $g_{cat}^{-1}$, mean Ru particle diameter 1.6 nm) supplied by Johnson Matthew. After pretreatment in 10% $O_2/N_2$ at 150 °C for 30 min (O150) the catalyst was exposed to pulse sequences. We performed the multi-pulse experiments in a home-built TAP reactor described in ref. [5]. Piezo-electrically driven pulse valves generated gas pulses (1.5-3.2×$10^{16}$ molecules per pulse) with high reproducibility. The effluent gas from the catalyst bed, which was fixed in a quartz glass microreactor, was detected by a quadrupole mass spectrometer (QMG 700, Pfeiffer) located in a UHV chamber (background pressure 8×$10^{-9}$ mbar).

**Results and discussion.** First, the reversible removal and replenishment of active oxygen on Ru/$Al_2O_3$ was monitored during alternating sequences of CO/Ar and $O_2$/Ar pulses at 190 °C, 250 °C, and 300 °C. The amount of active oxygen removal was determined from the amount of CO consumed or $CO_2$ formed in the CO pulse titration. At all temperatures, the CO pulses were able to completely reduce the $RuO_2$ particles formed during the O150 pretreatment, resulting in $CO_2$ pulses that left the catalyst bed, but also carbonate species which remained adsorbed on the support. In the following sequence of $O_2$ pulses approx. 60% of the initial oxygen content could be replenished at 190 °C, and this fraction increased with higher reaction temperature. Similar experiments using $CO_2$ instead of $O_2$ pulses demonstrated that also $CO_2$ is able to deposit oxygen on the pre-reduced Ru surface, but the deposition rate is significantly lower compared to $O_2$. In the presence of $H_2$ the amount of active oxygen deposition by $CO_2$ was significantly increased to a level comparable to that of $O_2$, which we attribute to the formation of highly reactive water (RWGS reaction). Finally, in multi-pulse experiments with isotope marked $C^{18}O_2$ on the pre-reduced catalyst, we followed the simultaneous i) deposition of active oxygen on the surface, ii) oxygen exchange between $CO_2$ and adsorbed species, and iii) decomposition of surface carbonate species.

In conclusion, the interaction of $CO_2$ with Ru/$Al_2O_3$ includes both changes in the Ru oxidation state and in the adsorbate layer under reaction conditions. Therefore, these TAP measurements are highly relevant for the mechanistic understanding of various catalytic reactions on supported Ru involving the $CO_2$.

# Influence of the catalyst activation temperature on the ethanol production in the $CO_2$ hydrogenation over Cu-UiO-67

Luana do N. R. de Paula[1], Janaina F. Gomes[1], José Mansur Assaf[1*]
[1]*Federal University of São Carlos, São Carlos, Brazil*
[*]*mansur@ufscar.com.br*

**Keywords:** $CO_2$ hydrogenation, UiO-67, metal-organic frameworks, reduction temperature

**Introduction.** $CO_2$ hydrogenation to higher alcohols, linked to the use of renewable energy, is a promising approach due to possibility of reducing dependence on fossil resources [1]. Nevertheless, catalysts with adequate selectivity and activity have not yet been found. In addition, the deactivation of catalysts, especially those based on Cu, has also been a challenge to be solved. Metalorganic frameworks (MOFs), e.g. UiOs, have been studied as support for Cu catalysts and have the potential to fill such gaps, since the control of specific sites and the protection of them from agglomeration is possible, making MOFs supported catalysts more selective to ethanol and more stable under reaction conditions [1,2]. Another obstacle of this reaction is the use of $H_2$ from fossil resources as a co-agent, since cleaner $H_2$ technologies are still not viable. Water, on the other hand, can be used as an alternative hydrogen source in the hydrogenation of $CO_2$ to alcohols [3]. In the present work, Cu-UiO-67 was synthesized, characterized, and applied to the $CO_2$ hydrogenation at atmospheric pressure and using water steam as hydrogen source, aiming to study the influence of the temperature of the catalyst activation on the ethanol production.

**Experimental/methodology.** The methodology used to produce UiO-67 was based on An et al. [4]. Briefly, UiO-67 was synthesized by the solvothermal method for 48 h at 120°C. Copper (20 wt.%) was incorporated into the MOF structure via ion exchange. Before the reaction, the catalyst was activated under $H_2$ stream at temperatures between 180-240 °C for 1h. $CO_2$ hydrogenation to alcohols was carried out at atmospheric pressure, using water steam as hydrogen source to the reaction. Products were quantified via GC-FID.

**Results and discussion.** In Fig 1(a), the $H_2$-TPR profile shows two overlapping peaks with different intensities, centered at 237 °C and 260 °C, both associated with the direct reduction of $Cu^{2+}$ to metallic copper [5]. The catalyst activation was performed in the range between 180 and 240 °C. After $CO_2$ hydrogenation at 180 °C with water steam, the samples were investigated by XRD, as shown in Fig 1(b). The formation of $Cu^{+}$ was favored with increasing activation temperature, as evidenced by the growing intensities of the peaks at 35.6° and 42.7°, assigned to (111) and (200) diffraction planes of $Cu_2O$, respectively. According to Fig. 1c, the production of ethanol augmented with increasing catalyst activation temperature, reaching 5.7 $\mu mol_{EtOH}/h.g_{Cu}$ for the activation temperature of 240 °C. This performance may be associated with the formation of $Cu^{+}$ species in the catalyst.

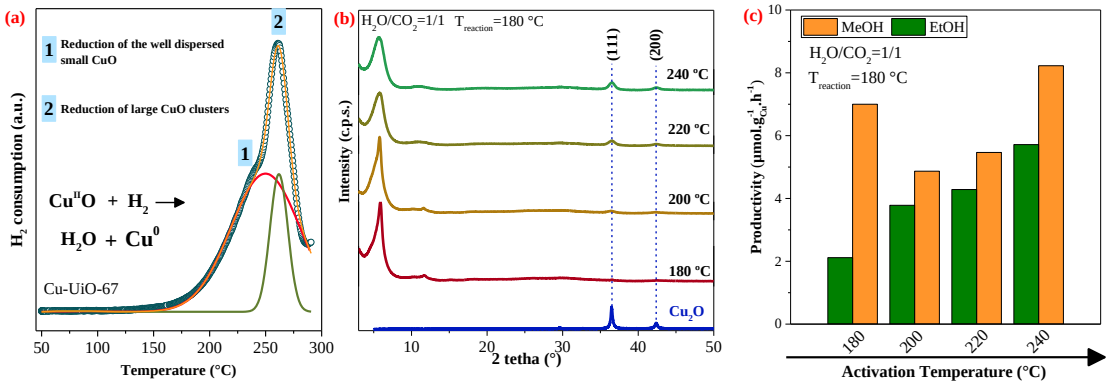

**Figure 1.** TPR-$H_2$ of Cu-UiO-67 (a); XRD of Cu-UiO-67 after $CO_2$ hydrogenation reaction using different activation temperatures (b); Effect of the activation temperature on the alcohols productivity (c).

# Propylene production via oxidative dehydrogenation of propane with carbon dioxide over composite metal oxides

A. Florou[1], G. Bampos[2], P. Panagiotopoulou[1*]

[1]*Technical University of Crete, Chania, Greece*
[2]*University of Patras, Patras, Greece*
[*]*ppanagiotopoulou@tuc.gr*

**Introduction.** Propylene ($C_3H_6$) is a versatile precursor for the formation of various derivatives (e.g. polypropylene, acrylic acid, acrylonitrile, cumene etc.) used in our daily life and thus, it is considered as a key component of the chemical industry [1]. Oxidative dehydrogenation of propane ($C_3H_8$) in the presence of $CO_2$ has recently gained interest as an alternative approach for the selective production of $C_3H_6$. This approach has the advantage that $CO_2$ participates both in (a) $C_3H_8$ conversion toward $C_3H_6$ and (b) hydrogen consumption via the Reverse Water-Gas Shift (RWGS) reaction [2]. Removing hydrogen from the gas stream can overcome the equilibrium limitations of $C_3H_8$ dehydrogenation, resulting in higher $C_3H_6$ yields. However, depending on the catalyst and reaction conditions employed, the reactions of $C_3H_8$ hydrogenolysis and $C_3H_8$ or $C_3H_6$ decomposition may also take place, resulting in a decrease of $C_3H_6$ yield and possibly surface carbon formation. Thus, in order for this method to be effective, the physicochemical characteristics of catalyst and operating reaction conditions should be properly selected.

**Experimental/methodology.** Composite metal oxide powders 10 wt.% $M_xO_y$-$TiO_2$ and 10 wt.% $M_xO_y$-$SiO_2$ (M: Ga, Cr, Ca, Sn) were prepared employing the wet impregnation method by using commercial $TiO_2$ or $SiO_2$ powder and an aqueous solution of the $M_xO_y$ precursor salt. The impregnation was followed by drying at 120 °C for 24 h and subsequent calcination at 600 °C for 3 h. Catalysts were characterized employing nitrogen physisorption at -196°C and X-Ray Diffraction (XRD). Catalytic performance tests were carried out in the temperature range of 550-750°C using a $CO_2$:$C_3H_8$ molar ratio equal to 5:1.

**Results and discussion.** Results showed that the addition of metal oxides on $TiO_2$ or $SiO_2$ surface results in higher $C_3H_8$ conversions ($X_{C3H8}$) compared to bare $TiO_2$ or $SiO_2$. In the case of $M_xO_y$-$TiO_2$ catalysts, catalytic performance is improved following the order $TiO_2$ (none)< $SnO_2$ < $Cr_2O_3$ < $Ga_2O_3$ < CaO, whereas in the case of $M_xO_y$-$SiO_2$ catalysts, the activity order was found to be $SiO_2$ (none) < CaO < $Ga_2O_3$ < $SnO_2$ < $Cr_2O_3$. In all cases the main products detected were $C_3H_6$, CO, $CH_4$ και $C_2H_4$. Selectivity toward $C_3H_6$ ($S_{C3H6}$) was found to be higher for $Ga_2O_3$-$TiO_2$, $Cr_2O_3$-$TiO_2$, $Cr_2O_3$-$SiO_2$ and $SnO_2$-$SiO_2$ catalysts and progressively decreases with increasing temperature for all catalysts examined with the exception of the CaO containing samples, where $S_{C3H6}$ remains stable in the entire temperature range examined. Carbon monoxide selectivity also decreases with increasing temperature above 660 °C and was found to be higher for CaO-$TiO_2$ and CaO-$SiO_2$ catalysts. Production of both CO και $C_3H_6$ indicates that, under the present experimental conditions, the desired reaction of oxidative dehydrogenation of propane takes place whereas part of the produced CO may be due to the RWGS reaction. Selectivities toward $CH_4$ και $C_2H_4$ exhibit similar behavior with temperature and increases slightly for T>650 °C, most possibly due to enhancement of their production via $C_3H_8$ hydrogenolysis and $C_3H_8$ or $C_3H_6$ decomposition reactions. Comparison of the results obtained for the two series of catalysts investigated implied that $M_xO_y$-$SiO_2$ catalysts are more active than $M_xO_y$-$TiO_2$ and exhibit significantly higher improvement compared to bare $SiO_2$ than that obtained for $M_xO_y$-$TiO_2$ samples. This is also the case for propylene yield which was found to be optimum for $SnO_2$-$SiO_2$ sample reaching the value of 30% at 730°C. DRIFTS studies have been also performed over selected catalysts in order to identify the nature and population of active surface intermediates and investigate the reaction pathway.

# Carbon nanobeads as active components for the production of methanol via $CO_2$ hydrogenation

G. Bonura, S. Todaro, C. Cannilla, A. Cajumi, J.F. Pérez Robles, F. Arena and F. Frusteri
CNR-ITAE "Nicola Giordano" Via S. Lucia Sopra Contesse 5 – 98126 Messina (Italy)

**Keywords:** $CO_2$ hydrogenation, Carbon nanobeads, CuZnZr catalyst, Methanol production

**Introduction.**
Methanol production via $CO_2$ reduction in presence of renewable hydrogen represents a topic of strategic interest in view of containing the carbon footprint in atmosfere. Although several catalytic systems have been so far investigated [1,2], the obtainment of high methanol selectivity at high $CO_2$ conversion level (>20%) remains a problem to overcome. To achieve this target, the promotion of $CO_2$ activation over specific surface sites is crucial and, furthermore, it is also necessary to address the problem of the presence of water which negatively influences the activity and stability of the catalyst. In this work, the performance of Cu-ZnO-$ZrO_2$ (CZZ) promoted by carbon nanobeads was investigated in the synthesis of methanol by comparing results with those obtained by using a previously optimized unsupported CZZ catalyst [2].

**Experimental/methodology.**
The carbon nanobeads (CNBs) were functionalized to anchor a methanol phase (CZZ) through the gel oxalate coprecipitation method, according the procedure elsewhere described [2]. Catalysts were characterized by several techniques (BET, XRD, TPR, TPD, SEM, TEM, etc…) and tested in a fixed bed reactor operating at 30 bar and 260 °C by feeding a stream of $CO_2/H_2/N_2$ (23/69/8 v/v) at 8,800 $NL/kg_{Cu}/h$.

**Results and discussion.**
Catalytic results are shown in Fig. 1. Apart from the bare sample containing only carbon (CNBs) which shows no activity, the carbon supported sample displays a superior catalytic performance compared to the unsupported sample (CZZ), especially in terms of $CO_2$ conversion (21.2% *vs.* 15.6%), which leads to a higher methanol yield (8.2% *vs.* 4.6%).

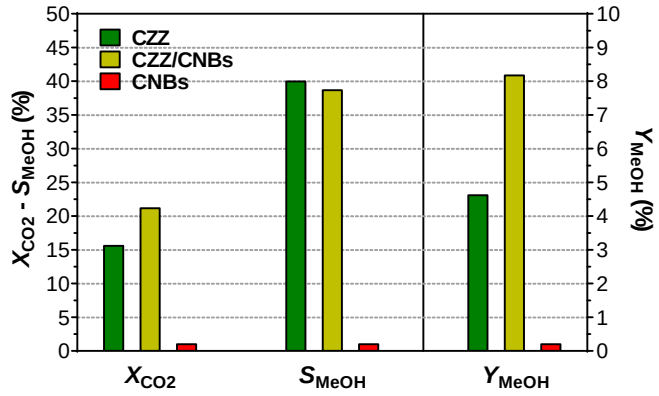

*Fig. 1. Catalytic data ($X_{CO2}$, $S_{CO}$, $S_{MeOH}$, $Y_{MeOH}$) in the $CO_2$ hydrogenation reaction (Experimental: 260 °C; 30 bar; $CO_2/H_2/N_2$, 23/69/8 v/v; 8,800 $NL/kg_{Cu}/h$).*

These results put clearly in evidence the beneficial effect obtained by the presence of carbon nanobeads in driving the production of methanol via direct $CO_2$ hydrogenation. This positive effect is not definitely understood, but very probably the carbon surface brings effective sticking points for $CO_2$ activation, also depressing the effect of water on catalyst lifetime. To demonstrate the specificity of carbon during reaction, IR measurements *in operando* conditions are in course.

**Keywords:** $CeO_2$, $CO_2$, 2-imidazolidinone, ethyleneurea

**Introduction.** 2-Imidazolidinone (EU) is a raw material for pharmaceuticals and resin additives. We reported that EU can be synthesized from ethylenediamine carbamate (EDA-CA) using $CeO_2$ as a heterogeneous catalyst and EDA as a solvent for EDA-CA (Fig. 1(a)) [1]. However, the generated EU sequentially reacts with EDA to form *N*,*N*'-bis(2-aminoethyl)urea (LU), resulting in low selectivity of EU (yield of EU 62% and LU 38% from EDA-CA) with a batch reactor. The formation of LU from EU and EDA proceeds easily in liquid phase without $CeO_2$ catalyst (Fig. 1(b)). Meanwhile, flow-type reaction has a great potential to suppress such sequential reaction since this type of reaction can be operated even at very low solvent/catalyst ratios that cannot be applied to batch reactions due to a lack of smooth stirring. Thus, in this study, we attempted to synthesize EU by applying a fixed-bed flow reactor [2].

**Experimental.** Granulated $CeO_2$ (Daiichi Kigenso Kagaku Kogyo, calcined at 873 K for 3 h in air) was used as a catalyst. An upflow-type fixed-bed tubular reactor was used with an HPLC pump. The standard reaction conditions were as follows: catalyst amount $W_{Cat}$ 0.50 g; an EDA-CA (9.2 mol%) solution in EDA (90.8 mol%) as a reaction solution; substrate flow rate $F_{Sol}$ 0.60 mL $h^{-1}$ ($F_{EDA\text{-}CA}$ 0.82 mmol $h^{-1}$); contact time $W_{Cat}/F_{EDA\text{-}CA}$ 0.61 g h $mmol^{-1}$; and temperature 363 K. Quantitative analysis of the products and unreacted EDA-CA was performed by $^1$H NMR and GC-FID. Selectivity and yield were calculated on an ethylene chain basis.

**Results and discussion.** The dependence of product selectivity on contact time ($W_{Cat}/F_{EDA\text{-}CA}$) was initially investigated at 363 K (Fig. 2). The yield of EU increased with an increase in $W_{Cat}/F_{EDA\text{-}CA}$ and reached as high as 94% at $W_{Cat}/F_{EDA\text{-}CA}$ of 3.5 g h $mmol^{-1}$. The yield of LU also increased slightly at the higher contact time but was still 1% when the maximum EU yield was provided. Therefore, the flow-type reaction greatly improved the selectivity of EU, compared to our previous batch reaction [1]. The detailed kinetic study revealed that this difference in selectivity is because the flow-type reactor enables the reaction operation even at the low $W_{EDA}/W_{Cat}$ ratios. Under such conditions, the formation of EU from EDA-CA, whose apparent activation energy ($E_a$) was experimentally determined to be 97 kJ $mol^{-1}$, becomes faster than the latter step of LU formation from EU and EDA ($E_a$ = 114 kJ $mol^{-1}$). We also found by $^{13}$C CP/MAS NMR that in long-term operation, $CeO_2$ was gradually deactivated due to the deposition of polyurea-like compounds on the surface.

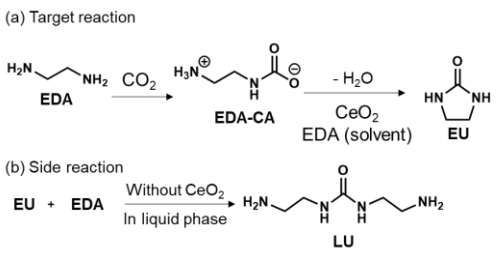

**Fig. 1.** Synthetic routes of EU from EDA

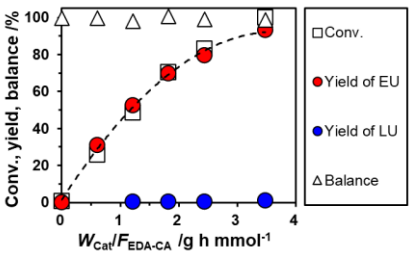

**Fig. 2.** Effect of contact time on the reaction of EDA-CA over $CeO_2$ catalyst.
Conditions: 9.2 mol% EDA-CA in EDA, 363 K, TOS 24 h.

**Keywords:** $CO_2$ hydrogenation, nickel catalyst, iron promoter

**Introduction.** Carbon dioxide produced during combustion of fossil fuels is commonly perceived as a major contributor to the greenhouse effect. It can be captured and then processed into valuable products, such as methane, methanol or higher hydrocarbons ($CO_2 + 4H_2 \leftrightarrows CH_4 + 2H_2O$). The use of so-called green hydrogen for the hydrogenation of $CO_2$ additionally allows the storage of renewable energy, as well as improving the efficiency of biomass conversion in biorefineries. The positive effects of the presence of small amounts of iron on the performance of nickel catalysts have been reported for numerous catalytic processes. However, a more comprehensive picture of surface changes of iron promoted alumina supported nickel catalysts in $CO_2$ hydrogenation is still lacking.

**Experimental/methodology.** A series of alumina supported catalysts obtained by the application of impregnation method with fixed Ni content (20 wt.% Ni) and different amounts of Fe (from 0 to 10 wt.%) were investigated. The properties of catalysts were studied by the application of versatile experimental methods, including X-ray diffraction, electron microscopy, temperature-programmed reduction, oxidation, $H_2$ and $CO_2$ desorption, in-situ DRIFTS CO and $CO_2$ adsorption/desorption and $CO_2$ hydrogenation reaction. The state of the catalysts on the different operation stages was investigated by Mössbauer spectroscopy and quasi in-situ photoelectron spectroscopy (XPS). The performance of catalysts in $CO_2$ hydrogenation reaction was determined using fixed-bed continuous-flow quartz microreactor [1-4].

**Results and discussion.** An introduction of iron into alumina supported nickel catalysts induced a number of effects, including small changes in the specific surface area and porosity, as well as the formation of mixed oxide species, transformed into the corresponding NiFe alloys under activation conditions. Complex changes in reducibility of oxide phases and the ability of reduced catalysts to form oxide species were evidenced. Although the presence of iron led to a decrease in the active surface area of catalysts, despite a similar nickel content, at the same time an increase in their activity in the $CO_2$ methanation reaction was observed. It was noticed that the optimal iron content guaranteeing the highest $CO_2$ conversion under the given conditions depended on the reaction temperature. Thermal analysis, electron microscopy and spectroscopic studies confirmed the formation of NiFe alloys in the catalysts. Their particular forms influenced surface and redox properties of catalysts resulted in the changes of the way of $CO_2$ activation during hydrogenation reaction, the stability and arrangement of differently coordinated intermediate surface carbonyl groups, formation and subsequent transformation of surface carbonate and formate species.

# Development of a Tailored Multiphase System for the Ru-catalyzed Synthesis of Cyclic Acetals

Niklas Gaelings[1] and Jürgen Klankermayer[1,*]

[1] *RWTH Aachen University, Institute for Technical and Macromolecular Chemistry, Aachen, Germany*
*gaelings@itmc.rwth-aachen.de and jklankermayer@itmc.rwth-aachen.de*

**Keywords:** bio-hybrid approach, $CO_2$ utilization, multiphase catalysis, catalyst recycling

**Introduction.** In order to reduce carbon dioxide emissions (CO2), a sustainable but also flexible carbon cycle must be made possible in the chemical value chains. In particular, the rapid avoidance of fossil carbon resources and the efficient use of renewable raw materials and energy sources are of the utmost importance.[1,2] Our approach tackles this challenge, by combining different sustainable resource streams into novel bio-based chemicals, namely cyclic acetals (CA), which can be used as solvents, monomers and synthetic fuel (additives).[3,4]

**Experimental/methodology.** In 2019 our group developed a catalytic system which enables the reaction of $CO_2$ with hydrogen and bio-based diols for the synthesis of cyclic (e.g. 1,3-dioxolanes, 1,3-dioxanes) and linear acetals.[5] The reaction is facilitated by a homogenous ruthenium catalyst [Ru(triphos)(tmm)] (triphos = 1,1,1-tris(diphenylphosphinomethyl)ethane, tmm = trimethylene methane) and tailored Lewis acid co-catalyst. A further optimization of the catalytic system led to a restriction of the reaction based on the thermodynamic boundary conditions. Together with the aim of developing an efficient strategy for product separation and recycling of catalysts in terms of a future process, we have transferred the reaction to a multi-phase system.

**Results and discussion.** Earlier investigations of the mechanism for the Ru(triphos)-catalyzed conversion of $CO_2$ revealed the importance of an active cationic formate species. A multiphase system was thus targeted, which is composed of an active polar phase with the catalyst and an apolar phase for the cyclic acetal product. Since the liquid substrate for the formation of cyclic acetals is a diol, the substrate was used as polar phase in the multiphase system. The formed cyclic acetals are themselves significantly less polar than the diol and can be extracted in-situ with an apolar solvent. Solvent screening revealed *n*-decane to be the most promising apolar solvent for product extraction. Using a multiphase system consisting of *n*-decane and diol leads to excellent catalyst and co-catalyst retention, while providing an extraction efficiency for the cyclic acetals of up to 85%.

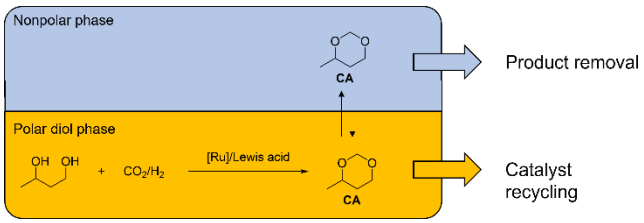

**Figure 1: Concept of the tailored multiphase system for the Ru-catalyzed synthesis of cyclic acetals**.

# Inverse $CeO_x/CoO_y$ catalysts for $CO_2$ methanation

Yu Gao, Nikolay Kosinov and Emiel Hensen*

*Eindhoven University of Technology, Eindhoven, The Netherlands*
*Email address:* y.gao1@tue.nl *e.j.m.hensen@tue.nl*

**Keywords:** inverse catalysts, $CeO_x/CoO_y$, $CO_2$ methanation

**Introduction**

Growing concerns about global climate make $CO_2$ capture and (re)utilization of an increasingly attractive opportunity. Ceria-based metals can be used as efficient catalysts for $CO_2$ hydrogenation due to the unique redox properties of ceria, which include facile formation of surface oxygen vancancies and specific metal-support interactions (MSI).[1] For example, the complex Co-O-Ce interface chemistry including (reverse) oxygen spillover and hydrogen spillover, render $Co/CeO_2$ catalysts highly active for $CO_2$ adsorption and activation.[2] Recently, we also reported that constructing Co-O-CoO interface helped to overcome the structure-sensitivity in $CO_2$ hydrogenation.[3] Herein, we studied inverse $CeO_x/CoO_y$ catalysts in an attempt to maximize interfacial Co-O-Ce sites for optimized $CO_2$ methanation.

**Experimental/methodology**

$CeO_x/CoO_y$ catalysts with different Ce mole fractions with respect to Co (0%, 1%, 5%, 10%, 20%, 50%, 90% and 100%) were prepared by flame spray pyrolysis (FSP). $H_2$-TPR experiments were carried out with a Micromeritics Autoche II 2920 instrument. In situ X-ray absorption spectroscopy (XAS) was performed at the ROCK beamline of Soleil synchrotron in France. $CO_2$ methanation reactions were performed in a 10-tube parallel high-throughput reactor.

**Results and discussion**

The $CO_2$ methanation results for the $CeO_x/CoO_y$ catalysts in Figure 1a shows that the catalytic performance strongly depends on the Ce content and reduction temperature. The highest $CH_4$ yield was observed for 10%Ce and 20%Ce samples reduced at mild temperature. $H_2$-TPR profiles (Figure 1b) reveal higher reduction temperature for inverse catalysts as compared with conventional $Co/CeO_2$, indicating stronger MSI. In situ XAS was used to determine the oxidation state of Co and Ce as a function of the reduction temperature (figure 1c). While metallic Co was formed over pure $Co_3O_4$ already after reduction at 200 °C, a mixture of Co-CoO was stable in a broad temeprature range for the 20%Ce sample. Ce $L_3$-edge XANES shows the reduction of $Ce^{4+}$ to $Ce^{3+}$ during reaction for the 20%Ce sample (Figure 1d). This finding indicates formation of abundant oxygen vacancies, facilitating adsorption and activation of $CO_2$.

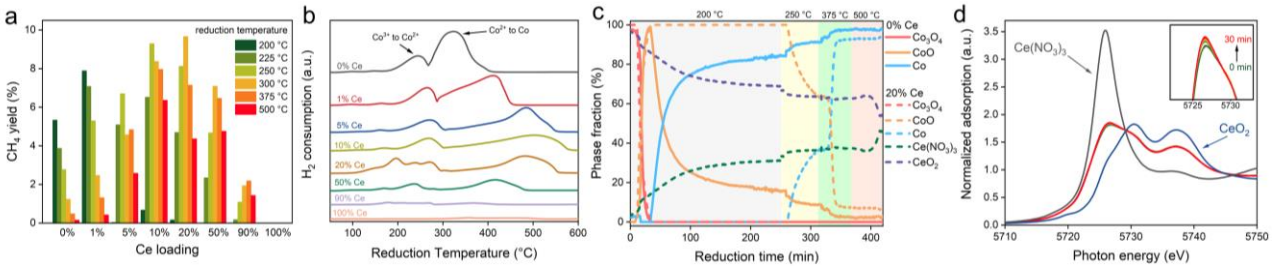

**Figure 1. (a) $CO_2$ methanation over $CeO_x/CoO_y$ catalysts in a flow of $CO_2$:$H_2$:He (v/v=1:4:15; total flow 50 ml/min). Samples pre-reduced in 15 vol% $H_2$ for 4 h at different temperatures; (b) $H_2$-TPR profiles of $CeO_x/CoO_y$ catalysts; (c) Linear combination fitting of Co K-edge XANES during $H_2$ reduction for 0%Ce and 20%Ce samples; (d) Normalized Ce $L_3$-edge XANES of 20%Ce sample during reaction, sample was pre-reduced under 375 °C.**

[*]*jegarcia@icb.csic.es*

**Keywords:** $CO_2$ capture, methanation, dual functional materials

**Introduction.** After the pioneering works of Farrauto et al. [1], dual functional materials (DFM) have emerged recently for been studied in the last years for the stepwise isothermal $CO_2$ capture and methanation. Different combinations of transition metals (Ni, or Ru) and alkali or alkaline earth metals have been explored [2]. For a real application, it is important to assess its cyclic stability at different temperatures under realistic conditions, such as real flue gas, which also contains $O_2$ and $H_2O$ and other impurities. In addition, it should be born in mind that operating at the lowest temperature as possible is also highly searched for. This would reduce the energy required for heating when the flue $CO_2$-containing gas is emitted at low temperature or for direct capture from the air (DAC). Herein, we have performed a parametric study of the effect of the reaction temperature on the cyclic performance of DFMs consisting of a metal active in methanation (Ni or Ru) and different alkaline metals (Na, K, Ba) with $CO_2$ capture ability [3].

**Experimental/methodology.** Six DFMs were prepared by combining one alkaline metal (Na, K or Ba) and a methanation metal (Ru or Ni) supported on alumina. The loading of alkaline metal was fixed at 10 wt%, the Ru at 3 wt% and Ni at 15 wt% Ni. The DFMs were prepared by sucessive impregnation. In the case of the Ni series, the Ni was added before the alkaline, while, in the case of Ru series, the alkaline was added before the Ru precursor. Finally, the DFMs were treated at 500 ºC first in $N_2$ and later in $H_2$ and characterised by $CO_2$-TPD, TPSR, XRD, XPS and TEM.

**Results and discussion.** Temperature programed surface reaction (TPSR, Figure 1 a and b) suggested that the COx-adspecies adsorbed at room temperature react at lower temperatures for Ba-contaning DFMs than for the other alkali metals (Na or K). This is an intrisic property of barium since it occurs both for Ni and Ru based sets of DFMs. This highest reactivity for Ba-Ru DFM explains the highest $CH_4$ productivity (50 µmol $g^{-1}$) in cycles at the lowest temperature tested of 250 ºC (Figure 1 c). At higher temperatures the highest productivity was provided by Na-Ru DFM (300 µmol $g^{-1}$) due to the larger $CO_2$ capture capacity.

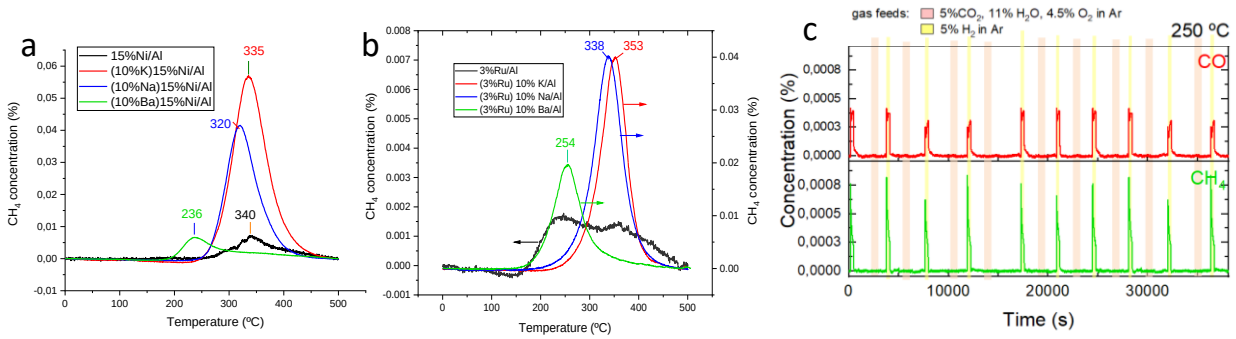

**Figure 1**. TPSR experiment for DFMs of the Ni series (a) and of the Ru series (b). Cyclic $CH_4$ and CO production during hydrogenation of previously captured $CO_2$ from a gas containing 5%$CO_2$, 11%$H_2O$ and 4.5% $O_2$ in Ar.

**Keywords:** $CO_2$ Hydrogenation, Off-gas upgrading, Hydroformylation, Single atom catalyst.

**Introduction.** The steady increase of $CO_2$ in the atmosphere owing to the excessive use of fossil fuels is seriously threatening the future of humankind by accelerating climate change. Among the proposed a carbon capture and utilization options, catalytic $CO_2$ hydrogenation is attractive because the process is very similar to the well-established CO hydrogenation. The $CO_2$ hydrogenation process usually involves two consecutive steps: the reverse water−gas shift (RWGS) and subsequent CO hydrogenation reactions. In $CO_2$ hydrogenation over Fe-based catalysts, the $Fe_3O_4$ phase catalyzes the RWGS reaction, and its reduced form, the Hägg iron carbide ($\chi$-$Fe_5C_2$) phase, provides active sites for CO hydrogenation and chain growth. $CO_2$ hydrogenation can produce a wide variety of products, including methane, light olefins, and heavier ($C_{5+}$) hydrocarbons. Gaseous by-products produced by $CO_2$ hydrogenation reaction contain large amounts of light olefins and paraffins ($C_2$–$C_4$). Hydroformylation not only simplifies the separation process by converting only olefins to liquid aldehydes and alcohols but also produces high-value-added chemicals with high commercial value. The newly developed Rh/$CeO_2$-$Al_2O_3$ single atom catalyst was applied to upgrade the off-gas generated from $CO_2$ hydrogenation by performing hydroformylation using a olefin/paraffin mixed gas.

**Results and discussion.** Monodisperse nanoparticles (NPs) of $CoFe_2O_4$ were synthesized as efficient catalyst precursors for $CO_2$ hydrogenation to produce high value-added $C_2$–$C_4$ olefin products. The resulting Na-promoted $CoFe_2O_4$ catalysts supported on carbon nanotubes (Na−$CoFe_2O_4$/CNT) exhibited high $CO_2$ conversion (~34%) and light olefin selectivity (~39%), outperforming other reported Fe-based catalysts under similar reaction conditions. Their performance was superior to that of single-metal NP catalysts (Na−$Fe_3O_4$/CNT and Na−Co/CNT) and a physically mixed (Na−$Fe_3O_4$ + Co)/CNTcatalyst.

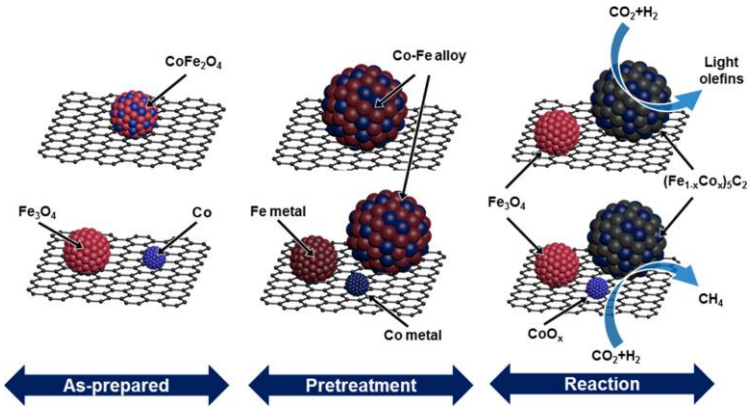

**Fig. 1.** Phase Transformations of $CoFe_2O_4$ NP catalysts during $CO_2$ hydrogenation.

Rh/$CeO_2$-$Al_2O_3$ single atom catalsyts were designed with a tailored Rh electron density as a function of Ce concentration. When 2 wt% of Ce was supported into the $Al_{penta}^{3+}$ sites of γ-$Al_2O_3$ and reduced at 600 °C, $Ce^{3+}$ species with abundant oxygen vacancies promote the formation of highly dispersed Rh single atoms. The highly optimized Rh/$CeO_2$-$Al_2O_3$ single atom exhibited the highest hydroformylation activity comparable to homogeneous Wilkinson's catalyst. Based on the combined analytical results and theoretical calculations, it was demonstrated that the higher the surface $Ce^{3+}$ ratio, the higher the Rh electron density and the lower the CO adsorption strength, which resulted in the high catalytic activity during hydroformylation.

**Keywords:** Methanation, Carbon dioxide, Hydrogen, Renewable energy, Reactor design

**Introduction.** The $CO_2$ hydrogenation ($CO_2+4H_2 \leftrightarrows CH_4+2H_2O$) allows the conversion of renewable $H_2$ into an easily storable and transportable carbon neutral synthetic natural gas ($CH_4$). The high exothermicity of the reaction can be an advantage to speed up the reaction kinetics, but an excessive increase of temperature can lead to thermodynamic limitations and accelerate catalyst aging [1]. In this context, reactor design assisted by modeling can be a very useful tool for the construction of large-scale methanation reactors with efficient heat management [2]. Thus, the aim of this work is to develop and validate a mathematical model that accurately predicts the reactor's performance under different operating conditions.

**Experimental/methodology.** Catalyst composition was 5%Ni/$Al_2O_3$. First, a kinetic study was carried out in an isothermal microreactor with 0.5 g of catalyst diluted with 50% quartz. Experiments were carried out at different temperatures (275-350 °C) with different spatial times ($W/F_{A0}$=2.5-10 g s $mol^{-1}$). Afterwards, experiments were carried out in a quartz reactor (D=9mm; L=25mm) loaded with 1 g of catalyst and placed inside a tubular furnace. The feed gas flowrate was 100 mL/min of $CO_2$ with a $H_2/CO_2$ ratio of 4. Temperature was measured by 6 thermocouples equidistantly placed along the reactor axial coordinate. Gas products at reactor outlet were measured by gas chromatography. Mathematical models with different complexity were built in Matlab, starting from 1D plug-flow (PF) pseudo-homogeneous model, to 2D heterogeneous models, which account for mass and energy transport in both the axial and radial coordinates.

**Results and discussion.** The reaction rate derived from the kinetic analysis was implemented in developed models to simulate the non-isothermal reactor performance. Figure 1 shows the experimental $CO_2$ conversion at the reactor outlet and temperature profile along the reactor with simulated profiles using 1D pseudo-homogeneous models with ideal or non-ideal PF, when gases were fed to the reactor at 300 °C. As can be observed, the ideal PF model is not able to describe experimental data. The consideration of mass and energy transport in the axial coordinate by the non-ideal PF model flattens conversion and temperature profiles with respect to ideal PF model. Heat is dissipated by conduction from the hot spot, which increases the temperature at the reactor entrance (520 °C) and promotes $CO_2$ conversion. After a hot spot (560 °C) located near the reactor entrance (2.5 mm), the reactor dissipates the heat of reaction to furnace surroundings, which reduces temperature and allows the $CO_2$ conversion to grow. $CO_2$ conversion at the reactor outlet and temperature profile are accurately described by the non-ideal PF model for estimated values of k=6 W/(m·K), $D=9\cdot10^{-3}$ $m^2/s$ and U=100 $W/(m^2\cdot K)$. At the operating conditions, heterogeneous models do not predict significant temperature and concentration gradients among gas and solid phases or inside the catalyst particle.

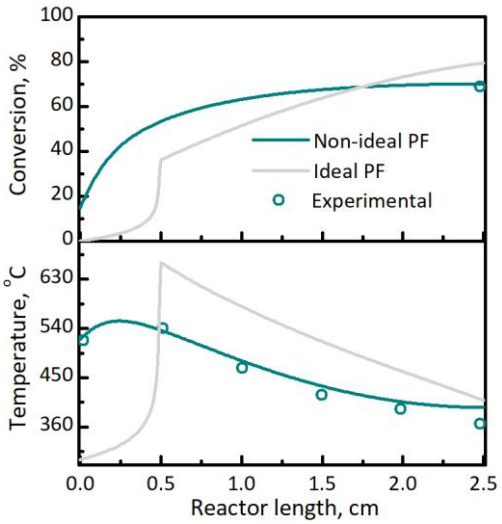

**Figure 1.** $CO_2$ conversion at reactor outlet along with temperature profile.

# Boosting the catalyst stability and activity of Ni/MgO-$Al_2O_3$ with different complexing agents for dry reforming of methane

Santiago S. Gonzalez, Hanan Atia*, Nils Rockstroh, Hendrik Lund, Stephan Bartling, Sebastian Wohlrab, Udo Armbruster

*All at Leibniz-Institut für Katalyse e. V., Albert-Einstein-Str. 29a, 18059 Rostock, Germany*

**Hanan.Atia@catalysis.de*

**Introduction** Reaching the industrial maturity of the dry reforming of methane (DRM; $CH_4+CO_2$ □ $2H_2+2CO$, ΔH=+247 kJ/mol) is challenging due to the lack of effective catalysts being resistant towards sintering and coke formation at the required high temperatures [1]. Closing this gap would possibly rely on the synthesis of robust catalyst based on cheap and abundant elements (Ni, Co) via up-scalable techniques. Hence, we explored the effects of assisting the synthesis of low-loading Ni-based (2.5 wt.%) catalysts with different organic ligands (L) to improve the catalyst stability and activity towards DRM.

**Experimental** In presence of the ligands glycine (Gly), citric acid (CA), ethylenediaminetetraacetic acid (EDTA) and pentetic acid (DTPA) at L/Ni=1.5, low Ni loads (2.5 wt%) were deposited on MgO-$Al_2O_3$ (50:50 wt%) via wet impregnation and subsequent calcination in static air at 800 °C for 6 h. The fresh, *ex-situ* reduced and spent catalysts were characterized (XRD, TPR, XPS, etc). The catalyst tests were performed in fixed-bed continuous flow quartz reactors with stoichiometric feeds ($CH_4/CO_2/N_2$ = 45:45:10 vol%) at high flow rate (GHSV = 170 L/($g_{cat}$·h)). Prior to testing, the catalysts (50 mg) were *in-situ* reduced (700 °C for 1.5 h under $H_2$). The temperature program followed the order 750-700-650-600-750 °C, 4 h each hold. The product gas was analyzed with GC-BID. The outperforming catalysts were subjected to long-term runs at 600 °C.

**Results and discussion** Assisting the catalysts' synthesis with different ligands affected their physicochemical properties and consequently, their performance. The TPR profiles (Figure 1a) showed that the Gly-assisted catalyst was endowed with the highest reduction temperature ($T_{red}$=930 °C), and thus, the strongest metal-support interaction (MSI) among the series. These observations pointed out to an enhanced Ni dispersion [2]. In terms of activity, the Ni(Gly) catalyst stood out at all temperatures. Special attention was paid to the lower temperature range (T=600-650°C), as the reaction is far from thermodynamic limitations but kinetically controlled and at the same time prone to coke formation [3]. Ni(Gly) showed $X_{CH4}$=41% and $X_{CO2}$=57% (Figure 1b and c, respectively) at 600 °C, forming 4.4 wt% coke after 20 h on stream (TOS). Even though Ni(EDTA) produced less coke (1.8 wt% C) than Ni(Gly), the activity of the former ($X_{CH4}$=35% and $X_{CO2}$=52%) was inferior to that of the latter. The above observations suggest that the strong MSI and presumably higher Ni dispersion of the Ni(Gly) catalyst play a crucial role for its notable performance and coke resistance. Within 20 h at varying temperatures and coke formation, the catalysts slightly deactivate.

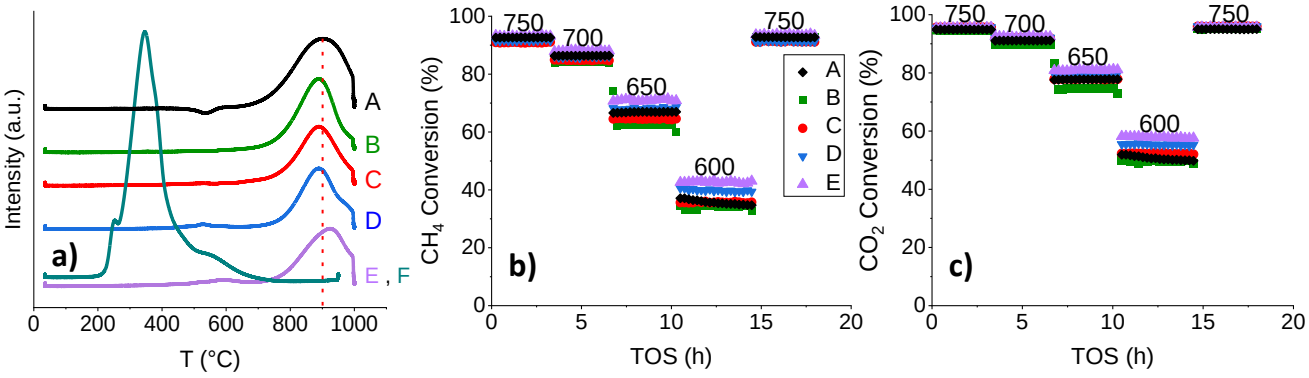

**Figure 1**. a) Temperature-programmed reduction profiles. Conversions with TOS for b) $CH_4$ and c) $CO_2$. The numbers on the top of each step indicates the temperature (in °C). Reaction conditions: P = 1 bar, $m_{cat}$ = 50 mg, GHSV = 170 L/($g_{cat}$·h), $CH_4/CO_2/N_2$ = 45:45:10 vol%. A = Ni/$Mg_{1.3}AlO_x$, B-E = Ni(L)/$Mg_{1.3}AlO_x$ (L= B: CA, C: EDTA, D: DTPA and E: Gly), F = NiO.

$CO_2$ is one of the main greenhouse gases thus reducing its emissions is an important issue. The methanation process, which results in the methane production through $CO_2$ reduction is a potential method to decarbonate industrial effluents. In a Power-to-Gas development, $CO_2$ methanation is a very promising way to use and storage $H_2$, produced by renewable energy into $CH_4$ for which storage and distribution network already exist. In the literature, supported catalysts based on noble metals (Ru, Rh) and on transition metals (Ni, Co) are frequently reported for the use over methanation reaction [1]. In order to obtain efficient catalysts, with similar properties as the noble based catalyst, it is important to produce materials with highly dispersed nanoparticles (NPs) of small sizes, together with improved thermal stability. In methanation reaction, Ni NPs size has a strong influence on the activity and the selectivity towards $CH_4$ production [2]. The aim of this study is therefore, to finely tune NPs size and to confine Ni NPs preferentially either into micro- or mesoporosity within a hierarchical silica type SBA-15. Controlled size nanoparticles generation will allow to investigate the evolution of the activity and selectivity for $CO_2$ methanation.

In the present study, a series of materials containing 10 wt.% Ni were prepared, with the aim of producing NPs of sizes ranging from 3 nm to 12 nm, using suitable methods: Melt Infiltration (MI) of nitrate precursor onto P123-SBA-15 (Ni/MI) and Incipient Wetness Impregnation (IWI) on SBA-15 (Ni/IWI). IWI was also used to prepare a reference catalyst impregnated on commercial $SiO_2$ ($Ni/SiO_2$). The calcined and activated ($H_2$) materials were characterized by XRD, $N_2$-physisorption S/TEM- coupled with EDX mapping, and $H_2$-TPR.

XRD confirms the presence of 9 nm crystallites for Ni/IWI and crystallites smaller than 3 nm for Ni/MI. In addition, microscopy confirms the presence of highly dispersed particles into the SBA-15 porosity (Fig 1a). $Ni/SiO_2$ is revealing presence of large NPs of > 12 nm, probably located at the external surface of the silica. NPs presence into microporosity is revealed by $N_2$ isothermes. TPR indicated the presence of NPs confined in Ni/IWI SBA-15 porosity, and NPs in strongly interaction with silica for Ni/MI. The evolution of the catalytic properties was assessed for the reduced materials over methanation reaction (Fig 1b). Results collected are proving benefit effect of 3 nm NPs by comparison to larger NPs sizes of 9 nm or 12 nm. Ni/MI has superior catalytic activity at low temperatures (yield of $CH_4$ = 93% at 360 °C) due to a higher covering with active sites of the smaller NPs.

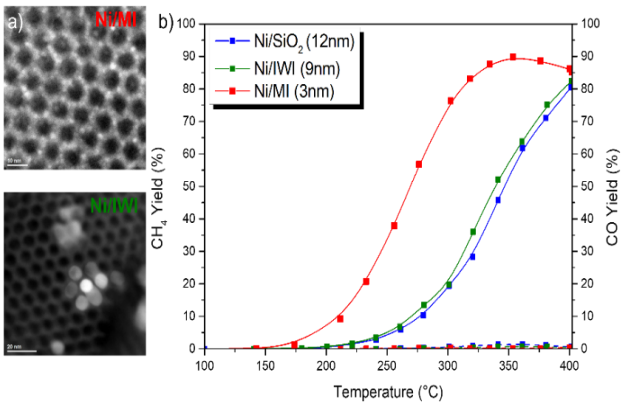

***Figure 1 :*** **a) HRTEM-HAADF for reduced Ni/IWI and Ni/MI b) $CH_4$ and CO yield of Ni/IWI, Ni/Mi and $Ni/SiO_2$**

In conclusion, by controlling Ni based catalysts NPs size the selectivity is oriented toward the production of methane with high yield at 360 °C with high thermal stability.

**Keywords:** carbon dioxide fixation, bifunctional catalyst, Al-porphyrin, silsesquioxanes, carbon nanotubes

**Introduction.** Valorization of $CO_2$ as C1 building block in chemical production is a topic of great interest. Then, synthesis of cyclic carbonates via addition of $CO_2$ to epoxides has received a paramount attention and, in this context, we have been involved in the development of hybrid catalytic systems based on carbon nanoforms or polysilsesquioxanes (POSS) coupled with covalently linked poly-imidazolium salts with or without supported Lewis acids as co-catalytic species.[1-4]

**Experimental/methodology.** Catalytic experiments were carried out using a Cambridge Design Bullfrog batch reactor equipped with temperature control and mechanical stirring. In each test, the catalyst and the proper epoxide (24 mL) were added to a Teflon vial and then the reactor was closed. After passing a flow of $N_2$ for 10 min and loading 25 bar of $CO_2$, the system was left to react at the target temperature reached by a ramp of 5 °C/min. In selected cases, a refill of $CO_2$ was carried out during the experiment. In these cases, the initial pressure of $CO_2$ was never overpassed. After the proper reaction time (3 h or 24 h), the reactor was cooled down to room temperature, depressurized and, then, the catalyst was recovered from the reaction mixture by centrifugation. Each catalyst was dried overnight under vacuum at 60 °C prior to the catalytic test.

**Results and discussion.** Here we report our studies using two different supports (POSS or CNT) modified only with polyimidazolium salt having halides as counterions or modified with polyimidazolium salt/aluminium-porphyrin complex. These materials were prepared following a straightforward synthetic procedure based on polymerization of suitable precursors, then, they were fully characterized. The synergic cooperation between catalyst and co-catalyst moieties was observed when halide/Lewis acid were present. All the materials proved to be recoverable and reusable with high TON, TOF and Productivity values. A peculiar behaviour was observed in the case of polyimidazolium-modified carbon nanoform-modified catalysts that showed an increased activity after recycling, ascribed to a change in their morphology. [3,5].

**Keywords:** methanation, biogas, sorption enhancement, power to gas, fluidized bed

**Introduction.** This work studied the potential application of *Power to Gas Technologies* (*PtG*) for biogas upgrading assisted by water removal. *PtG* can transform gas flows rich in $CO_2$ (such as biogas 70% $CH_4$ and 30%$CO_2$) into methane through Sabatier's reaction. The set-up chosen for the methanation was a fluidized bed reactor filled with a mixture of lab-made Fe-Ni/γ-$Al_2O_3$ catalyst [1] and zeolite 5A as water adsorbent. Fluidized-bed reactor was proposed as alternative to conventional fixed-bed reactors because of its thermal properties, avoiding the generation of "hot spots". In order to improve the fluidization of zeolite 5A ($d_p$: 200-250 µm), gamma alumina particles ($d_p$: 100-160 µm) were also included as fluidizer assistant. It was found an accurate isothermal behavior, elevated conversions of $CO_2$ during the intensification period and high selectivity to methane.

**Experimental/methodology.** Experimental set-up consisted in a fluidized-bed reactor of 7 cm (bed length in repose) thermally monitoring by 5 thermocouples along the bed length (during reaction). Gas inlet was introduced at atmospheric pressure and 570 ml/min STP, in order to ensure the total fluidization. Feeding rate was the stoichiometric $CO_2$:$H_2$ (4:1) and for biogas upgrading the rate $CH_4$:$CO_2$ was a representative sweetened biogas concentration (7:3). Temperature influence in the methanation reaction was tested at different temperatures (250-400°C).

**Results and discussion.** Results from the methanation cycles are showed in Figure 1, were M are the methanation cycles. Between methanations inert gas was introduced in order to regenerate the zeolites, also between M3 and M4 a reactivation step was performed. It was found the positive effect in the $CO_2$ conversion due to including zeolite 5A in the reactor bed (Table 1). Zeolite enhances the first moments of the methanation by its water removal properties, shifting the equilibrium to the products. After the zeolite is saturated the intensification behavior is reduced until showing a stationary conversion value (Fig. 1).

# Catalyst supports based on ceria-praseodymia as oxygen carriers for applications in methane reforming reactions.

L. Herráez-Santos*, A. García-García

*Grupo MCMA, Departamento de Química Inorgánica e Instituto Universitario de Materiales, Universidad de Alicante, Sant Vicent del Raspeig, Alicante, SPAIN*

*lucia.herraez@ua.es

**Introduction.** Both the catalytic reaction of dry methane reforming (DRM) and the reforming reaction of methane with steam using an oxygen carrier (Chemical Looping Steam Methane Reforming), require catalyst supports with very labile oxygen, which actively participates in these reactions, or potentially gasify unwanted carbonaceous deposits that are generated during the dry reforming reaction [1]. In this sense, the development of supports based on ceria-praseodymia mixed oxides with a known high reducibility and capacity to generate a high population of oxygen vacancies and, therefore, with high ability to store and release oxygen, seems appropriate in this context. These oxides will be employed as supports for Ni and Co active phases in order to conduct a preliminary study related to the catalytic dry reforming of methane.

**Experimental/methodology.** As a preliminary study**,** several supports based on ceria-praseodymia have been designed (exploring the full range of composition in Ce/Pr) and characterised to analyse their lattice oxygen under different reaction atmospheres ($H_2$, He and in contact with a carbonaceous compound, which is used as a test reaction to simulate the carbonaceous deposit created under real reaction conditions). The support with the best characteristics was impregnated with nickel and/or cobalt precursors (5% w/w) and subsequently tested for the dry reforming of methane reaction.

**Results and discussion.** Pure praseodymia presents the best features to be used as a support of catalysts in the selected reaction (see Table 1).

**Table 1. Comparison of the level of non-stoichiometry generated after the reduction in different atmospheres.**

| Support | [1]δ | [1]Formula after reduction | [2]δ | [2]Formula after reduction |
|---|---|---|---|---|
| **$PrO_2$** | 0,261 | $PrO_{1,74}$* | 0,332 | $PrO_{1,67}$* |

[1]No stoichiometry and formula reached after reduction under He atmosphere.
[2]No stoichiometry and formula reached after reduction under $H_2$ atmosphere.
*Values close to the theoretical value of the Bevan Cluster ($PrO_{1,71}$-$PrO_2$).

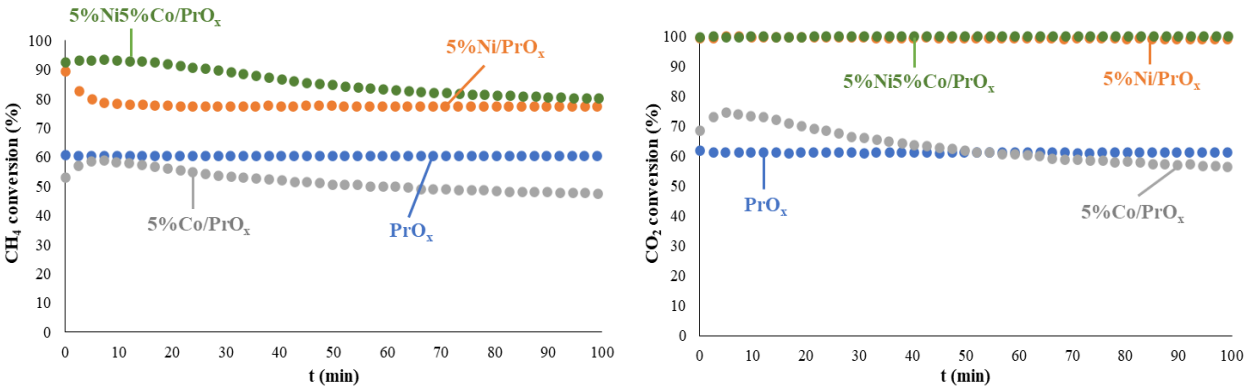

**Figure 1.** $CH_4$ and $CO_2$ conversions versus time. (Conditions of the catalytic tests: pre-reduction under 5%$H_2$/He at 500ºC; flow rate = 40 mL/min and reaction conditions: $CH_4$/$CO_2$/He (4/4/92) at 750ºC, with a flow rate of 60 mL/min, 50 mg catalyst/100 mg SiC).

As can be seen in Figure 1, pure praseodymia seems to be a promising support for this catalytic reaction and the designed catalysts (especially those containing Ni) are characterised by high activity and selectivity, reaching 100% of $CO_2$ conversion.

**Keywords:** metal-organic frameworks, Cu catalysts, $CO_2$ hydrogenation to methanol

**Introduction.** Thermocatalytic $CO_2$ hydrogenation to value-added chemicals and fuels such as methanol is one of the promising approaches for reducing $CO_2$ emissions. As a frontier of catalysis, heterogeneous single-site catalysts have shown excellent catalytic performance in many applications.[1] However, their applications in thermocatalytic $CO_2$ hydrogenation to methanol are rarely reported.[2] In terms of preparing single-site catalysts, MOFs (metal-organic frameworks) with tunable structures, morphologies and compositions hold great potential.[1] Cu-based nanoscale catalysts have been extensively studied due to its low cost and the effective methanol synthesis from $CO_2$ hydrogenation, but still suffer from insufficient activity and stability.[3] Therefore, there is a need to deeply study MOFs-based Cu single-site catalysts for methanol synthesis from $CO_2$ hydrogenation.

**Experimental/methodology.** Zr-based MOF UiO-66 samples were prepared by a solvothermal method. Zirconyl chloride octahydrate, terephthalic acid and acetic acid were dissolved in N,N-dimethylformamide (DMF), and then the mixture was sealed and heated for 18 h. The products are denoted as "UiO-66-L/Mx-AAy-Tz" where x is the molar ratio of ligand to metal precursors (L/M) in synthesis; y represents the amount of acetic acid (AA) added; z stands for synthetic temperature (T).

Cu catalysts supported on UiO-66 or UiO-66-derived $ZrO_2$-C were synthesized by an impregnation and heat treatment method. UiO-66 was added to the solution containing $CuCl_2{\cdot}2H_2O$ dissolved in DMF and then the mixture was sealed and heated at 90 °C for 18 h. The resultant $CuCl_2$/UiO-66 samples were heated under 5% $H_2$/Ar at 300 °C for 3 h or $N_2$ at 600 °C for 3 h to form Cu/UiO-66 or Cu/$ZrO_2$-C, respectively (UiO-66 in Cu/UiO-66-1 and Cu-$ZrO_2$-C-1 is UiO-66-L/M1-AA50-T90, while for Cu/UiO-66-2 and Cu-$ZrO_2$-C-2 is UiO-66-L/M1-AA100-T90). The catalytic performance of these catalysts was tested for $CO_2$ hydrogenation at 230-250-270 °C.

**Results and discussion.** XRD, SEM, TGA and $N_2$ adsorption/desorption isotherms results show that the crystalline, size, morphologies, and defects of UiO-66 can be tuned by changing the synthetic conditions. Among four catalysts, Cu/UiO-66-2 showed both highest methanol selectivity (52%) and productivity at 270 °C of 1324 $mmol_{MeOH}$ $h^{-1}$ $kg^{-1}$ with *ca*. 1 wt. % Cu loading of 0.2 g used in the reaction.

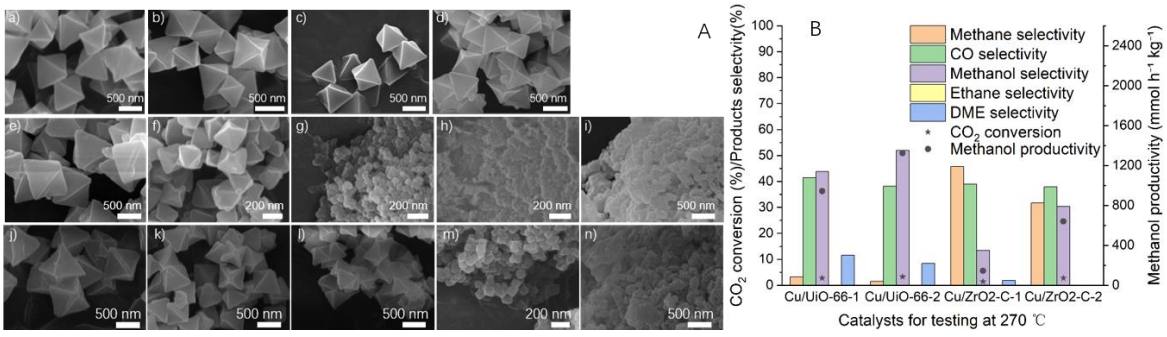

**Figure 1 (A) SEM images of UiO-66 samples under different conditions: (a-d) a, b, c, and d represent 120, 110, 100, 90 °C (L/M=4.6, AA=125 mL); (e-i) e, f, g, h, and i with 100, 75, 50, 25, 0 mL acetic acid (L/M=4.6, T=90 °C); (j-n) j, k, l, m and n with 100, 75, 50, 25, 0 mL acetic acid (L/M=1, T=90 °C); (B) Catalytic results of different catalysts at 270 °C, 20 bar, 30 ml/min ($CO_2$:$H_2$:Ar:$N_2$ 20:50:5:25), 0.2 g catalyst.**

# Investigating the influence of ionic liquids on the visible-light induced photoelectrochemical reduction of $CO_2$

B. Hulaj[1*], D. Apaydin[2], K. Bica-Schröder[1]

**Keywords:** ionic liquid, carbon dioxide valorization, photoelectrochemistry, polymer

Valorization of carbon dioxide is a promising approach that could simultaneously address multiple global issues. Reduced emission to the atmosphere signifies minimized impact on global warming, while the abundant, non-toxic, and renewable nature of $CO_2$ is aligned with the vision for sustainable processes. Nevertheless, the viability of this option requires an efficient catalytic system since the reduction of this greenhouse gas to value-added chemicals is hindered by a high thermodynamic and kinetic barrier [1].

Research on visible light photocatalyzed carbon dioxide reduction revealed that photocatalytic systems consisting of a ruthenium-based photosensitizer and a rhenium-based photocatalyst exhibit high selectivity for carbon monoxide formation. Additionally, electrochemical reduction provides the possibility to control the process by varying the applied potential in a compact set-up [1,2]. Photoelectrochemical reduction of carbon dioxide combines photo- and electrocatalysis towards mutually beneficial interactions. The applied potential can improve the separation of charges, while light irradiation reduces the required overpotential of the electrocatalytic process. Hence, the photocathodes act as both, catalyst and light harvester. Furthermore, past research demonstrated the advantages of ionic liquids as cooperative media, due to their ability to solubilize large concentrations of carbon dioxide and, in specific instances, minimize the required applied potential for the reduction [1]. Consequently, we aim to combine the advantages of these methods into a photoelectrochemical set-up and investigate the influence of ionic liquids on the reduction efficiency of carbon dioxide to carbon monoxide.

Preliminary UV-Vis spectroscopy data, as shown in figure 1, have already confirmed that the synthesized materials combining rhenium, ruthenium and an ionic liquid in a polymer framework show high correlation with reported absorbance values for the corresponding monomers (i.e., $[Ru(bpy)_3][PF_6]$, $Re(bpy)(CO)_3Cl$, and EMIM Br), enabling photocatalytic reduction in the visible-light region above 445 nm [3]. By fabricating a conductive polymer film of these components on a cathode, the reduction can be further enhanced through the applied potential in a photoelectrochemical set-up to determine the optimal reaction conditions.

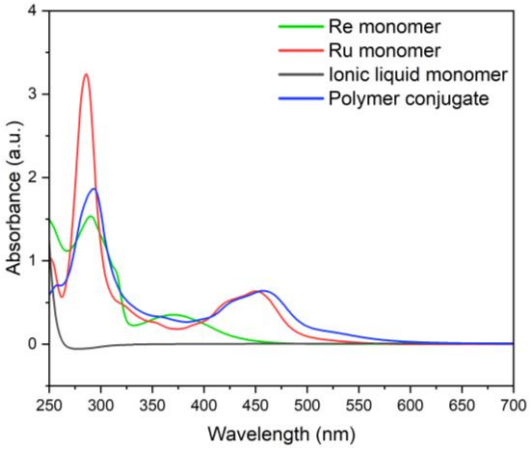

Figure 1 UV-Vis spectra of a Re, Ru and ionic liquid monomer, and a polymeric conjugate of the three monomers

Keywords: Doped ceria, DRM, lattice oxygen, coking, Ni supported catalyst, SBA-15

**Introduction:** The renewed intrest in dry reforming of methane (DRM: $CH_4+CO_2 \leftrightarrow 2CO+2H_2$) reaction is linked to the production of synthesis gas with $CO/H_2$ of unity, which can be used to produce high value-added chemicals and fuels via Fischer-Tropsch (FT) process [1-3]. Additionally, DRM provides a direct route for biomass ($CH_4$: 50–70 % and $CO_2$: 25–50 %). The lack of an economically feasible, stable, and coke resistance catalyst has hinderend the industrialization of this process. Ni-based catalysts offer a cheap alteranative compared to the noble-metal based counterparts as they have a similar catalytic activity. However, coke formation through $CH_4$ decomposition and CO disproportionation are the main reaction routes of carbon formation during DRM [1,3]. Our previous study on Ni/Ce-M-10Cu-O (M = La or Sm) synthesized via enhanced microwave (EMW) synthesis showed that Ni/Ce-La-10Cu catalyst exhibited the lowest carbon formation [6].

**Experimental:** In this study, SBA-15 was used as a carrier of the ceria-doped oxide with different loadings of Ce-La-10Cu-O (X=0%, 10%, 20%, 30% and 40%) and finally the surface was decorated with 5 wt.% Ni. SBA-15 was utilized to highly disperse the ceria and tune its interface with Ni metal, since SBA-15 presents a high internal surface area (400-900 $m^2/g$) and is predominantly mesoporous silica sieve with hexagonal pores and a pore diameter that ranges between 5-15 nm [7].

**Results and discussion:** A suite of analytical techniques was used to get an insight on the catalyst structure and undertand how this links with the performance. Powder XRD, BET, HAADF-STEM, SAED, EELS, elemental mapping, Raman, $CO_2$-TPD, $H_2$-TPR, $H_2$-TPD and Solid State NMR were employed to characterize the complex multi-elemental composition of the catalysts. XRD and Raman results (X>20%) confirmed the cubic flourite stucture of ceria and the mesoporous structure of SBA-15 as well as the presence of oxygen vacancies in the catalyst. Solid state NMR was used to probe the formation of Si-O-M bond and the anchoring of the ceria phase onto the silica matrix. $H_2$-TPD studies showed that 5%Ni/30%CeLa10Cu-SBA-15 catalyst had the highest Ni dispersion (%) and the smallest Ni size amongst all the catalysts; this corroborates with the higher $CO_2$ and $CH_4$ conversion rates compared to the rest X% CeLa10Cu promoted catalysts. HR-TEM showed the dispersion of Ni and Ce-La-10Cu-O, some areas exhibited Cu exsolution resulting in NiCu alloying specially in the case of 30% and 40% CeLa10Cu loading. The catalyst with the highest CeLa10Cu loading (40%) showed the highest coke balance (%) after 12h time on DRM stream, which can be linked to the oxygen storage capacity of ceria that gasifies carboneous species. However, it exhibited the lowest $CH_4$ and $CO_2$ conversion. Stability tests (DRM: 20%$CH_4$/20%$CO_2$/He, 100h) performed on the best performing catalysts, namely, 5% Ni/ SBA-15 and 5% Ni/30%CeLa10Cu-SBA-15 catalyst showed a monotonic decrease in coversions rates. Whereas, the conversion rates reached a plateau after approximaitly 40h in the case of the latter catalyst (5% Ni/30%CeLa10Cu-SBA-15).

Keywords: Doped ceria, DRM, lattice oxygen, coking, Ni-Co bimetallic catalyst, chitosan, DFT

**Introduction:** The resurging intrest in dry reforming of methane (DRM: $CH_4+CO_2 \leftrightarrow 2CO+2H_2$) reaction compared to other reforming processes such as steam refirming and partial oxidation is due to the fact that DRM eliminates two main green house gases ($CH_4$ and $CO_2$) [1,2]. Consequently, providing an alternative for $CO_2$ capture, utilization and recycling [3]. Furthermore, the syngas produced is close to unity making it ideal for the Fischer–Tropsch industry [2, 4-5]. However, $CH_4$ decomposition and CO disproportionation are the main reaction routes of carbon formation during DRM which are the main contributors of catalyst deactivation [4].

**Experimental:** In this study the optimization of the CeLa10Cu support was performed attempting its synthesis using chitosan and different precipitating agents so to introduce mesoporosity; the CeLa10Cu support with the highest porosity support was used as a carrier of a bimetallic (NiCo) catalyst. Namely, 5 wt.% Ni/CeLa10Cu, 5 wt.% Co/CeLa10Cu, 4.5 wt.% Ni-0.5 wt.% Co/CeLa10Cu, and 2.5 wt.% Ni-2.5 wt.% Co/CeLa10Cu. Alloying of Ni with Co is anticipated to decrease the size of the Ni ensemble and thus to inhibit the formation of carbide and graphite in the reforming reactions. DFT modelling of Ni(111) surface and NiCo(111) surfaces were presented and compared with the experimental results.

**Results and discussion:** The prepared catalysts were charactarized via a range of techniquies namely XRD, BET, HAADF-STEM, SAED, EELS, elemental mapping, XPS, Raman, $CO_2$-TPD, $H_2$-TPR, $H_2$-TPD. Raman and XRD confirmed the cubic fluorite structure and some heterogeneous phases. Based on the XPS opposite direction peak shifts and HR-TEM images, the formation of NiCo and NiCu bimetallic alloy could be suggested. This could lead to an achieved ensemble size control that ultimately can give rise to decreased carbon formation during DRM. Additional verification of the bimetallic species formation came also from the reducibility profiles of the catalysts. The use of sacrificial template (chitosan) successfully increased the surface area of CeLa10Cu support compared to the same ternary metal oxide support synthesized via EMW reported in [7]. DFT modelling performed on NiCo(111), showed weaker adsorptions for CHx (x=1-4) species, precursors of coke, compared to the Ni(111) surface alone. This is consistent with the reports that weaker C binding suggests a higher surface mobility that lessen carbon deposits over NiCo. Again, the relatively higher CO and O adsorption energies on NiCo (111) compared with Ni(111) surface is expected to facilitate more the DRM reaction while simultaneously decreasing coking. This was also observed in the catalytic studies, where the Ni monometallic (formation of NiCu alloy) and NiCo (4.5 wt. %:0.5 wt.%) bimetallic catalysts supported on CeLa10Cu showed the best catalytic performane towards DRM amongst the other catalysts. The latter catalysts exhibited superior stability over prolonged period of time (DRM: 20%$CH_4$/20%$CO_2$/He, 100h) compared to other catalysts.

# Cu-based catalyst deactivation in methanol synthesis by water presence

L. Azancot*, L. Lefferts

*Catalytic Processes and Materials, University of Twente, Enschede, The Netherlands*
**l.azancot@utwente.nl*

**Keywords:** $CO_2$ hydrogenation, Methanol synthesis, catalyst deactivation, $Cu/ZnO/Al_2O_3$ catalysts.

**Introduction**

The reduction of $CO_2$ concentration from the atmosphere is the most relevant challenge for society. For this reason, the researchers and industry have highly emphasised in the study of $CO_2$ reduction, focusing on $CO_2$ storage and transformation by catalytic processes to liquid fuels or other valuable chemicals. In this way, direct $CO_2$ hydrogenation to methanol is a promising alternative on a large scale.
The methanol synthesis by $CO_2$ hydrogenation (Eq. 1) is an exothermic reaction that, based on thermodynamic equilibrium and Le Chatelier's principles the reaction must work at high pressure and low temperature [1].

$$CO_2 + 3H_2 \leftrightarrow CH_3OH + H_2O \quad \Delta H_{298\,K} = -49.5 \text{ kJ mol}^{-1} \quad \text{(Eq. 1)}$$

$$CO_2 + H_2 \leftrightarrow CO + H_2O \quad \Delta H_{298\,K} = 41.2 \text{ kJ mol}^{-1} \quad \text{(Eq. 2)}$$

The water-induced deactivation is an almost unavoidable issue playing a significant drawback in the process, provoking premature catalyst deactivation [2]. The water is produced by the oxygen removal from $CO_2$, and the reverse Water Gas Shift (rWGS) reaction (Eq. 2) that is thermodynamically favoured under methanol synthesis conditions [3].

The use of Cu-based catalysts for $CO_2$ hydrogenation is extensive due to is considered a low-cost catalyst. The industrial $Cu/ZnO/Al_2O_3$ catalyst is widely studied for methanol synthesis from syngas or direct $CO_2$ conversion, nevertheless presents a significant deactivation over time in industrial conditions [4,5]. It is crucial to understand the structural catalyst surface evolution over time and insight into the deactivation causes. An important task that is still under debate that providing different opinions. In this context, this work is focused on the catalyst properties changes during the methanol synthesis reaction using a commercial $Cu/ZnO/Al_2O_3$ catalyst.

# Stability promotion of Ni foam catalysts for dry reforming of methane

A. Choya[1*], B. de Rivas[1], J.I. Gutiérrez-Ortiz[1], R. López-Fonseca[1]

[1]*Chemical Engineering Department, Faculty of Science and Technology, University of the Basque Country UPV/EHU, E-48940, Leioa, Spain*

**Keywords:** dry reforming, nickel, ceramic foams, stability, coke

**Introduction**

The dry reforming of methane (DRM) reaction is a very promising catalytic process to produce syngas, using greenhouse gases as feedstock, which can then be used to synthesise valuable chemical and fuels [1]. Catalysts derived from the $NiAl_2O_4$ spinel have demonstrated a promising performance for the DRM reaction due to the strong metal-support interaction [2]. Further, the incorporation of this type of materials on a structured support, such as a ceramic foam, can allow for the efficient operation under high space velocities and moderate temperatures. However, the main drawback of this technology is the favoured formation of carbonaceous deposits on the catalyst surface, which strongly affects catalyst durability [3]. Thus, in this work, we study the promotional effect of $La_2O_3$ over the stability of a $NiAl_2O_4$-mediated nickel catalyst supported over ceramic open cell foams.

**Experimental**

The foam catalysts were synthesised by solution combustion synthesis. The $\alpha$-$Al_2O_3$ foams were submerged for 5 min in a solution of glycine (fuel) and nickel, aluminium and lanthanum nitrates. The concentration of nitrates was adjusted to obtain a stoichiometric $NiAl_2O_4$ phase with a concentration of La in the 0-10%wt. range. Then, the impregnated foams were placed in an oven at 300 °C for 30 min to start the combustion reaction. The impregnation/combustion cycle was repeated 4 more times to deposit a total metallic loading of 10%wt., and then the coated foams were calcined at 850 °C for 4 h. The catalysts were characterised by XRD and $H_2$-TPR and tested in a bench-scale reactor at 700 °C for 72 h. The reaction feedstream was composed of 10%$CH_4$/10%$CO_2$/80%$N_2$ with a space velocity of 96,000 $h^{-1}$. Prior to the reaction the calcined foams were subjected to reduction with 5%$H_2$/$N_2$ at 850 °C for 4 h.

**Results and discussion**

The characterisation of the calcined foam catalysts by XRD only detected signals attributable to the ceramic matrix of the foam and a phase of $NiAl_2O_4$. No signals associated with segregated $La_2O_3$ were observed, which pointed out a good dispersion of this promoter. After reduction, the $NiAl_2O_4$ precursor converted into Ni crystallites with an average size around 10 nm. The analysis by $H_2$-TPR did not evidence differences in the reducibility of the $NiAl_2O_4$ spinel with the La loading. Also, the quantification of the $H_2$ uptake evidenced that more than 90% of the deposited Ni was in the form of $NiAl_2O_4$, with very low amounts of segregated NiO. The evolution of $CH_4$ conversion with time on stream (Figure 1) of the freshly reduced samples evidenced a promotional effect of the added La on the catalyst stability. Hence, the La-free sample suffered a dramatic loss of activity after 60 h, while the La promoted catalysts were able to operate for the whole 72 h interval with a constant conversion of 58-63%. After the reaction runs, direct gravimetry of the unpromoted spent catalyst revealed a coke generation of 1.47 $g_C$ $g_{CAT}^{-1}$ , in line with its drastic deactivation. Conversely, coke formation for the La promoted catalysts ranged between 0.40 $g_C$ $g_{CAT}^{-1}$ for the 6La sample, which exhibited almost no activity loss, and 0.90 $g_C$ $g_{CAT}^{-1}$ over the 10La sample, which suffered a significant conversion loss at the start of the run.

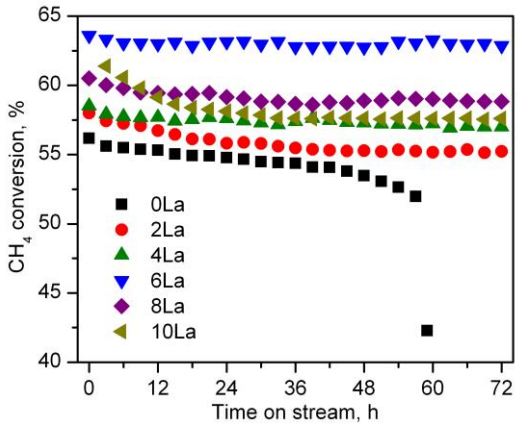

**Figure 1. Evolution of $CH_4$ conversion with time on stream at 700 °C.**

# Direct Alcohol Synthesis Over Cu-zeolite Catalysts

D. Iltsiou[1*], J. Mielby[1], S. Kegnæs[1]

[1]*Department of Chemistry - Technical University of Denmark, Lyngby, Denmark*
**dimilt@kemi.dtu.dk*

**Keywords:** catalysis, zeolites, hydrogenation

**Introduction.**

As an inexpensive, abundant and non-toxic, renewable carbon source, the use of $CO_2$ has received a great interest in many areas. Lately, the focus of researchers is the production of fuels and high-value-added chemicals such as alcohols, throughout the hydrogenation of $CO_2$. Among alcohol products, ethanol attracts great attention due to its notable energy density and current engine knowledge. However, the conversion of $CO_2$ to ethanol has been difficult, due to the presence on the catalyst of various functional groups and the high energy barrier of the C-C coupling [1]. Therefore, the development of novel stable heterogeneous nanoparticle catalysts, for the selective production of ethanol directly from $CO_2$, is of great importance. Zeolites are the most widely used industrial heterogeneous catalysts. They are classified as aluminosilicate materials with intracrystalline pores and cavities of molecular dimensions. The catalytically active sites in zeolite micropores can be acid sites that result from the charge compensation of the framework with protons, which is necessary when e.g. $Al^{3+}$ substitutes $Si^{4+}$ in the framework. Alternatively, it can also be redox active sites resulting when the charge compensation is done with redox active ions such as Cu(II), rather than with protons [2].

**Experimental/methodology.**

Here we report the synthesis and encapsulation of three different zeolite frameworks, with metal nanoparticles, through the interzeolite transformation of FAU [1]. The different zeolite-based catalysts were tested under high pressure continues flow conditions in order to optimize the selectivity for ethanol. We have shown that, the structure of the zeolite framework has great influence on the catalytic activity. All the obtained materials were characterized using IR, XRD, BET, TEM and ss-NMR [1]. Figure 1 shows the different zeolite frameworks used, as well as an illustration of the flow reactor.

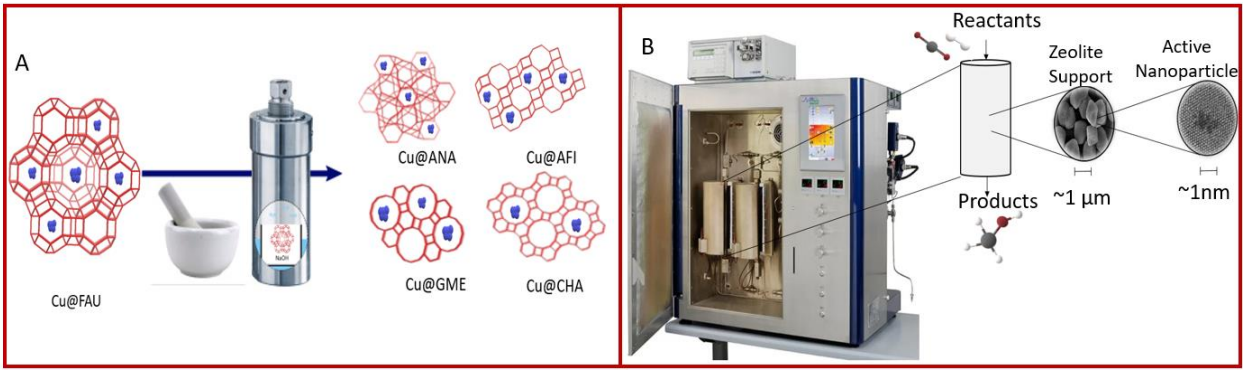

**Figure 1. Overview of the zeolite synthesis and the formation of ethanol from $CO_2$ in a flow reactor.**

**Keywords:** Colloidal Synthesis, Ligand Removal, Operando Spectroscopy, Nickel, $CO_2$ methanation

**Introduction.** $CO_2$ methanation over supported Ni catalysts has recently attracted much attention for energy storage and grid stabilization. Better catalysts with accurate size control are needed since $CO_2$ methanation was found to be structure sensitive with an optimal activity at 2-3 nm Ni particle size.[1,2] Here, we have employed colloidal synthesis to precisely and independently tune Ni nanoparticle size, catalyst weight loading and support type. We report a colloidal synthesis method using novel phosphine-free ligands capable of yielding Ni NPs sized below 3 nm, which is smaller than reported before in literature.[3] Ligand removal is neccesary to allow surface access during catalysis, but has proven challenging since harsh oxidative treatments can cause the Ni NPs to sinter.[3] Here, we present a chemical method for ligand removal, which does not require heating and maintains the pristine Ni NP size.

**Experimental/methodology.** Ni NPs were synthesized by injection of a borane tert-butylamine solution into a toluene solution of Ni(acetylacetonate)$_2$ and benzonitrile or mesitylamine as ligand. The Ni NPs were supported on silica and treated with triethyloxonium tetrafluoroborate (Meerwein's reagent, MR) to remove the ligands. Reduction of the Ni/$SiO_2$ powder at 550 °C, yielded the final catalyst material.

**Results and discussion.** By optimization of several synthesis parameters, such as reaction temperature, type of ligands, and equivalents of ligands and reducing agents, we obtained Ni nanoparticles in sizes ranging from 1.4–6.6 nm (Figure 1A). To remove the ligands, the Ni/$SiO_2$ catalysts were treated with MR, which is thought to alkylate the coordinating N moiety of the ligands (Figure 1D), rendering them unable to bind to the Ni surface. DRIFTS was used to follow the ligand removal process. In Figure 1B the vibrational features of the original ligands are shown, while after the treatment these signals are not longer present (Figure 1C, red box). However, large peaks belonging to Si-ethoxy groups are present between 2800–2900 $cm^{-1}$. By applying a reduction step these ethoxy groups were removed, yielding an active $CO_2$ hydrogenation catalyst. The catalytic $CO_2$ hydrogenation activity per Ni surface atom increases by particle size to an apparent plateau (Figure 1E, red; "hockey stick plot"), in contrast to the sharp optimum at ~ 2-3 nm reported in our earlier work for Ni/$SiO_2$ catalysts (Figure 1E, dark-blue).[1,2] A potential explanation is a decrease in the number of defect sites, which were responsible for the maximum in TOF reported earlier.[4]

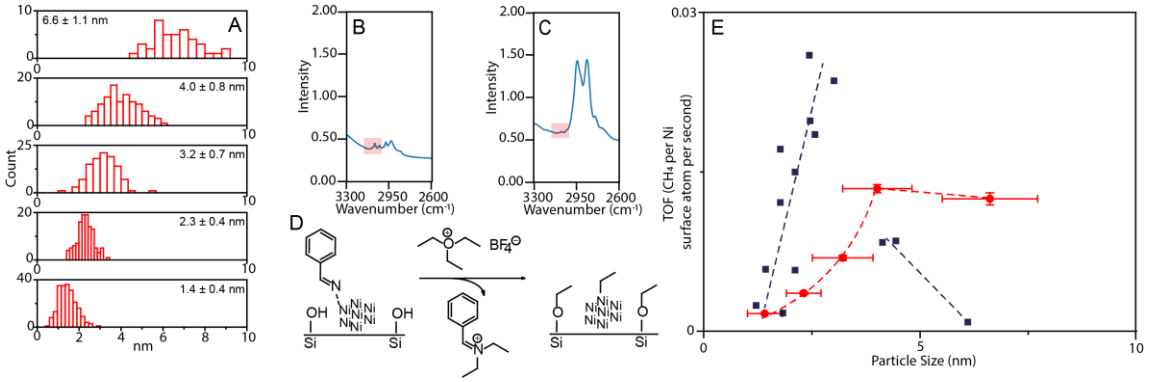

Figure 1: A: Ni nanoparticle diameter distribution based on TEM from various syntheses. B,C: DRIFTS spectrum of Ni/$SiO_2$ with (B) original ligands or (C) after ligand removal. D: reaction scheme of ligand removal procedure. E: TOF for different mean particle sizes of colloidal-based (this work, red) and deposition-precipitation (dark-blue, previous work) Ni/$SiO_2$ catalysts in $CO_2$ hydrogenation towards methane.[1,2] The dotted lines are intended as a guide to the eye.

**Keywords:** methanol synthesis, copper, zinc, active site, SSITKA

**Introduction.** Copper-based catalysts are widely studied for $CO_2$ hydrogenation to methanol, especially Cu/ZnO catalysts which have received attention due to their commercial relevance in the syngas to methanol process. Different active site configurations have been proposed, such as: (i) $Cu^+$ sites on ZnO, (ii) $Cu^0$ sites on ZnO (interface) and (iii) CuZn alloy [1,2]. Despite the many studies that have been carried out on Cu/ZnO catalysts, there are still some scientific questions that have not been answered, such as the effect of Zn content on the nature of the active sites and the mechanism. Here we study the role of ZnO on the Cu surface and how the nature of these sites varies as the Zn concentration varies.

**Experimental/methodology.** Silica-supported Cu and Cu/Zn catalysts were prepared by incipient wetness impregnation method. They were characterized by ICP-OES, HR-TEM, *in situ* XRD, $N_2O$-titration, IR-CO titration (low temperature), $H_2/D_2$ isotopic exchange and *quasi-in situ* XPS (before and after reaction). The $CO_2$ hydrogenation was carried out in a fixed bed reactor at 220-280°C, 8 bar, $H_2/CO_2$=3 and 1.67 $cm^3\ g_{cat}^{-1}s^{-1}$. SSITKA-DRIFTS experiments were performed in a low volume *in situ* cell at 220°C, $H_2/CO_2$=7, 3 bar and 6.3-12.5 $cm^3\ g_{cat}^{-1}s^{-1}$.

**Results and discussion.** CO adsorption shows that $Cu/SiO_2$ catalyst present a mainly metallic Cu surface after reduction, while the CuZn(0.01) catalyst presented a variety of surface sites, mainly composed of $Cu^0$, $Cu^+$ and CuZn alloy. However, CuZn(0.20) presented only $Cu^0$ and $Cu^+$ type sites, indicating that these Zn loads do not favor the formation of CuZn alloy type sites (Fig. 1a). In addition, a correspondence was found in the behavior of TOF to methanol with the superficial molar ratio Zn/(Cu+Zn), while $TOF_{CO}$ was adjusted to the Cu content on the surface (Fig. 1b). Zn was found to further promote restructuring of the metallic copper surface when exposed to highly reducing conditions. The SSITKA-DRIFTS experiments revealed, for CuZn(0.01), the formation of highly active sites for CO (Fig. 1c), while for methanol it is only favored by an increase in the number of sites. However, on the CuZn(0.20) catalyst, a 50% reduction of the CO sites was found and an increase of up to almost double the number of methanol sites with respect to the non-promoted catalyst (Fig. 1c), which corresponds to the transformation of active sites to CO on active sites of methanol. In addition, in this catalyst, formate species were identified that proved to be reactive intermediates in the reaction. According to the different chemical states of the surface and the characteristic active sites of each catalyst, a reaction mechanism was proposed that includes the possible reaction pathways that Zn-promoted Cu catalysts can follow.

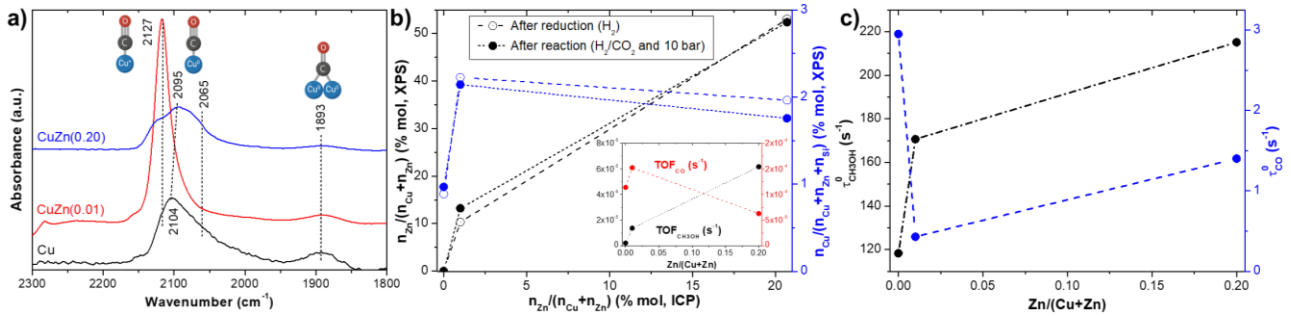

**Figure 1.** (a) IR spectra of CO adsorption at -160 °C. (b) Surface quantification by XPS: after reduction (empty symbols) and after reaction at 10 bar (full symbols). Small graph its relationship with the methanol and CO formation. (c) Corrected residence time of methanol and CO intermediates as a function of Zn content, determined by SSITKA.

# Mixed metal oxide and zeolite catalysts for carbon dioxide conversion to olefins: A small pore zeolite exploration

Ahmed Sajid[1], Julien Devos[1], Cedric Aelbers[1], Ibrahim Khalil[1], Michiel Dusselier[1*]

[1]*Center for Sustainable Catalysis and Engineering, Celestijnenlaan 200F, KU Leuven, 3000 Leuven, Belgium*
[*]*Michiel.dusselier@kuleuven.be*

**Keywords:** $CO_2$ hydrogenation, small pore zeolites, olefins, methanol

**Introduction:** Combining mixed metal oxides and zeolite catalysts is well known for $CO_2$ conversion to olefins (CTO) via methanol [1,2]. The process occurs via 2 steps in which the difference in the optimum operating temperatures is significant. The hydrogenation of $CO_2$ to methanol occurs on the metal oxides typically at 250-300 °C, while the further conversion of methanol into olefins (MTO) takes place over the zeolites, usually at $T \geq 375$ °C [2]. Thus, to improve the efficiency of CTO, the temperature gap must be reduced either by developing new metal oxides with higher operating temperatures (Zn, Zr, Ga, In, Cr), while keeping selectivity for CO minimal; or zeolites with high MTO performance at lower temperatures [1]. In this work, we investigated self-made small pore zeolites [3] in combination with an optimised $ZnZrO_x$ catalyst for $CO_2$ conversion to olefins. Next to the effect of lattice type, the effect of phyisicochemical zeolite properties such as Al content, acidity, Al speciation, and cation content will be investigated.
**Experimental/methodology:** $ZnZrO_x$ was synthesized by co-precipitation method, using $ZrO(NO_3)_2$ and $Zn(NO_3)_2$ precursors, while interzeolite conversion was utilized for zeolite synthesis. Physico-chemical properties of the catalysts (acidity) as well $CO_2$ and $H_2$ adsorption capacity by TPD were measured. Crystallinity and surface area of the $ZnZrO_x$ and zeolites were detremined by using X-ray diffraction and $N_2$ physisorption. The activity of the granular-mixed metal oxide and zeolite catalyst was measured in continuous reactor at $P$ = 40 bar, $T$ = 340-380 °C, GHSV = 18000 $ml.g_{cat}^{-1}.h^{-1}$, $H_2/CO_2$ ratio of 3.
**Results and discussion:** Figure 1 demonstrates high space time yield (STY) for products derived via MeOH ($STY_{MeOH + DME + olefins + paraffins}$). In comparison, MeOH production for the bare $ZnZrO_X$ only mounts to 11 $mol_{MeOH}$ $kg_{cat}^{-1}.h^{-1}$ (@ 360°C). This demonstating that the equillibrium is shifted towards the product side, despite the dilution of metal oxide catalyst by zeolites (2 oxide/1 zeolite). For the family of CHA (SSZ-13) zeolites, partial cation exchange ($Mg^{2+}$) slightly improved propylene selectivity, while AEI frameworks (SSZ-39 and SAPO-18) showed great potential. A structure-performance map for different zeolites will be shown.

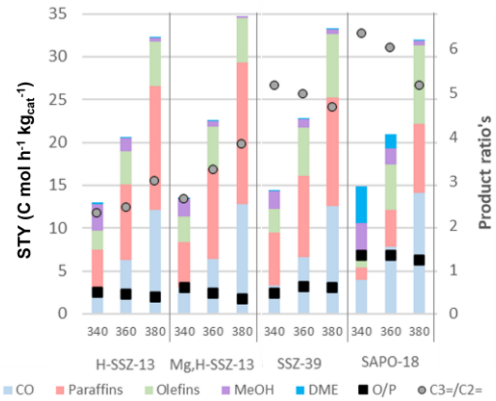

**Figure 1: Activity (STY, per gram catalyst) and product distribution of ZnZrOx in tandem with different zeolites.**

**Keywords:** Metal-Organic Frameworks(MOFs), $CO_2$ hydrogenation, Fischer-Tropsch synthesis(FTS)

**Introduction.**

Productions of fuel-grade hydrocarbons by $CO_2$ hydrogenation and CO hydrogenation included in syngas are very interesting topics for carbon capture and utilization (CCU). There are two possible routes for $CO_2$ hydrogenation reaction by using cobalt-based catalysts. One method is the formate pathway where main active sites are metal oxides which mainly produce methane [**1**]. By using the cobalt-based catalysts, $CO_2$ methanation reaction is also followed by formate pathway. The other route is reverse water-gas shift (RWGS) reaction route where the main active sites are metallic phases, which forms CO to successively be utilized for Fischer-Tropsch synthesis (FTS) reaction. By using the iron and cobalt-based bimetal catalysts, hydrocarbons are synthesized by $CO_2$ hydrogenation reaction through the second reaction pathway. Iron-cobalt bimetal catalysts can be prepared by using metal-organic frameworks (MOFs) as well. Since the metallic cobalt nanoparticles have a lot of advantages such as higher RWGS activity and higher $CO_2$ hydrogenation to light hydrocarbons, the adjustment of long chain hydrocarbons ($C_2$ - $C_4$ and $C_{5+}$) can be controlled by introducing iron metal precursors during the MOF-derived catalysts preparation.

**Experimental/methodology.**

Iron nitrate nonahydrate, cobalt nitrate hexahydrate and terephthalic acid were well mixed at the ratio of x:1:2 in the solution, which was mixed with N,N-Dimethylformamide (DMF) and triethyl amine (TEA). (where x = 5, 3, 2, 1) After stirring and filtering, the successive washing step was performed with DMF and dried at 40 °C. As-prepared brown color powders were obtained and its was denoted as $Fe_xCo_1$-BDC. For pyrolysis step, well-made catalysts was pretreated at 600 – 900 °C on $N_2$ atmosphere. And its was named as $P_y$-FeCo – BDC (y = pyrolysis temperature, 600 – 900 °C)

**Results and discussion.**

Catalytic performances of each catalyst were displayed in **Figure 1.** Different activities were observed in terms of $CO_2$ conversion, CO selectivity, and hydrocarbons selectivity as well. Increased conversion and decreased CO selectivity were attributed to the cobalt metal contribution as well as increased hydrocarbons and decreased methane selectivity were mainly attributed to the iron carbides phases.

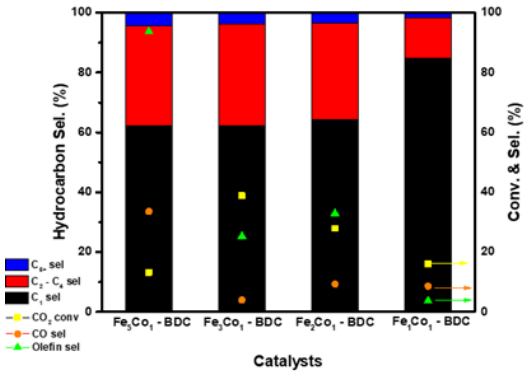

**Fig. 1. Catalytic activity of $Fe_xCo_1$ – BDC (x = 5, 3, 2, 1 for molar ratio between iron metal and cobalt metal precursor)**

**Keywords:** Double metal cyanide complex catalyst, $CO_2$ chemical utilization, $CO_2$ Polyol, Rheology

**Introduction**

Carbon dioxide ($CO_2$) is being generated from many industrial operations, and it is recognized as the major component for global warming. Therefore, Carbon Capture and Utilization (CCU) technology is being offered as a solution to this problem. An interesting strategy appears to be the direct chemical use of $CO_2$ as a co-monomer in polymerization reactions to produce value-added materials [1]. Polyols, which have two or more hydroxyl groups per molecule, are the major raw material for polyurethane foams (PUFs) [2]. The catalytic copolymerization reaction of propylene oxide (PO) and $CO_2$ produces polycarbonate (PC) polyol or poly(propylene) carbonate (PPC) polyol depending on the catalysts [1]. The PC polyol is difficult to employ to prepare flexible PUFs due to its technical limitations such as high glass transition temperatures ($T_g$) and high viscosity at ambient temperature [1,3]. On the other hand, PPC polyol can be produced over the Double Metal Cyanide (DMC) catalysts, which has a favorable $T_g$ and low viscosity [4]. Thus, we investigated the effect of carbonate content on the rheological behavior of $CO_2$-based polyol to find affordable content for manufacturing flexible PUFs.

**Experimental/methodology**

DMC catalysts were prepared with $ZnCl_2$ as a metal salt and $K_3[Co(CN)_6]$ as a metal cyanide salt in the presence of P123 as a complexing agent. Copolymerization of PO with $CO_2$ was carried out in a 450 mL high-pressure reactor at 115 °C. PPG-1000 was used as an initiator for copolymerization. The reactor pressure maintained by using $CO_2$ from 5 to 25 barg. After purifying the polyols to remove cyclic propylene carbonate (cPC), the rheological properties with respect to the carbonate contents were analyzed.

**Results and discussion**

The calcination temperature of the DMC catalyst was optimized to increase catalytic activity. Among them, DMC-P123 catalyst calcined at 100 °C showed the highest productivity and the shortest induction period mainly due to the formation of monoclinic structure of the catalyst. The carbonate contents ($F_{CO2}$) in the polyols over this catalyst were controlled by altering the reactor pressure (Fig. 1a). The viscosity of PPC polyols tended to increase along with their carbonate content (Fig. 1b). This result demonstrates that the carbonate groups in the polyols create greater interaction between them and provides crucial information on choosing $CO_2$-based polyols for flexible PUFs.

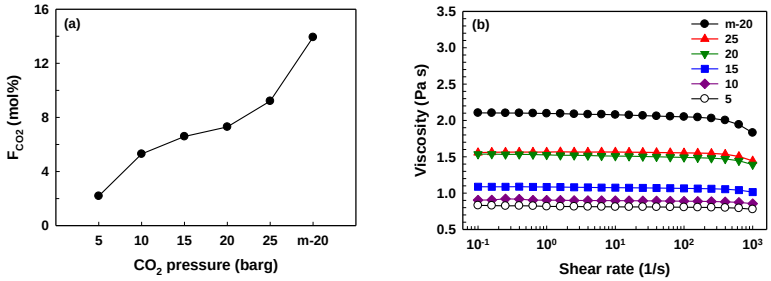

**Fig. 1. Effect of reactor ($CO_2$) pressure on (a) $CO_2$ mole fraction and (b) viscosity vs. shear rate flow curves of PPC polyols.**

**Keywords:** High Pressure, $CO_2$ reduction, Acetone, Interparticle spacing

**Introduction:** The anthropogenic $CO_2$ emission can be mitigated by developing electrochemical reduction of $CO_2$ ($CO_2$RR) to value-added chemicals and fuels [1]. Several heterogeneous metal and metal oxides-based catalysts have been developed for $CO_2$RR, but it is still a great challenge to improve the current density and Faradaic efficiency (FE) of the single product. In typical aqueous $CO_2$RR, the FE is limited due to the competitive hydrogen evolution reactions (HER). The electrocatalytic performance is improved by increasing supply of $CO_2$ to the cathode compartment. The hydrated $CO_2$ (aq) and $H_2CO_3$ species play a crucial role in $CO_2$RR according to Henry's law. Typically, Sn-based metal oxides at high pressures reveal the selective production of formate/formic acid, an important chemical for large-scale industrial products and processes [2]. The extensive investigation reveals that the exposure of atomic-scale spacing has been demonstrated as an effective approach toward the enhancement of kinetics and mass transport, which results in enhanced product selectivity towards acetone.

**Experimental/methodology:** The LiET(S) $SnO_x$ catalyst was synthesized by the lithiation process, and the structure can be controlled by the galvanostatic discharge voltage which varies with the extent of Li insertion.

**Results and discussion:** A 3D STEM tomography is the technique to determine the precise structure of a sample in atomic-scale resolution. Fig. 1, shows the series of STEM images at certain titled angles and tomographic images. A clear and smooth surface of pristine $SnO_2$ was observed without any significant changes in the structure as seen TEM image and STEM tomography. Furthermore, the formation of disintegrations/defects was confirmed by the TEM and STEM tomography analyses. The application of non-noble Sn-based nanoparticles was synthesized by generating grain boundaries with controlled sub-nanoscale-sized spaces. It has been a great challene to convert $CO_2$ to $C_{2+}$ products using Sn-based catalysts because of the high $CO_2$ activation barrier and C-C coupling. The combination of the confinement effect and high pressure on LiET(S) $SnO_x$, reveals the selective production of acetone (FE ~ 55 %) at high pressure of 100 bar at industrially relevant conditions.

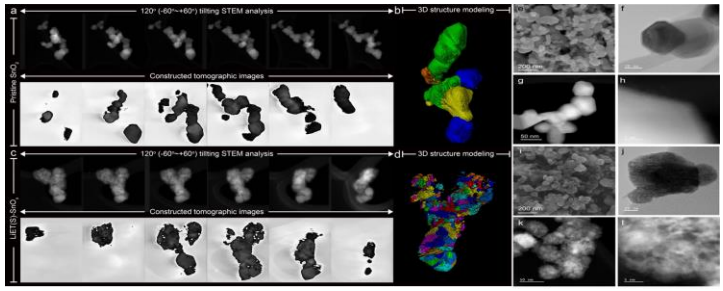

Fig: 1. (a and c) STEM images along 120˚ rotating from -60 to +60˚, 3D STEM-tomography and (b and d) reconstructed 3D structure modeling images of pristine $SnO_2$ and LiET(S) $SnO_x$, (e to h) SEM and TEM images of pristine $SnO_2$ while (i-l) SEM and TEM images of LiET(S) $SnO_x$.

# Effect of $La_2O_3$ and $CeO_2$ Promotion on $CO_2$ Conversion to Methane Using Mesoporous ZSM-5, US-Y and BEA Supported Ni-Catalysts

A. Kızıl[1], B. Ipek[1*]
[1]*Department of Chemical Engineering, Middle East Technical University, Ankara, Turkey*
[*]*bipek@metu.edu.tr*

**Keywords:** $CO_2$ Methanation, Zeolites, Nickel

**Introduction.** $CO_2$ methanation is a promising process that can reduce $CO_2$ emissions. Nickel-based catalysts are economical catalysts; however, Nickel particle size is inversely related to catalytic activity [1], [2]. Zeolites are appropriate supports for $CO_2$ methanation because of their thermal and hydrothermal stability, hydrophilic or hydrophobic characteristics depending on the Si/Al ratio and $CO_2$ adsorption ability due to compensating cations. In addition, they have modifiable pore structure via formation of mesopores, which can potentially prevent sintering of reduced Nickel particles [3]. $La_2O_3$ and $CeO_2$ promotions are reported to improve the surface properties of Nickel-based catalysts, enhancing methanation activity [4]. This study aims to develop mesopores in three different zeolite frameworks, FAU, BEA and MFI, with similar Si/Al ratios to understand the effect of $Na^+$ and $Cs^+$ as compensating cations and $La_2O_3$ and $CeO_2$ as promoters on the $CO_2$ methanation.

**Experimental/methodology.** ZSM-5 was synthesized by hydrothermal method. Consecutive dealumination and desilication were applied using steaming and NaOH treatment to increase the mesopore volume. Beta was obtained commercially. Mesopores on commerical Beta (Thermo Fisher, Si/Al=19) were formed by dealumination using 0.065 M $HNO_3$ solution. Mesopore added US-Y was obtained commercially (Thermo Fisher, Si/Al=40). All samples were ion-exchanged by $Na^+$ and $Cs^+$ using $NaNO_3$ and $CsNO_3$. Nickel and $La_2O_3$ and $CeO_2$ promoters were added using incipient wetness impregnation method. Crystal structure, chemical composition, physico-chemical properties, surface basicity, $H_2$ consumption rates and morphology were analyzed by XRD, ICP-OES, $N_2$ Physisorption, $CO_2$-TPD, $H_2$-TPR and SEM, respectively. The catalytic activity tests were performed in a fixed bed reactor at atmospheric pressure under the flow of $H_2$:$CO_2$ with a 4:1 molar ratio at a constant GHSV of 12500 $h^{-1}$ at 300, 350 and 400 °C.

**Results and discussion.** US-Y, BEA and ZSM-5 having similar Si/Al ratio of 40 with 10 wt% Ni and 2.5 wt% $La_2O_3$ or $CeO_2$, had mesopores after dealumination/desilication, resulting in $Ni^0$ particle sizes of the order of 10 nm. $La_2O_3$ enhanced the total basicity and $CeO_2$ improved $Ni^0$ dispersion by decreasing the $Ni^0$ particle size, both showing improved $CO_2$ methanation activity. US-Y and BEA exchanged with $Cs^+$ and $Na^+$ showed similar $CO_2$ methanation activity; however, $Cs^+$-exchanged ZSM-5 showed very low activity, which may be attributed to 18 nm of $Ni^0$ particle size and pore blockage by $Cs^+$ ions. At 300 °C, Ni-$CeO_2$/$Na^+$-BEA catalyst exhibited the highest $CO_2$ conversion of 83% with 99% $CH_4$ selectivity, having $Ni^0$ particle size of 8 nm. Ni-$CeO_2$/$Na^+$-BEA catalyst was stable for 30 h at 300 °C, and resistant to sintering.

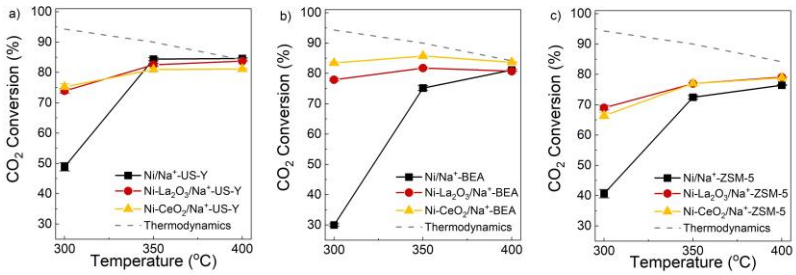

**Figure 1. $CO_2$ Methanation Activity of $Na^+$-Exchanged Zeolites a) US-Y, b) BEA, c) ZSM-5**

**Keywords:** Dimethyl Ether (DME), $CO_2$ hydrogenation, 3D printing, bifunctional catalysts, ZSM-5

**Introduction.** One-step Dimethyl Ether (DME) synthesis from $CO_2$ presents an attractive approach for $CO_2$ emissions reduction through its valorization. Thermodynamically, the catalytic hydrogenation of $CO_2$ to DME is favorable. However, the one-step process poses significant challenges, as it requires the use of suitable bifunctional catalysts, containing both metallic and acidic active sites for simultaneous $CO_2$ hydrogenation and methanol dehydration respectively at the same reaction conditions. Even though catalyst design via 3D printing is still in infancy, it can prove extremely useful for the customized fabrication of structured materials with improved catalytic performance and transfer phenomena. In this study, we explore the use of additive manufacturing to develop Cu-ZSM-5-based catalysts for the one-step $CO_2$ hydrogenation to DME.

**Experimental/methodology.** ZSM-5 based monoliths (3D40, 3D50, 3D60) were prepared via the Direct Ink Writing method, using pastes with different concentrations of bentonite binder and ZSM-5 zeolite, selected due to its high acidity [1]. The materials were first screened in the methanol dehydration to DME reaction. The optimum catalyst was then impregnated with different Cu/Zn content and calcined at 350 °C for 6 h in air. The catalysts were characterized to determine their textural properties (BET), crystallinity (XRD), acidity (FT-IR pyridine) and metal content (ICP-AES). The catalytic performance was assessed in a continuous high-pressure dual fixed-bed reactor unit. A mechanical mixture of commericial ZSM-5 and $Cu/ZnO/Al_2O_3$ catalysts in powder form was also used as reference in a mass ratio 1:1.

**Results and discussion.** Characterization of the 3D printed monoliths revealed that the ZSM-5 crystals retain their physicochemical characteristics and are not significantly affected by the 3D printing process. Increasing the ZSM-5 content in the monoliths led to better activity results in the methanol dehydration reaction, which is related to the increased acidity. All catalysts achieved 100% DME selectivity under the investigated conditions.

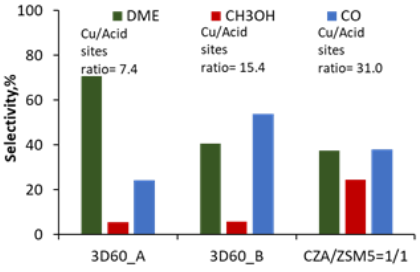

**Figure 1 Product selectivities over Cu-ZSM-5-based catalysts (T=250 °C, P=70 bar, $H_2$:$CO_2$=3, W/F=0.3g.s/cm$^3$)**

The optimum ZSM-5 based monolith (3D60) was impregnated with Cu/Zn at a weight ratio of 1.5 with different total loading (3D60_A: 8.5 wt. %, Cu, 5.7 wt.% Zn | 3D60_B: 15.2 wt. % Cu, 10.4 wt. % Zn). Impregnation led to additional diffractions in the XRD diffractograms characteristic of CuO and ZnO, whose intensity increases with higher metal content. The metals also affected significantly the acidity, by completely blocking the Brønsted acid sites, but increasing the total acidity by generating new acid sites of Lewis nature. Testing in the one-step $CO_2$ hydrogenation reaction (T=250 °C, P=70 bar, $CO_2$:$H_2$=3) revealed a correlation between the Cu/acid sites ratio and the product distribution and activity, highlighting the prospects of 3D printing in catalytic applications.

**Keywords:** Plasma-catalytic methanation, Nickel, Ceria, Zeolite, promoters.

**Introduction.** Carbon dioxide hydrogenation into synthetic fuels and value-added chemicals constitutes a suitable strategy to stabilize anthropogenic greenhouse gas emissions. Methanation or Sabatier reaction is one of the potential pathways to valorise $CO_2$, being the use of catalysts required. Ni-based catalytic systems have been the most widely explored [1] while, in the last years, plasma-assisted methanation has revealed promising results and is reaching nowadays an industrialisation process [2]. However, catalysts' design is still under debate, being multiple supports reported. In this way, improving catalysts' formulation to boost plasma catalysis synergies towards $CO_2$ methanation is key [3]. In the present work, thermal and non-thermal plasma (NTP)-assisted $CO_2$ methanation were performed over promoted Ni-based zeolites with the aim of identifying the promotion effect on their chemical and physical properties and their performances for methane production.

**Experimental/methodology.** Zeolite-based catalysts containing 10 wt% of Ni and variable loadings of promoters (e.g., Ce, Co, La) were prepared by wet impregnation followed by calcination at 500 °C. For this purpose, a commercial HUSY zeolite (Si/Al=38) was used as support. Samples were characterized by powder X-ray diffraction (XRD), $N_2$ sorption, temperature programmed reduction with $H_2$ ($H_2$-TPR), temperature programmed desorption of $CO_2$ ($CO_2$-TPD) and transmission electron microscopy (TEM). Thermal $CO_2$ methanation tests were conducted from 200 to 500 °C in a tubular fixed-bed glass U-type reactor at 1 atm. Plasma catalytic tests were performed in a DBD plasma reactor after a cleaning step under $H_2$ flow for 10 min at 12.3 kHz and 21 kV. In the plasma-catalytic hybrid process, the energy was supplied by a high voltage 30 kHz (MiniPuls 6) and voltages applied ranged from 21 to 29 kV (peak to peak). The applied voltage was measured by a digital picoscope with a probe. The same gas hourly space velocity (GHSV) was kept in all tests, to allow a proper comparison with the results from the thermal experiments. In both cases, metal-containing catalysts were pre-reduced at 500°C for 1 h under a flow of 5%$H_2$/Ar.

**Results and discussion.** The incorporation of cerium over Ni/Zeolite by an optimized wet impregnation strategy led to an improvement of the thermal and NTP catalytic activity towards $CO_2$ methanation. Indeed, a $CH_4$ yield increase from 4 to 28% at 350 °C was registered under thermal conditions for Ni/Zeolite and NiCe/Zeolite, respectively. In the case of plasma catalysis, Ce addition led to an increase of the $CH_4$ yield from 15 to 40% at 14.5 kV. This beneficial effect was attributed to the enhanced of $CO_2$ activation and $Ni^0$ dispersion after Ce incorporation. Furthermore, doping this optimized NiCe/Zeolite system with additional promoters such as Co or La did not lead to a systematic improvement of the catalytic performances. Indeed, among the tested promoters, Co was the one leading to highest improvement of the $CO_2$ conversion and $CH_4$ selectivity both under thermal and NTP catalytic conditions. This effect was again ascribed to the reduction of the average $Ni^0$ crystallite size and the improvement of the number of basic sites after cobalt addition.

**Keywords:** $CO_2$, hydrogenation, Reverse Water-Gas Shift reaction, RWGS

**Introduction.** Constant and not fully controlled development has led modern civilization to a breakthrough point in which further operating on the current principles may lead to a climate catastrophe. The $CO_2$ concentration in the atmosphere has reached an alarming level and the detrimental effects are already visible [1]. Fortunately, the solution to this vital problem could bring more benefits than a clean atmosphere. Catalytic hydrogenation of $CO_2$ via Reverse Water-Gas Shift reaction (RWGS) can be an excellent source of syngas used for sustainable production. Countless catalysts have been tested for this reaction all around the world [2]. Nevertheless, there is still a strong need to search for better and more economically balanced catalysts. In the presented work we demonstrate the catalytic behavior of not previously tested Manganese based catalysts and show the influence of various support materials and the promoting effect of alkali metals on their performance in Reverse Water-Gas Shift reaction.

**Experimental/methodology.** All catalysts have been tested under atmospheric pressure in a flow reactor equipped with a NDIR detector, tuned for $CH_4$, CO and $CO_2$. Catalytic experiments were performed at a range of temperatures with additional high temperature stability test (1 atm, $H_2$:$CO_2$ ratio - 3:1). Selected samples were subjected to operando IR studies in Nicolet iS50 FTIR spectrometer equipped with a Harrick Praying Mantis Cell with an on-line mass spectrometer by Pfieffer Vacuum OmniStar. Catalysts' structural and physicochemical properties were determined by $N_2$ physisorption, TPR, XRD, XPS, SEM and TEM measurements.

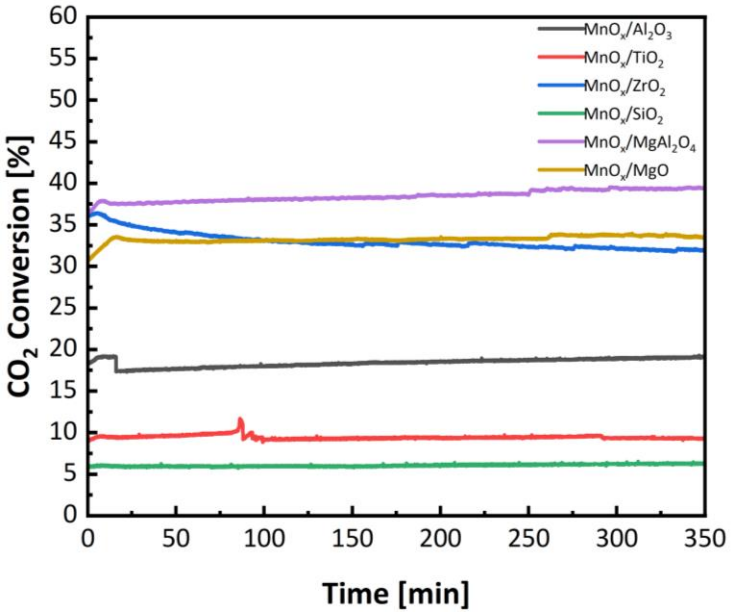

Figure 1. Catalytic hydrogenation of $CO_2$ with Manganese supported catalysts (1 atm, $H_2$:$CO_2$ - 3:1).

**Results and discussion.** Manganese based catalysts demonstrated entirely different catalytic performance depending on the used support materials (Figure 1) [3]. The observed differences are related to the physicochemical properties of the catalysts, e.g. the presence of oxygen vacancies, basic and acidic sites. Furthermore, we observed the beneficial effect of the addition of alkali metals on the catalytic performance of such catalytic systems. Additional operando measurements revealed intermediate species in the $CO_2$ hydrogenation on Manganese catalysts, which allowed us to draw some conclusions regarding the reaction mechanism.

# Fe-Zr catalysts for direct synthesis of light olefins via $CO_2$ hydrogenation

E. Kraleva[1*], U. Armbruster[1], S. Wohlrab[1]

[1]*Leibniz Institut for Catalysis, Rostock, Germany*
*elka.kraleva@catalysis.de*

**Keywords:** carbon dioxide; hydrogenation; light olefins; iron-zirconium catalysts

**Introduction**

The demand for light olefins $C_2$-$C_4$ as raw materials for the production of chemicals (e.g. plastics and fibres) increases worldwide every year. Recently, there has been a growing interest to produce light olefins in an innovative sustainable way from $CO_2$ and green $H_2$ as feedstock. The main challenge is the development of effective catalysts for this $CO_2$ hydrogenation, which implies high $CO_2$ conversion, high $C_2$-$C_4$ selectivity, high olefin/paraffin ratio and low CO and $CH_4$ selectivity [1-2].

**Experimental/methodology**

Fe-Zr metal oxide catalysts with La and K addition were prepared by impregnation and via citrate combustion. After calcination, the structural features were studied by XRD, $N_2$ physisorption, XPS, TPR-$H_2$. The catalysts (200 mg, 0.2-0.4 mm) were tested in $CO_2$ hydrogenation at isothermal conditions in a single-channel set-up. A layer of SiC (800 mg, SiC, 0.3-0.5 mm) was added on top of the catalyst bed to preheat the feed and to ensure plug flow. Feed and product gas were analyzed by on-line gas chromatograph (FID + TCD). Before testing, the as-prepared catalysts were heated to 400 °C and reduced in $H_2$ for 4 h (1.0 bar). Then, the catalysts were evaluated in $CO_2$ hydrogenation ($CO_2/H_2/N_2$ = 1:3:1; 30 bar; 300, 350 and 400 °C; GHSV = 6000 $ml \cdot h^{-1} \cdot g^{-1}$; each condition 10 - 24 h).

**Results and discussion**

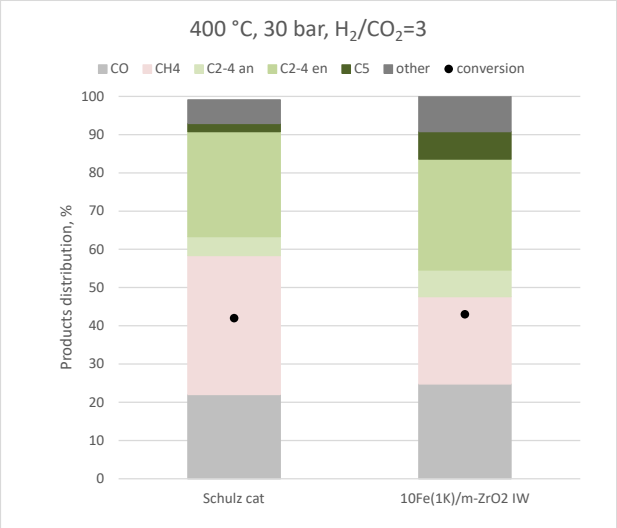

*Figure 1. Catalytic activity of the samples for $CO_2$ hydrogenation. Comparison between benchmark catalyst (Schulz cat) and our 10Fe(1K)/m-$ZrO_2$ IW sample under the same reaction conditions.*

Our research focuses on the effect of different $ZrO_2$ carriers on the evolution of active Fe phases for $CO_2$ conversion to light olefins. Moreover, we investigate the effect of promoters, like La or K, on the properties of Fe-Zr-K catalysts to regulate the product distributions and to enhance the yield of desired light olefins. By means of *in situ* characterization techniques (XRD, XPS, and TPR) we also investigated the synergetic effect between La and Zr on the dynamic evolution of iron and surface carbon species. Thus, a structure-activity relationship between the dynamic evolution of active species and the rate of $CO_2$ hydrogenation to light olefins is proposed. At a Fe loading of 10 wt %, the catalyst 10Fe(1K)(1La)/m-$ZrO_2$ showed remarkable $CO_2$ conversion (42%) and high selectivity and stability to light olefins (32%). The Fe(K)/m-$ZrO_2$ sample demonstrated better product distribution under the same reaction conditions compared to a benchmark catalyst from literature (FeCuAlK) [3], with lower methane formation and high olefin selectivity (Figure 1).

**Keywords:** $CO_2$ hydrogenation, ethylene, light olefins, gallium oxide, bifunctional catalyst

**Introduction**

Nature possesses many carbon cycles in which energy is stored[1]. Likewise, thermo-catalytic hydrogenation of carbon dioxide enables energy to be converted and stored in the chemical bonds of produced hydrocarbons. Current production of high-value chemicals such as ethylene and propylene is based on fossil feedstocks and emit at least 0.81 $tons_{CO2}$ per ton of the produced chemical[2]. Carbon dioxide when used as a carbon feedstock along with hydrogen retrieved from renewable resources offers an alternative green pathway for the synthesis of these hydrocarbons.

Direct $CO_2$ hydrogenation to olefins follows either a methanol-mediated or a modified Fischer-Tropsch pathway. The selectivity in the latter is strongly limited by the Anderson-Schulz-Flory distribution[3]. An efficient catalyst for methanol-mediated $CO_2$ hydrogenation to olefins is bifunctional and should be active for both methanol synthesis and methanol dehydration/coupling under the same conditions[3,4]. The goal of this work is to investigate the effect of gallium oxide incorporation into an $In_2O_3$/SSZ-13 bifunctional catalyst on the formation rate of ethylene and light olefins in methanol-mediated thermo-catalytic $CO_2$ hydrogenation.

**Experimental/methodology**

Mixed oxides composed of $In_2O_3$ and $Ga_2O_3$ at desired ratios were prepared by coprecipitation, using aqueous solutions of their respective nitrate hydrate salts. The precipitates were aged, filtered, washed with deionized water, dried and then calcined. Both metal oxides and SSZ-13 zeolite were crushed and grinded separately. Then they were physically mixed.

Crystallinity and phases of the samples were analyzed by XRD. Electronic properties and surface oxygen vacancy concentrations were analyzed by XPS. Textural properties of the catalysts were retrieved from $N_2$ sorption experiments. $H_2$-TPR was conducted to check the reducibility of the samples. Solid-state NMR was conducted to check the local coordination in the metal oxides. Catalytic performance results were acquired from a microreactor coupled with a gas chromatography.

**Results and discussion**

The effect of $Ga_2O_3$ content in an $In_2O_3$/SSZ-13 bifunctional catalytic system is investigated by performing $CO_2$ hydrogenation experiments with different Ga-In ratios in the mixed oxides at 20 bar. It was found that increasing Ga/In ratios leads to increase in selectivity of hydrocarbons with shorter chains, tuning the product distribution mainly towards $C_2$-$C_4$ product range. More specifically, the ethylene formation rate was greatly enhanced with higher x values of $Ga_xIn_{2-x}O_3$. Placement of indium and gallium species throughout the catalysts and their distributions were mapped by STEM-EDX. $Ga^{3+}$ is incorporated into the $In_2O_3$ lattice as XPS confirmed. The specific surface area increases with increasing gallium oxide content. NMR results indicated coordination environment pattern of the mixed oxides.

A strong correlation between product type evolution and bifunctional catalyst structure was observed. This work will give an insight in how $CO_2$ hydrogenation products are tuned towards double bond functionalization by the catalyst design.

**Keywords:** $CO_2$ conversion, M(Mn, Zr)/$CeO_2$ catalysts, Dimethyl carbonate, ANN modelling, Gibbs energy

**Introduction.** Carbon dioxide ($CO_2$) is predominantly discussed negatively as a greenhouse gas and the main cause of anthropogenic climate change. Recently, $CO_2$ has received more attention as an abundant carbon source and readily available raw material for the production of value-added products, rather than being treated as an environmentally harmful greenhouse gas. In recent decades, the use of $CO_2$ has attracted the attention of scientific groups, especially those concerned with industrial and environmental processes. In this direction, $CO_2$ has recently been used as a renewable C1 feedstock for high-value chemicals. Among the various strategies, the carbonylation of alcohols with $CO_2$ is attractive for the synthesis of dimethyl carbonates (DMC) [1].

**Experimental/methodology. T**he synthesis of $CeO_2$-based catalysts using a template approach to convert $CO_2$ to DMC. The relationships between the structure of M(Mn, Zr)/$CeO_2$ and their catalytic activity have created a need for new synthetic routes for improved surface properties. These synthetic routes are more industrially applicable due to higher activities and lower costs. The effects of the M(Mn, Zr)/Ce molar ratio on the surface properties and structure of the M(Mn, Zr)/$CeO_2$ catalyst, reaction conditions, and catalyst reusability study for direct conversion of $CO_2$ were investigated.

**Results and discussion.** The catalytic activity of the synthesized M(Mn, Zr)-$CeO_2$ catalysts was closely related to the basic and acidic sites. The optimization of reaction conditions was investigated for various reaction parameters. The reusability of $CeO_2$-based catalysts was also investigated. In addition, the heat of the reaction and Gibbs free energy were determined using an equation of state (Peng-Robinson-Stryjek-Vera (PRSV-EoS)) with a one-fluid (van der Waals) reaction condition. DMC yields from the direct conversion of $CO_2$ and methanol in the presence of M (Mn, Zr)/$CeO_2$ catalysts. Moreover, the experimental response data were validated by the developed artificial neural network (ANN) model [2]. The ANN model was tested by direct comparison and parity plots. The parity plots compare the actual and predicted value of DMC yield. For all data points, the predictions of the ANN model were found to be quite close to the experimental results. The nature of the input data indicates that the model is able to effectively predict the $CO_2$ conversion and DMC yield under the reaction conditions studied. The parity plots are used to evaluate the over- and under-prediction of the model. The results presented are promising and useful for identifying the key relationships between reaction conditions and targeted performance. This can help in the development of efficient design or screening for heterogeneous catalysts with desired properties.

**Keywords:** epoxidation, green chemicals, $CO_2$ utilization

**Introduction.** Carbon Capture and Utilization (CCU) technologies enable industrial waste-stream carbon dioxide circulation for value-added products.[1] VTT is currently developing a concept (Figure 1) where polycarbonate polyols are produced from $CO_2$ and renewable power. In our concept, 100 % of the polyol carbon originates from $CO_2$, that can be captured e.g. from bioenergy production facilities (BECCU). First, carbon monoxide is produced by a combination of rWGS reaction and catalytic partial oxidation (CPOX). Then, carbon monoxide and hydrogen undergo Fischer-Tropsch (FT) synthesis using a proprietary Fe-based catalyst leading to a high yield (> 45 %) of light C2-C4 olefins.[2] The produced light olefins are further oxidized with hydrogen peroxide into a mixture of epoxides, which are co-polymerized with $CO_2$ and a starter polyol into polycarbonate polyols to be applied for polyurethanes. However, light olefins are typically epoxidized separately and an industrial process for their combined epoxidation does not exist yet.[3] A direct mixed epoxidation step would bypass the need for challenging and expensive olefin separation, and thus contribute to significant process intensification. This work focuses on the experimental work of liquid-phase epoxidation of light olefins using commercial and in-house synthetized heterogeneous catalysts and hydrogen peroxide as an environmentally friendly oxidant in a continuous flow reactor system. The process concept is shown in Figure 1.

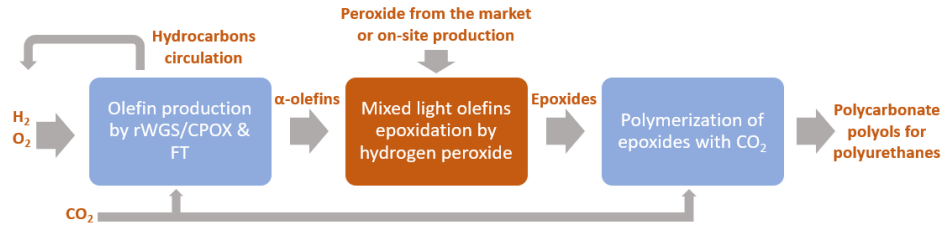

**Figure 1. Concept from $CO_2$ and green hydrogen to polycarbonate polyols.**

**Experimental/methodology. L**iquid-phase epoxidation experiments of mixed light olefins in a fixed bed reactor by hydrogen peroxide on porous silicate supported metal catalysts were performed in a continuous fixed bed reactor. The experiments were conducted under mild conditions using an appropriate solvent (methanol or acetonitrile). The catalysts screened were commercial titanium silicate TS-1, in-house acid-modified TS-1 and two in-house synthetized mesoporous silicate supported catalysts; Nb-KIT-10 and W-KIT-6. The analysis of the epoxidation products was conducted by gas chromatography. The catalysts were characterized by nitrogen physisorption, SEM, EDS and ICP-OES.

**Results and discussion.** A comparison of the olefins revealed differences in their reactivities. On the other hand, the reactivities of the olefins in the mixtures were surprisingly similar to the olefins tested individually. Furthermore, the product selectivity towards the epoxide product was highly dependent on the process temperature and residence time in the flow reactor. Nonetheless, high selectivities of the corresponding mixed epoxides can be achieved with careful process optimization. Some in-house catalysts gave better performance compared to the commercial TS-1 catalyst.

# Direct $CO_2$ hydrogenation to long-chain hydrocarbons via methanol

F. Lappa[1,2], M. Dusselier[1], G. Leonard[2]

[1]*KU Leuven, Leuven, Belgium*
[2]*ULiege, Liege, Belgium*
[*]*foteini.lappa@kuleuven.be*

**Keywords:** Carbon dioxide, hydrogenation, methanol, gasoline, heterogeneous catalysis, zeolite, oxide

**Introduction.** Carbon capture and utilization, CCU, is gaining attention due to the energy crisis and the environmental problems that our society is facing. In particular, $CO_2$ can react towards long-chain hydrocarbons via two main pathways. First, the Fischer-Tropsch synthesis is an industrialized process based on carbon chain growth, traditionally using CO as a starting point, which is thus the main intermediate from $CO_2$. On the other side, $CO_2$ can react towards methanol which is then sent to a Methanol to Gasoline unit (MTG). Not a lot of research has be done in combining $CO_2$-to-methanol with MTG targeting longer hydrocarbons despite the potential benefits of a direct pathway. As the state of the art indicates, $In_2O_3$ [1] and $ZnZrO_x$[2] are commonly used for the production of methanol from $CO_2$. Regarding MTG, zeolites are famous to catalyze this reaction [3]. The combination of both processes in one step reaction still remains quite a challenge, both from catalyst development as from process design points of view.

**Experimental.** A series of oxides were synthesized ZnZrOx[2], PdZnZrOx[4], Co/$In_2O_3$, InCo [5,6] and PdInCoOx. Medium and large-pores zeolites were tested such as TON, ZSM-5 and BEA. Si/Al ratio variations and the effect of the acidity were studied. All materials were characterized with XRD and BET, ICP (Si/Al ratio), $NH_3$-TPD and FTIR. In addition, different bed configurations are under study.

**Results and discussion.** Fig 1. shows that ZnZr-oxides and InCo are methanol production catalysts. When tested without the presence of zeolite the main product was methanol. When combined with BEA zeolite, paraffins are the main product and this effect is enhanced for the dual bed configuration. Large pores zeolites such as BEA have the possibility to allow longer-chain hydrocarbons to escape the pores. In dual bed, methanol is first produced in the oxide layer and then converted to hydrocarbons in the BEA layer. This first screening sets the stage for investigating other zeolites as well the effect of the acidity and other synthetically accessible properties of BEA zeolites in this reaction. The main aim is to map the effects of the $CO_2$ hydrogenation conditions, especially high partial pressures of $CO_2$ and water and a reducing environment, on the selectivity and long alkane MTG performance of the zeolite.

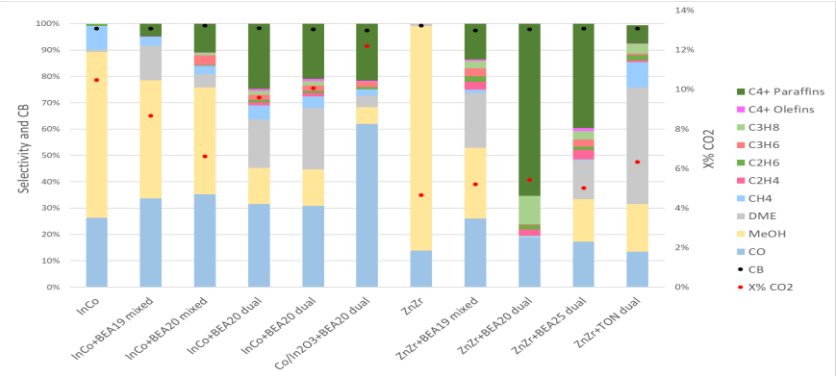

**Fig1. $CO_2$ conversion, carbon balance (CB) and selectivity of products in the presence of different catalytic materials.**

[*]*piotr.legutko@uj.edu.pl*

**Introduction.** In recent years, the efficient reduction of the emission of GHGs into the atmosphere became one of the most important scientific and societal challenges worldwide. Satisfactorily, the solutions proposed by environmental catalysis seem to meet the expected goals One of the possible technological options oriented towards effective $CO_2$ utilization is its conversion into synthesis gas. The target mixture can be catalytically obtained in the reaction called dry reforming of methane (DMR): $CH_4 + CO_2 \rightarrow 2CO + 2H_2$. The DMR is a highly endothermic reaction, so a high temperature and an active catalyst are indispensable to gain satisfactory conversion and selectivity. A lot of investigations were performed to develop a promising catalytic system such as $Ni/CeO_2$-$ZrO_2$, but the effect of active component loading is still not fully explained. This study aimed to understand in-depth and to elucidate the influence of both nickel content and support phase composition on the physicochemical properties and catalytic activity of $Ni/CeO_2$-$ZrO_2$ catalysts active in DMR.

**Experimental/methodology.** $CeO_2$-$ZrO_2$ support (containing 0-100% $ZrO_2$) was synthesized by the Pecchini method from cerium(III) nitrate(V), citric acid and ethylene glycol. The obtained gel was dried overnight at 120 °C and then calcined at 800 °C for 6 h. Final catalysts were prepared by impregnation of the binary support with nickel nitrate(V) solutions (0 – 10 wt.% of Ni). After impregnation, all samples were dried overnight at 120 °C and then calcined at 400 °C for 3 h to decompose the precursor. Subsequently, the samples were characterized by XRD, RS, SEM, XPS, DRIFT and UV/Vis-DR. The catalytic activity of reduced samples (5% $H_2$/Ar, 2h) has been investigated in the temperature range 550-800 °C with the composition of gases: 2.5% $CH_4$ and 2.5% $CO_2$ in He.

**Results and discussion.** The obtained results showed that optimal nickel loadings can be determined for all support compositions and it was shifted from 3 wt.% of active phase supported on bare $CeO_2$ (see Fig. 1) to around 5% for mixed supports and 10% for bare $ZrO_2$. Moreover, it was found that optimal loading can be different for the same support composition but with different synthesis methods. In general, activity and stability optima are in the same Ni concentration but in some cases, higher nickel loading results in stability enhancement. Investigated $Ni/CeO_2$-$ZrO_2$ catalysts meet most of the DMR requirements and their effective optimization is also helpful for large-scale application designing.

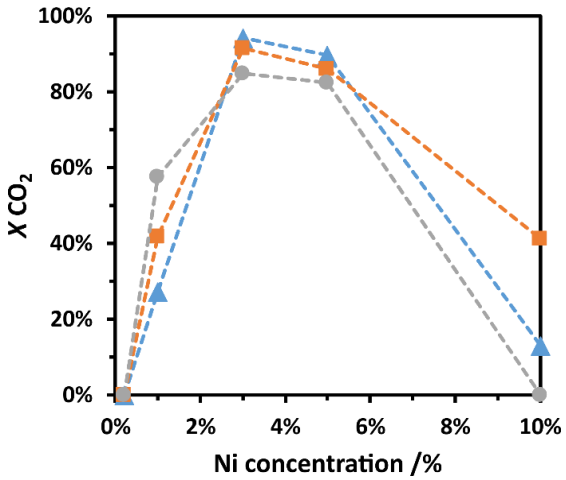

**Fig. 1. Catalytic activity expressed as $CO_2$ conversion observed during DMR process as a function of nickel loading in $Ni/CeO_2$ catalyst: at 700 °C (circles), at 750 °C (squares), and at 800 °C (triangles).**

# $CO_2$ Reduction to Methanol at a Cu/Zn–$ZrO_2$ Interface via DFT Calculations

A. Lempelto[1*], L. Gell[1], T. Kiljunen[1], K. Honkala[1]

[1]*University of Jyväskylä, Nanoscience Center, Jyväskylä, Finland*
[*]*aku.p.lempelto@jyu.fi*

**Keywords:** Heterogenous catalysis, Density Functional Theory, $CO_2$ utilisation

**Introduction.** A combination of Cu/Zn/$ZrO_2$ has been found to efficiently catalyse $CO_2$ conversion to methanol (CTM) [1,2]. It has been suggested that the Cu and Zn components can form a partial alloy under reaction conditions although this interpretation remains controversial [3,4]. Previous computational studies have mainly focused only on binary systems of Cu-ZnO or Zn-$ZrO_2$.

**Experimental/methodology.** We have studied the CTM capabilities of the CZZ system using density functional theory (DFT) calculations and zirconia-supported periodic Cu nanorod models, similar to those in our previous work [5], with some or all interfacial Cu atoms replaced by Zn. A simple kinetic analysis of DFT results was done using the energetic span model [6,7] in order to identify TOF controlling states.

**Results and discussion.** Our results demonstrate that $CO_2$ hydrogenation intermediates binding to interfacial metal atoms adsorb more strongly to Zn sites than to geometrically equivalent Cu sites at the metal—support interface where the active sites lie. We show that the promoter has little effect on the binding of intermediates which are not in direct contact with the metal component of the system, including some key intermediates identified with the ESM analysis such as the formate and methoxy. Additionally, the results have highlighted the importance of considering hydrogen spillover in computational studies. We show that by including hydrogen spillover, the activation energies for some hydrogenation reaction steps involving zirconia-bound intermediates are much lower than previously reported. These effects lead to an energetic preference for the so-called reverse water—gas shift (RWGS) route of $CO_2$ hydrogenation (yellow in Fig. 1). Our results therefore help quantify the effect of metallic Zn sites on catalytic properties such as selectivity.

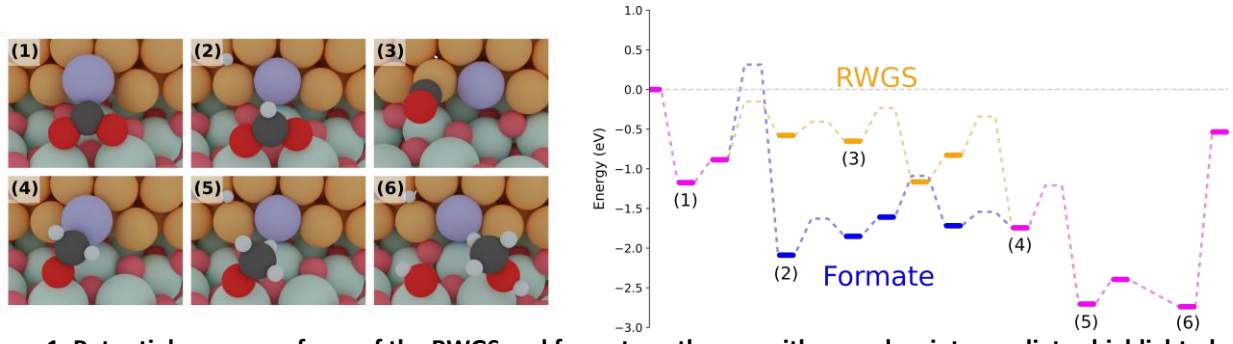

**Figure 1. Potential energy surfaces of the RWGS and formate pathways with some key intermediates highlighted.**

**Introduction.**
Cu-based catalysts are industrially applied to convert syngas mixtures ($CO_2$/CO/$H_2$), while the conversion of single-carbon-oxide $CO_2$/$H_2$ and CO/$H_2$ feeds attracts increasing attention in the context of emerging power-to-X technologies. Despite the established character of these catalyst systems for methanol synthesis, the nature of the metal-oxide promotion effects, as well as the prevailing reaction mechanism and optimal catalyst design for $CO_2$ vs CO hydrogenation, remain open scientific questions.[1] Herein, we extend our studies on the mechanistic role of the electron withdrawing character (acidity) of Lewis acid sites (LAS) at the Cu/oxide periphery,[2] as a means to rationalize mechanistic similarities and differences for $CO_2$ and CO hydrogenation reactions.

**Experimental/methodology**.
A series of model catalysts consisting of Cu nanoparticles dispersed on various transition metal oxide overlays coated on a common γ-$Al_2O_3$ substrate (1.5$Cu_{at}$/$MO_x$@$Al_2O_3$, $MO_x$, M=Ta, Zr, Sc and Y) was synthesized as reported earlier.[2] Methanol synthesis tests were performed with $H_2$/$CO_2$=3 or $H_2$/CO=2 feeds at WHSV=1-3 $h^{-1}$, T=503-523 K, and P=25 bar.

**Results and discussion.**

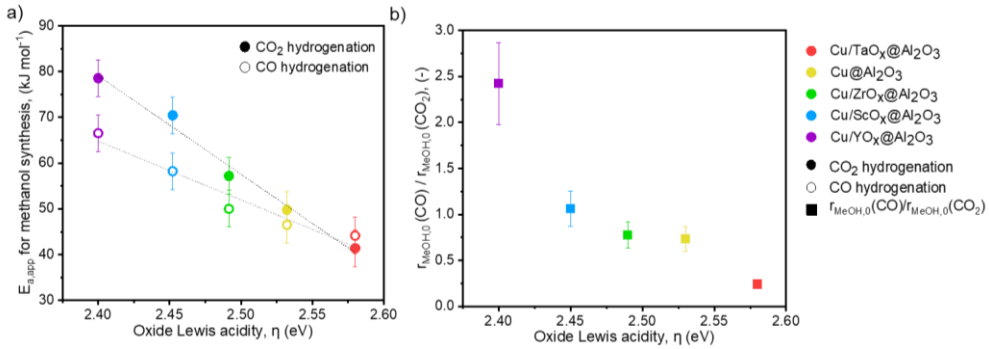

**Figure 1: Evolution of a) the apparent activation energy for methanol formation, and b) ratio of initial methanol formation rates for CO/$H_2$ and $CO_2$/$H_2$ feeds at 513 K, as a function of the relative electron withdrawing character of the oxide support LAS (quantified by the IMCT energy of adsorbed 1,2-dihydroxy-9,10-anthracenedione as probe (η)).**

Independently from the identity of the carbon oxide in the feed, the apparent activation energy for methanol formation decreased rather linearly with increasing the electron withdrawing character of the *cus* on the oxide support (Fig. 1a). These comparable trends for $E_{app}$ suggest a mechanistic parallelism for the hydrogenation of both $CO_x$, i.e. in both cases, LAS (likely at the Cu/oxide periphery) are involved in a kinetically relevant step which becomes facilitated by LAS with stronger electron withdrawing character, particularly so for $CO_2$ hydrogenation. However, reaction rates did show remarkable differences for $CO_2$ and CO feeds (Fig. 1b), suggesting differences in either TOF or the number of active sites at work. Oxides of stronger electron withdrawing capacity are notably more effective hydrogenating $CO_2$ than CO and vice versa. Isotopic H/D exchange and *in situ* FTIR studies provide complementary insights into the mechanistic similarities and differences for methanol synthesis reactions by hydrogenation of the two carbon oxides.

**Keywords:** DRM, nickel, ceria, photo-thermal catalysis, operando DRIFT

**Introduction.**
The dry reforming of methane (DRM) reaction represents an effective way of utilization two major greenhouse gases into syngas, but it is highly endothermic and thermodynamically limited reaction ($CH_4$ + $CO_2$ ↔ $H_2$ + CO; $\Delta H_{298K}$ = +247 kJ/mol).[1],[2] Implementation of visible light into thermally driven DRM reaction is an attractive alternative for surpassing the thermodynamic equilibrium limits and achieving high catalytic activity and selectivity at low temperatures.[3] The aim of this work is to determine how calcination in different atmospheres (oxidative, inert and reductive) affects on activity of nickel-ceria based catalysts during thermal, as well as photo-thermal DRM reaction. Furthermore, detailed insight studies were performed to elucidate the photo effect on catalytic performance regarding DRM reaction.

**Experimental/methodology.**
The catalysts based on ceria rod morphology were synthesized by hydrothermal treatment, whereas 2 wt. % of nickel as active metal was loaded by deposition precipitation method.[4] The samples were separately calcined in different atmospheres, namely Air, Ar and $H_2$ before and after the deposition of Ni. All catalytic tests for thermo and photo-thermal DRM reaction were performed in modified Harrick reaction chamber (HVC-MRA-5) at ambient pressure.[3] The same reaction chamber combined with microGC analysis were also used to perform *operando* DRIFTs analysis, using a Perkin Elmer IR spectrophotometer. The visible light used during photo-thermo conditions was provided by Schott KL2500 LED source (400 <λ< 700 nm) with the intensity of 613 mW/$cm^2$.

**Results and discussion.**
Under thermal conditions, the best performing catalysts are 2Ni-R $H_2$ and 2Ni-R Ar, followed by 2Ni-R Air. When the reaction is thermally driven, no activity is observed below 380°C. With introduction of concentrated visible white light, the catalytic activity and $H_2$ selectivity further increased in case of all studied catalysts as well as the catalytic reaction was extended to 140°C. The photocatalytic gains in $CH_4$ and $CO_2$ rates and $H_2$ selectivity become more prominent over 2Ni-R $H_2$ and 2Ni-R Ar compared to 2Ni-R Air catalyst. Furthermore, the most dominant impact on observed $CH_4$ as well as $CO_2$ photocatalytic activity has the hot charge-carrier driven photocatalytic mechanism (PT). The provided operando DRIFTs analysis reveals that introduction of visible light promotes the photocatalytic oxidation of formate species to CO, therefore preventing them to further hydrogenate into $CH_4$. Moreover, visible light also induces removal of carbonyl groups from nickel, meaning more active sites are available for methane dissociation. Based on the *in-situ* XANES/EXAFS measurements, higher Ni dispersion was noticed on samples calcined in inert and reductive atmospheres compare to the sample calcined in air. Overall, the improved dispersion of Ni by calcination in inert or reductive atmospheres is the main factor for enhancement in catalytic activity during DRM reaction under thermal and photo-thermal conditions.

**Keywords:** BiOBr, $CO_2$ reduction, g-$C_3N_4$, Oxygen atoms, Photocatalysis

**Introduction.** Photoreduction of $CO_2$ to fuels is promising to mitigate climate warming and increase the renewable energy supply, while conventional photocatalytic $CO_2$ reduction systems with $H_2O$ or sacrificial agents generally face problems such as low catalytic activity and inefficient atom economy[1,2]. In this work, $NH_4Cl$-modified g-$C_3N_4$ is combined with BiOBr for the efficient photocatalytic $CO_2$ reduction coupled with selective styrene oxidation. The interfacial heterostructure promotes the formation of surface amino groups and oxygen vacancies, which facilitates the adsorption and chemical reduction of $CO_2$, and also improves the separation of photogenerated electron-hole pairs and enhances the photocatalytic activity. Compared with the conventional $CO_2$ reduction process where oxygen atoms removed from $CO_2$ are converted to the no added valuable $H_2O$ or $O_2$ destroyed the reduction system[3], in our synergistic system, the oxygen atoms are efficiently involved in the styrene oxidation half-reaction. This study provides a novel strategy for designing high-efficient photocatalytic $CO_2$ reduction system and new insights into the reaction mechanism.

**Experimental/methodology.** 0.1 mmol styrene, 10 mg photocatalyst and 5 mL acetonitrile were added in a 50 mL autoclave with a glass window. The light source was a CEL-HXF300 Xe lamp (Beijing China Education Au-light Technology Co., Ltd) with a light density of 43 $mW \cdot cm^{-2}$. The photocatalytic redox reaction was carried out in a $CO_2$ atmosphere (0.1 MPa) under magnetic stirring at room temperature for 3 h. The $CO_2$ reduction products were analyzed using a GC (Fuli GC979011) with a flame ionization detector (FID) and thermal conductivity detector (TCD). The styrene oxidation products were qualitatively analyzed with a gas chromatograph-mass spectrometer (GC-MS, GC-Agilent 6890A) and quantitatively analyzed using a GC (Shimadzu, Japan) with a flame ionization detector (FID) and an SH-Rtx-1 capillary column (30 m×0.25 mm×0.25 μm).

**Results and discussion.** The BiOBr-NCN heterojunction catalyst is constructed to achieve efficient oxygen atom utilization in the photocatalytic $CO_2$ reduction by coupling with styrene oxidation at room temperature. The heterostructure facilitates the formation of surface amino groups and oxygen vacancies, which is beneficial to the adsorption and chemical reduction of $CO_2$. The heterostructure also improves the separation efficiency of photogenerated charge carriers and enhances the photocatalytic response. The simultaneous consumption of photogenerated electrons and holes is favorable to both the reduction and oxidation half-reactions. A high CO generation rate of 802 μmol $g^{-1}$ $h^{-1}$ with a 96.2% selectivity is achieved, and the production rates of benzaldehyde and styrene oxide are 684 and 139 μmol $g^{-1}$ $h^{-1}$, respectively. A novel mechanism is proposed based on the results of in situ FTIR, in situ EPR, isotope tracer and control experiments, and the BiOBr-NCN heterostructure sample also shows good cycling stability and universality.

**Keywords:** Electrocatalysis, Carbon dioxide conversion, dual-atom catalysts, Mn−Ni site

**Introduction**

The electrochemical reduction of $CO_2$ (ECR) into value-added products provides a promising strategy to realize a carbon-neutral energy [1]. However, the current ECR process still has challenges of $CO_2$ activation and the complicated product distribution, which limits practical $CO_2$ reduction. Therefore, it is deisrable to develop electrocatalysts with good activity and high selectivity for ECR. Single-atom catalysts (SACs) have demonstrated appealing performance for ECR to CO due to high atomic efficiency, unique geometric and electronic structure [2]. However, the simplicity of active center limits the efficiency of catalytic reaction due to the multistep-coupled proton-electron transfer of ECR process. For instance, Ni SACs generally show excellent CO desorption capability and suppression of HER, whereas suffer from sluggish kinetics of the first proton-coupled electron transfer [3]. Fe SACs exhibit low free energy barrier for the formation of *COOH intermediate, but the CO desorption from active site is diffcult because of strong binding of CO to Fe atom [4]. To solve these issues, one strategy is to construct diatomics site with unique geometric and electronic property by incoporating extra heteronuclear metal atoms into SACs.

**Experimental/methodology**

Five catalysts including Ni−N−C, Mn−N−C, Ni−Ni−N−C, Mn−Mn−N−C and Mn−Ni−N−C supported on N-doped carbon black were synthesized via a facile ion adsorption and calcination process.

**Results and discussion**

The catalysts were charactered by XRD, Raman, HRTEM, HAADF-STEM, XANES, EXAFS, XPS, $N_2$-physisorption, etc. XRD results indicated that there are no Ni and Mn metallic clusters or compounds in the Mn−Ni−N−C catalyst (Fig. 1a). EDX mapping revealed that Mn, Ni, N, and C species distribute uniformly over the Mn−Ni−N−C catalyst. XPS results suggest that the Ni and Mn species are likely to be in a partially oxidized state. The atomically dispersed Ni and Mn species were verified by HAADF-STEM as shown in Fig. 1b. Finally, the Mn−Ni−N−C catalyst exhibits the highest ECR activity, yielding a current density of 17.1 mA/cm² under −0.70 V (vs. RHE) and maximum FE(CO) of 98.7% (Fig. 1c).

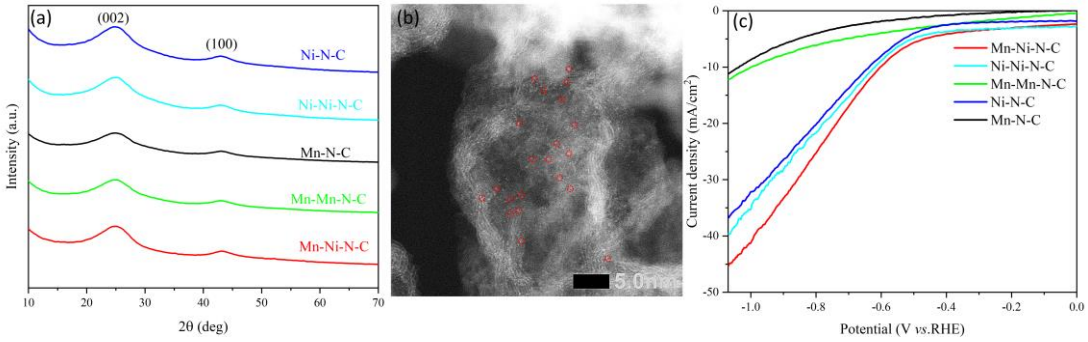

**Figure 1. (a) XRD patterns of the five catalysts; (b) HAADF-STEM of the Mn−Ni−N−C catalyst, where Mn-Ni atom pairs are highlighted in red circles; (c) LSV of the catalysts.**

**Keywords:** ZIF-8, ZIF-67, ZIF-8@ZIF-67, $TiO_2$, Heterojunction, $CO_2$ photoreduction

**Introduction.** $CO_2$ photoconversion appears as a very promising way to answer to the environmental crisis that human are facing. Titania is one of the most studied semiconductor for $CO_2$ photoreduction but one of the main issues is the lack of efficiency. Indeed, the gas-phase photocatalytic $CO_2$ reduction by $H_2O$ over titania leads to the formation of hydrogen as preferential/competitive process, limiting the overall $CO_2$ reduction yields and the selectivity. In order to avoid this phenomena, the use of suitable co-catalyst appears as a promising way to control $TiO_2$ photoactivity and selectivity toward $CO_2$ reduction.

**Experimental/methodology.** ZIFs materials were prepared in aqueous media [1-2]. 1.4667 g of zinc nitrate ($Zn(NO_3)_2.6H_2O$) was dissolved in 100 mL of MeOH. 3.2647 g of 2-methyl imidazole was also dissolved in 100 mL of MeOH. The second solution was added dropwise and strirred for 2 hours, the sample was washed with MeOH and distilled water and finally vacuum dried at 80°C overnight. The same procedure was apllied for ZIF-67 using cobalt nitrate ($Co(NO_3)_2.6H_2O$) as metal precursor. Composite materials were obtained via wet impregnation between $TiO_2$ and ZIF materials.

**Results and discussion.** The photocatalytic measurement were done using a gas phase reactor under simulated sunlight and continuous flow (0.3 mL/min) (**Figure 1**). One can observe that increasing the amount of ZIF materials from 1 to 10 wt.% leads to the preferential formation of C-compounds compared to the production of $H_2$ with a full C-compound selectivity obtained using ZIF-8@ZIF-67 as co-catalyst.

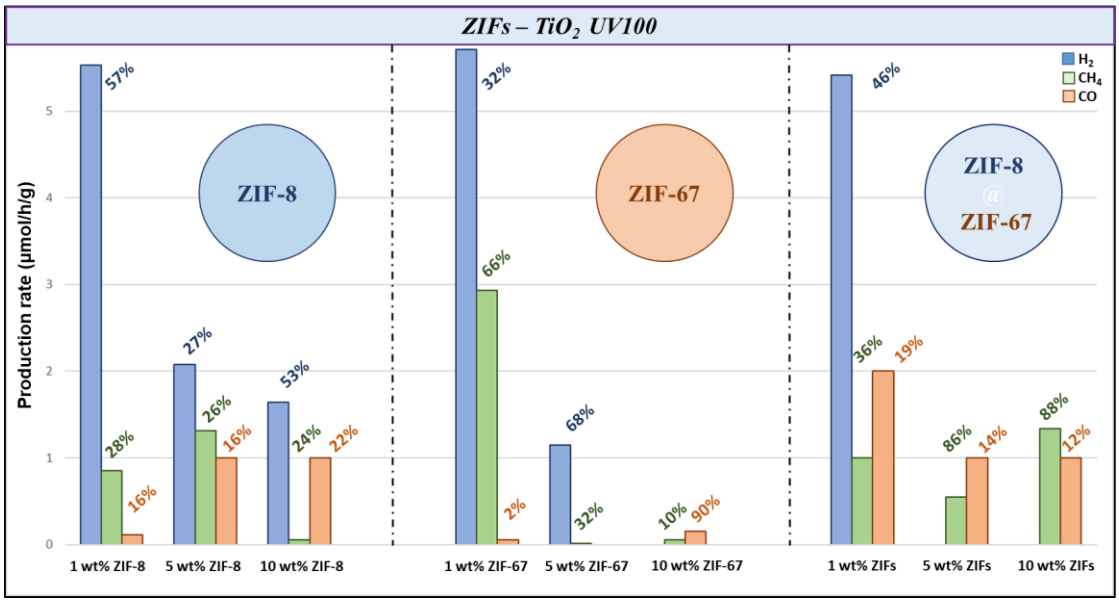

*Figure1: $CO_2$ photoreduction over ZiF/$TiO_2$ materials*

**Keywords:** $CO_2$ reduction, molybdenum carbide, synthesis gas, Power-to-X

**Introduction.** The widely discussed Power-to-X (PtX) processes [1] assume that the renewable energy sector will grow significantly over the coming years resulting in very cheap electricity at times of high production and low consumption. This essentially free electricity provides opportunities such as the large-scale electrolysis of water yielding $H_2$ and a subsequent hydrogenation of captured $CO_2$ to so called hydrocarbon based powerfuels, especially in the aviation sector which is unlikely to be directly electrified. A first step in this process is the activation of $CO_2$ with $H_2$ in the reverse water-gas-shift (RWGS) reaction to CO. Due to its thermodynamically limited conversion even at very high reaction temperatures, the RWGS represents a significant challenge in the PtX process to powerfuels both regarding catalyst stability and performance. Molybdenum carbides ($Mo_2C$) have been shown to be promising candidates for the activation of $CO_2$ [2].

**Experimental/methodology.** The present study investigates the performance of various $Mo_2C$-based catalysts under RWGS conditions. The catalysts are prepared via a common slurry impregnation method on various metal oxide support materials, with the carburization process being optimized using several *in situ* characterizing techniques, such as XRD, Raman, XAS and TGA-MS. To obtain an active and stable catalyst, it is important to limit the carbon build up on the surface of the catalyst during carburization of the precursor materials but still obtaining a pure carbide phase without oxidic species. The obtained catalysts were tested in a ¼" tubular fixed bed reactor, varying feed gas composition and space velocity.

**Results and discussion.** Our results indicate that the optimum temperature for a pure phase carburization of ammonium heptamolybdate (AHM) supported on conventional fumed silica is 600°C, according to *in situ* XRD. *In situ* Raman analysis confirms that at these conditions no significant carbon deposition has taken place and no surface oxidic phases ($MoO_x$) are present. In terms of the RWGS performance (see Figure 1), the catalysts were evaluated for 24 hours at 600°C using a $H_2$ to $CO_2$ feed at a ratio of 2.5. Limited catalyst deactivation can be observed for all catalysts. The conversion level of the $Mo_2C$-based catalysts is heavily influenced by the support material. The inert $SiO_2$ support is the best performing catalyst, suggesting that $Mo_2C$ can fully support the $CO_2$ activation as well as the subsequent oxygen removal by $H_2$, forming $H_2O$, on its own. The selectivity towards CO is approaching 100 C-% for all catalysts, confirming that there is no significant CO or $CO_2$ methanation taking place. $Mo_2C$ promises to be an active, effective and cost efficient (compared to PGM alternatives) catalyst for the RWGS reaction.

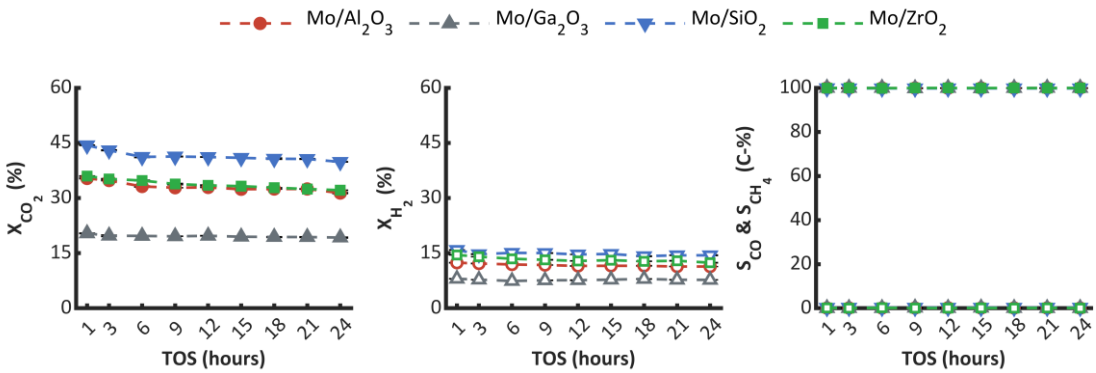

**Figure 1.** $CO_2$ and $H_2$ conversions as well as CO and $CH_4$ selectivity of the metal oxide support Mo catalysts under RWGS conditions.

**Introduction.** The worrying rise in greenhouse gas emissions has led to the necessity of limiting the consumption of fossil sources on one hand, and on the other to develop new technologies for capturing, storing and utilising these gases [1]. In this perspective, $CO_2$ photoreduction, paired with water splitting, presents a great potential for the synthesis of fuels and other building block molecules of high value, *e.g.* methane ($CH_4$), carbon monoxide (CO) and other C1-based products [2]. To develop an effective and selective photocatalytic system, the perovskite barium titanate ($BaTiO_3$) was chosen as a new promising photoactive material with respect to other common photocatalysts, *e.g.* titanium dioxide ($TiO_2$) and zinc oxide (ZnO). Copper (II) oxide was introduced as a co-catalysts to hinder charge recombination [3], enhacing the activity and selectivity of the perovskite.

**Experimental/methodology.** $BaTiO_3$ was synthesized by hydrothermal method, modified from literature [4], and was compared with commercial $TiO_2$ (Degussa P25, Evonik) and a lab-synthesized ZnO (synthesized by precipitation [5]). CuO was synthesized by hydrothermal method [6] and introduced as a co-catalyst by impregnation (2.5 wt%) on $BaTiO_3$, $TiO_2$ and ZnO. The photocatalysts were tested in a gas and liquid phase.

**Results and discussion.** Experiments performed in gas phase resulted in the production of methane and hydrogen, in accordance with the proposed reaction mechanism [7]. Pristine $BaTiO_3$ was less active with respect to $TiO_2$ (79 vs 104 µmol $g_{cat}^{-1}$ $h^{-1}$ of $CH_4$, respectively), but the presence of CuO both improved both its activty and resulted in a minor $H_2$ production with respect to CuO/$TiO_2$ (221 vs 169 µmol $g_{cat}^{-1}$ $h^{-1}$ of $CH_4$ and 239 vs 414 µmol $g_{cat}^{-1}$ $h^{-1}$ of $H_2$, repectively). Experiments performed in liquid phase under neutral pH resulted in the production of formic acid and methanol [7], whereas under basic pH only HCOOH was detected. The basic enviroment also provided a ten-fold total productivity in C-based molecules with respect to pH 7. Under these reaction conditions, the materials showed similar activity and the introduction of CuO did not lead to significant improvements. Thus it is possible to argue that $CO_2$ photoreduction performed in liquid phase is driven by reaction conditions, whilst in gas phase the choice of the appropriate photocatalyst can redirect the activity and selectivity of the reaction.

**Keywords:** Heterogeneous catalysis, $CO_2$ valorization, carbon materials, light olefins

**Introduction:** Carbon dioxide ($CO_2$) is a greenhouse gas and its increasing concentration in the atmosphere due to anthropogenic activity is related to global warming. For this reason, it is necessary to find efficient and clean processes to transform $CO_2$ into value-added products, such as light olefins. Light olefins are of great interest in the chemical industry since they are used as raw materials in the production of surfactants, plasticizers, solvents, etc. Usually, iron catalysts are used as they can catalyze the reverse water gas shift reaction (RWGS) over $Fe_xO$ and the C-C coupling via Fischer-Tropsch (FT) over $Fe_xC$ [1]. The present work studies the activity of Fe catalysts over graphite supports doped with potassium and nitrogen for the hydrogenation of $CO_2$ to light olefins.

**Experimental/methodology:** The support was a high surface area graphite (Timcal, $S_{BET}$: 400 $m^2/g$) impregnated and grounded with melamine (10 wt.% N) and heated at 600 °C for 1 h under $N_2$ flow. The catalysts were prepared by incipient impregnation using $Fe(NO_3)_3{\cdot}9H_2O$ (15 wt% Fe) and dried overnight at 100 °C. Catalyst pretreatments were: $H_2$ at 500 °C 2h (Fe/G-N/$H_2$), CO at 350 °C 4 h (Fe/G-N/CO) and He at 500 °C 2h (Fe/G-N/He). A portion of the catalyst was impregnated with $K_2CO_3$ (Fe:K molar= 4:1) (Fe(K)/G-N/$H_2$) and a catalyst not N-doped was also prepared (Fe(K)/G/$H_2$). The reaction was performed with 350 mg of sieved catalyst at 300 °C and 10 bar using a total flow of 80 ml/min (45% $H_2$, 15% $CO_2$, 40% He).

**Results and discussion:** The characterization of the N-doped support indicated that it has a BET area of 353 $m^2/g$. The XPS showed a N/C ratio of 0.02, with the main contributions in the N1s region located at 398.3, 399.7 and 400.8 eV attributed to pyridine-N, pyrrole-N and graphite-N respectively. Conversion among N-doped catalyst was similar and higher than that of Fe(K)/G/$H_2$ (Fig.1), except for the catalyst prepared under inert atmosphere (not shown) with which the conversion was around 6% and 98% selective to CO. Interestingly, small selectivity differences are observed between pretreating the catalyst under $H_2$ or CO flow, and even the former produces more C2-C4 compared to $CH_4$. The K-promoted catalyst, Fe(K)/G-N/$H_2$, showed higher selectivity towards light olefins than Fe/G-N/$H_2$, while $CH_4$ and C2-C4 decreased. This agrees with what has been reported: K may favor smaller iron particles, enhances iron carburization, and provides a better yield to light olefins [2]. The characterization of the catalysts by XRD and EPR showed different phases on the fresh catalyst: (Fe ($H_2$-treated), $Fe_xC$ (CO-treated and $Fe_3O_4$ for $N_2$-treated), so ongoing characterization under reaction conditions is being studied to provide more insights into the active phases.

# $CO_2$ valorisation with earth-abundant metals using visible-light

S. Realista, R. T. Marques, N. A. G. Bandeira, R. G. Santos, P. N. Martinho*

*Centro de Química Estrutural, Institute of Molecular Sciences, Departamento de Química e Bioquímica, Faculdade de Ciências, Universidade de Lisboa, Campo Grande, Ed. C8, 1749-016 Lisboa, Portugal*

**Keywords:** carbon dioxide, photoreduction, visible-light, methane, carbon monoxide

**Introduction.** One of the most important players in molecular activation is carbon dioxide due to its crucial role in the environment with consequences for the climate and heating the earth's surface by trapping infrared radiation in the atmosphere. Unfortunately, the expansion of the human population and the energy demand resulting from there, derived in an increase in carbon dioxide concentration unbalancing the earth's carbon cycle, thus affecting the energy balance of the planet. As a result, scientists have struggled to reduce $CO_2$ into added-value chemicals such as carbon monoxide, formic acid, methane and methanol that can be used as fuels. Catalysis has been the most attractive approach with a recent scientific interest increase in the catalytic $CO_2$ photoreduction, as light is a sustainable electron source essential for the conversion – artificial photosynthesis.[1] We have previously reported a metal cryptate that can capture and convert $CO_2$ into carbon monoxide and methane triggered by visible light and we now aim at transferring this catalytic system from the lab to the pilot scale.[2] To reach this goal we will first optimise the catalytic conditions (eg.: light configuration, catalysts' structure, photosensitiser, etc) at the lab scale.

**Experimental/methodology.** Preparation of the already published[2] cryptates and new cryptates (Fig. 1) having different aromatic ring substituents (-H, -Br, -I, -CCH, -OMe) and metal centres ($Zn^{II}$, $Co^{II}$). Evaluation of their catalytic $CO_2$ photoreduction to CO and $CH_4$ performance using blue visible light.

**Results and discussion.** The aromatic ring substituent and a different metal centre influence the reactivity towards $CO_2$ photoreduction. We also optimised the photocatalytic system, by introducing a reversible quencher.

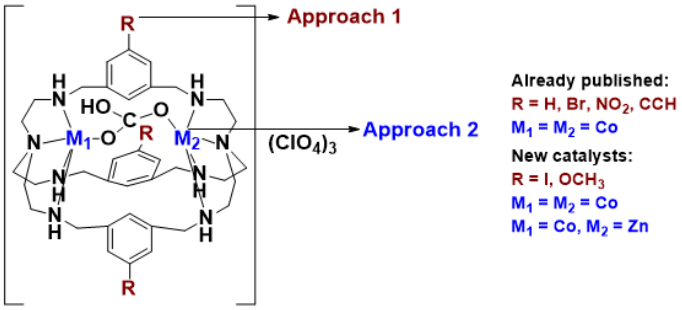

Fig. 1 – Approaches for the optimisation of the cryptates' structure

**Keywords:** $CO_2$; Methanation; Ru; $SiO_2$; Ti; Flame spray pyrolysis

**Introduction.**

Recently, $CO_2$ released from the combustion of fossil fuel are known as the main pollutant that can lead to global warming and climate shift. Thus, it is very necessary to control the $CO_2$ emission into the air by converting the $CO_2$ in to value-added compound. Methanation reaction is the reaction that can converts $CO_2$ and hydrogen, and is a popular method of hydrogen retention which can reduced the $CO_2$ content [1].

Flame spray pyrolysis (FSP) is a very interesting process for nanomaterial synthesis because it can produce high-purity nanocrystalline materials in one-step process, low operating cost, and suitable for large scale production of catalytic materials [2]. The aim of this research is to study the effect of Ti loading content in $Ru/Ti\text{-}SiO_2$ catalysts and $Ti\text{-}SiO_2$ supports prepared by using the FSP technique and the Ru deposition method on the physiochemical and catalytic properties of synthesized catalysts.

**Experimental/methodology.**

Synthesis of $Ru/Ti\text{-}SiO_2$ catalysts were carried out by one-step using flame spray pyrolysis and impregnation methods. The liquid feed solution was prepared by dissolving the desired amounts of all precursors in xylene. The precursor solution was fed to flame reactor as the conditions in our previous work [2]. In this work, the Ru deposition was done by directly added the Ru precursors in FSP solution and impregnation of Ru on FSP-made $Ti\text{-}SiO_2$ supports. Loading content of Ru was fixed at 2wt% and the Ti loading contents were varied from 2 to 12wt%.

**Results and discussion.**

Figure 1 plots between the $CO_2$ conversion and reaction temperatures of all prepared catalysts. In all tests, there was no CO formation in all catalysts. Among all catalysts, $Ru/SiO_2$ exhibited the lowest catalytic performance. Addition of Ti in $Ru/SiO_2$ catalysts resulted in the improvement of catalytic performance. In order to find the maximum Ti loading that can improve the catalytic activity, 12wt% of Ti was doping in FSP-made $Ru/SiO_2$ catalyst and $Ru/12Ti\text{-}SiO_2$ exhibited the highest $CO_2$ conversion. Moreover, deposition of Ru on $Ti\text{-}SiO_2$ support by impregnation method exhibited much higher catalytic performance than one-step FSP synthesized $Ru/Ti\text{-}SiO_2$ catalysts. After various physiochemical characterization of the catalysts, the FSP-maed catalysts exhibited very strong interaction between Ru and the supprt, which occurred by the coverage of $SiO_2$ particles around Ru species. This coverage was occurred due to the mix crystallization of both phase at nearly same time under the flame. This interaction prevent the reduction of $RuO_2$ phase to Ru activeside, which lower the the adsorption of $CO_2$ on the catalyts surface and catalytic activity of FSP-made catalysts. However, the impregnation-one can completely reduced and exhibited higher $CO_2$ catalytic performance. Addition of Ti also resulted the incrased of the catalytic activity in $CO_2$ methanation. Presence of $TiO_2$ phase promote the catalytic activity by increasing of Ru dispersion and retard the $RuO_2$ sintering during the high temperature process, which according to the increased of interaction between $RuO_2$ and $TiO_2$ species

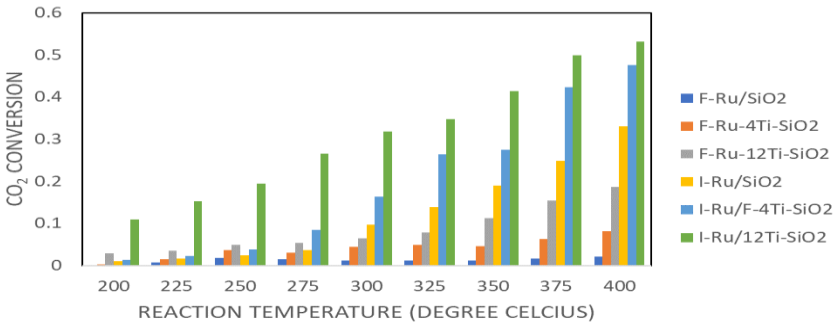

Figure 1 Plot between the CO2 conversion and reaction temperatures of all prepared catalysts**.**

**hesham.mena@catalysis.de*

**Introduction**:

The hydrogenation of $CO_2$ became one of the most promising routes not only to mitigate atmospheric $CO_2$ emissions but also to produce valuable single carbon (C1) products. Among them, methanol is a clean, biodegradable, high energy fuel, and can be further converted into value-added chemicals such as olefins, longer-chain alcohols and hydrocarbons [1]. Continuing our previous work [2], this study deals with improving methanol selectivity at industrially relevant degrees of $CO_2$ conversion [3] as a future part of a membrane reactor system for further enhancement of methanol productivity.

**Experimental:**

A series of CuZn-based catalysts were prepared and screened for $CO_2$ hydrogenation to methanol in a fixed-bed, continuous-flow stainless steel reactor under different reaction conditions. The feed gas and the reaction products were analyzed with an on-line gas chromatograph. The influence of reaction temperature, pressure, and feed gas composition on catalyst performance was studied. The most active $CuZnAlO_x$ catalyst was characterized by ICP, BET, XPS, TPR, TEM and XRD techniques.

**Results and discussion:**

Among the catalysts tested, a low-cost and ecologically friendly $CuZnAlO_x$ catalyst reached high methanol selectivity at industrially relevant $CO_2$ conversion. Figure 1 shows the $CO_2$ conversion and MeOH selectivity over 1900 h under different reaction conditions (T=180-250 °C, p=20 and 50 bar, $H_2/CO_2$=3, GHSV=280-4220 $ml_n\ g_{cat.}^{-1}\ h^{-1}$) . The highest methanol selectivity of about 93% was achieved at about 19% $CO_2$ conversion at 200 °C and 50 bar using a stoichiometric reaction feed. In repetitive measurements at a fixed set of reaction parameters (see figure 1, green circles), a slight asymptotic decrease in $CO_2$ conversion (16.0→13.5→12.9%) and in MeOH-selectivity (85.0→84.2→83.5%) was registered after 313 h and 1900 h on stream, respectively. Such capability to manage different reaction conditions is a basic requirement for catalysts to be combined with a membrane reactor, as temperature and concentration profiles change much more significantly along the reactor bed than in a classic tubular reactor. The presented catalyst is being tested for this application.

# $CO_2$ Capture and Utilisation by Using Switchable Dual Function Materials

Loukia-Pantzechroula Merkouri[1*], Tomas Ramirez-Reina[1,2], Melis S. Duyar[1]
[1]*School of Chemistry and Chemical Engineering, University of Surrey, Guildford GU2 7XH, UK*

**Keywords:** $CO_2$ capture and utilisation, switchable dual function materials, heterogenous catalysis, $CO_2$ methanation, reverse water gas shift, dry reforming of methane, adsorption, direct air capture

**Introduction.** Global warming is increasing at an alarming rate and efforts, such as the Paris Agreement in 2015, are continuously made in an attempt to achieve net zero $CO_2$ emissions by 2050. To address the needs of energy transition, we have previously developed switchable catalysts for $CO_2$ utilisation, offering flexibility in production of methane, CO and syngas.[1] Herein we further extend this idea to the development of switchable dual function materials (DFMs).[2] DFMs capture $CO_2$ and convert it directly to a product, using hydrogen or hydrocarbons as co-reactants. They offer a unique opportunity to directly synthesise value added chemicals from sources of emissions, but also from the atmospheric air.[3]

**Experimental/methodology.** The three DFMs were prepared by impregnation and the materials were obtained from nitrates precursors. All the DFMs consisted of 15 wt.% of Ni, 1 wt.% of Ru, and 10 wt.% of either $Na_2O$, $K_2O$, or CaO supported onto $CeO_2$-$Al_2O_3$ (20-80 wt.%). Their $CO_2$ adsorption behaviour was investigated at 350-650°C by thermogravimetric analysis. $H_2$-TPR was performed to evaluate their reducibility and products were detected using a mass spectrometer. The feasibility study that included cycles of $CO_2$ capture and either $CO_2$ methanation, reverse water-gas shift (RWGS) or dry reforming of methane (DRM) were performed to observe their versatility. Time-resolved operando DRIFTS-MS studies were also employed to elucidate their capture and conversion mechanisms.

**Results and discussion.** Figures 1 reveals the feasibility of switchable DFMs, where 100% selectivity in conversion of captured $CO_2$ to either methane or CO is obtained for all 3 reactions (methanation, RWGS and DRM). In all cases, the $CO_2$ was captured at the desired temperature and was subsequently converted into $CH_4$, CO, and syngas, depending on the temperature and the co-reactant used. In terms of overall performance, DFMs can be ranked in the order NiRuCa>NiRuK>NiRuNa. A striking finding was the detection of $CH_4$ during this experiment during $H_2$-TPR (Figure 2), which demonstrated that these DFMs were able to adsorb $CO_2$ directly from atmospheric air after synthesis, showing the promise of using DFMs for flexible chemicals synthesis from the $CO_2$ in air.

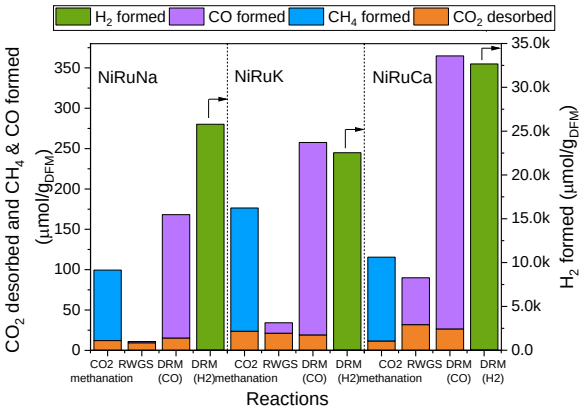

**Figure 1.** Results of feasibility study of flexible DFMs, showing the amount of $CO_2$ desorbed and products formation in each reaction ($CO_2$ methanation, RWGS and DRM) for NiRuNa, NiRuK and NiRuCa.

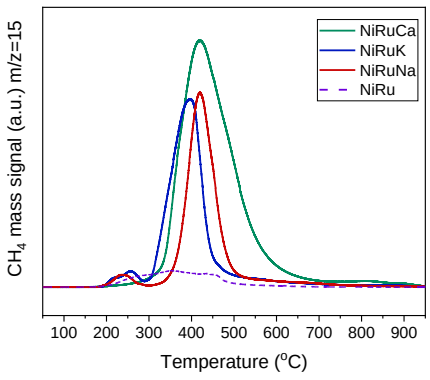

**Figure 2.** $CH_4$ signal during $H_2$-TPR with 10% $H_2$/Ar and 10 °C/min to 950 °C (WHSV= 60 $L.g^{-1}.h^{-1}$) for the three DFMs (NiRuNa, NiRuK and NiRuCa) and the reference material NiRu

# Nickel embedded silica catalyst for highly stable performance of dry reforming of methane (DRM)

Haehyun Min[1], Young Jin Kim[2] and Sung Bong Kang[1*]

[1] *Gwangju Institute of Science and Technology, Gwangju, Republic of Korea*
[2]*Korea Research Institute of Chemical Technology, Daejeon, Republic of Korea*
[*]*sbkang@gist.ac.kr*

**Introduction.**

The catalytic reaction of the dry reforming of methane (DRM, $CO_2 + CH_4 \rightarrow 2H_2 + 2CO$) has been extensively receiving more attention to actively address tremendous emissions of greenhouse gases ($CO_2$ and $CH_4$) converting to syngas ($H_2$ and CO) [1]. However, the catalyst deactivation by metal sintering and carbon coking is a significant issue in applying DRM to a chemical process. Here, we report a highly active catalyst in the DRM reaction; Ni embedded in silica structure (NiES), demonstrating long-term stability up to 500 hrs of time-on-stream under high flow rate conditions up to 450 $Lg_{cat}^{-1}h^{-1}$.

**Experimental/methodology.**

The NiES catalyst was prepared by (1) introducing a certain amount of a Ni precursor into the amine-functionalized silica by introducing oleic acid and uniformly mixing it with the silica and (2) subsequently adding the Ni precursor to the mixture (1) obtaining a final loading of 10 wt.% Ni. The final mixture was calcined at 800 °C for 2 hrs after drying at 80 °C. The catalytic performance was evaluated under a feed containing 0.3:0.3:0.4 of $CH_4$:$CO_2$:Ar ratio at 250-450 $Lg_{cat}^{-1}h^{-1}$ of GHSV.

**Results and discussion.**

Figure 1a shows an outstanding performance of the NiES catalyst, of which 98% and 97% of $CO_2$ and $CH_4$ conversions and a stoichiometric $H_2$/CO ratio, respectively, at 800 °C, without any degradation. Furthermore, we have demonstrated that (1) NiES consists of only active metals and supports without promoters, (2) is prepared in a feasible method that all steps are performed in one pot, and (3) has excellent catalytic activity and durability at high space velocities (as compared in Figure 1b). These activity results were confirmed by detailed studies and controlled experiments, and the outstanding catalytic activity was derived from the catalyst structure. Highly dispersed nano-sized (2 nm, Figure 1c and d) Ni particles are phyllosilicate-like forms that are embedded in silica structures preventing sintering due to the confinement effect. The formation of Ni-O-Si interaction by phyllosilicate-like forms enhanced properties such as reducibility and surface acidity of the catalyst, and these properties greatly contributed to the mechanism of DRM. Based on the vital intermediates identified by the DRIFT spectra the mechanism over the NiES surface was proposed.

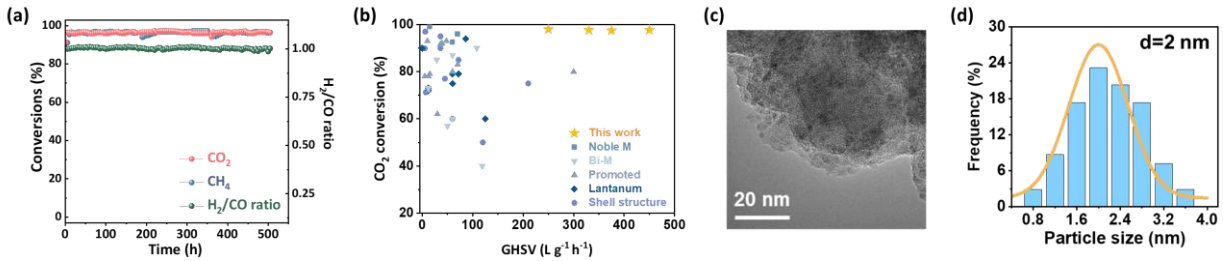

**Figure 1** (a) Long-term stability of the NiES at 800 °C with a flow of 250 $Lg_{cat}^{-1}h^{-1}$, (b) Comparison of catalytic performance of NiES with literature reports as a function of GHSV, (c) TEM image of NiES and (d) Size distribution of Ni particles.

# Investigating the effect of nickel loading on Ni/$CeO_2$-nanorods for plasma-catalytic $CO_2$ methanation

J. Barauna[1*], B. Musig[1], T. Garcia[1], M.V. Navarro[1,]

[1] *Grupo de Investigaciones Medioambientales, Instituto de Carboquímica ICB-CSIC, Zaragoza, Spain*

**Keywords:** CO2 methanation, plasma catalysis, single atom catalyst

**Introduction:** CO2 valorization is a crucial research area for reducing greenhouse gas emissions and tackling climate change. In that context, plasma-assisted catalysis is a promising technique for synthesizing valuable compounds from CO2, using the unique characteristics of plasma, coupled with the tuning effects of catalysts to improve selectivity and conversion. It is well known that the amount of active phase on a catalyst affects its performance, but in the particular case of plasma-catalysis this may differ due to the mutual influence of catalyst composition and plasma. This happens due to strong electric fields, surface charging, hot spot formation, and morphological changes of the catalyst [1]. Also, active phases and supports have great mismatch in electric conductivity, heat capacity and other important properties and these have an effect on the plasma [2]. Ni-based catalysts and CeO2 supports are commonly used in CO2 methanation, with nanostructured CeO2 being particularly effective due to its excellent redox properties and ability to adsorb and desorb oxygen [3] while Ni is commonly employed in thermal CO2 methanation due to its favorable selectivity and performance, low cost and ability to perform well even in mild conditions

**Materials and methods:** In this study, CeO2 nanorod supports were impregnated with three different loadings of Nickel and tested in the CO2 methanation using a packed-bed dielectric barrier discharge (PB-DBD) reactor. The nanorods were synthesized hydrothermally and then wet impregnated with 5%, 10%, 15%wt. Ni, calcined in air at 550°C and reduced in 5% H 2 at 600°C for 2 hours. The catalysts were characterized, before and after the discharge, using XRD, XPS, $H_2$-TPR, $CO_2$-TPD, TGA and $N_2$ physisorption.

**Results and discussion:** results show that the nanorods retain its shape after the reduction of Nickel and the dispersion of the active phase is greatly impacted by the loading. While samples containing 5% nickel were populated by uniform small Ni particles, 15% %wt. Ni results in larger particles with a great distribution of sizes. Nevertheless, plasma exposure can change the dispersion of the active phase and larger Ni particles can be reduced in size and redistributed, as it is reported for plasma-treat catalysts [ref]. This reflected in the results, and the best performing catalyst was the one with 15% nickel (82% $CO_2$ conversion and selectivity to methane close to 100%), since plasma during the reaction was effective in redistributing the nickel over the support, allowing it to benefit from the higher amount of active-phase. We can then conclude that while some similarities with other types of catalysis can hold, plasma-catalysis has unique features that can change paradigms and greatly affect the performance of $CO_2$ methanation.

**Keywords:** $CO_2$ reduction, Thermo-photo catalysis, Local Surface Plasmon Resonance (LSPR) , Methane

**Introduction.** $CO_2$ capture and valorization[1] as a climate change mitigation measure has recently attracted the scientific community interest.[1] In catalysis, many strategies have been studied to reach the goal. One of the most recent and potentially winning strategies is to use a combination of heat and light to maximize the activity of catalysts towards carbon dioxide reduction.[2] Light would minimize the thermal energy supply and improve selectivity stimulating the LSPR phenomenon of metal catalysts nanoparticles (Au, Rh, Cu)[3,4] The aim of this work is to deeply investigate this phenomenon in Sabatier reaction over Rhodium-supported Cerium-Titanium Mixed Oxides, chosen for the well-known plasmonic effect of Rh[5], and the interesting surface arrangements attained with $CeO_2$-$TiO_2$ solid oxide solutions[6], which have a positive role in $CO_2$ activation[7].

**Experimental.** Different Cerium-titanium mixed oxide compositions (X mol%$CeO_2$: (1-X) mol%$TiO_2$, X=100, 80, 50, 20) where prepared by Sol-Gel route. Rhodium was added by incipient wet (IW) impregnation of Rh-acetate or by ball milling (BM) the rhodium salt and the oxides. The final supported catalysts were calcined at 500°C and reduced in situ in $H_2$ before testing. Physico-chemical properties of materials were investigated with XRD, BET-porosimetry, $H_2$-TPR, SEM-EDS techniques. LSPR response of the different catalysts and the their thermo-photocatalytic activity ($CO_2$ conversion, $CH_4$ yield) were investigated in presence and absence of light using a 300W Xenon lamp light source.

**Results and discussion.** The LSPR effect of metal nanoparticles was confirmed by a 3% increase in temperature that was registered for the Rh-supported catalysts in comparison to bare supports upon illumination under inert atmosphere. The better catalytic performances were obtained for BM catalysts, with an optimum for the composition 80mol%$CeO_2$-20mol%$TiO_2$. This formulation showed a 19% enhancement in conversion and almost 100% selectivity in light condition at 300°C with respect to the dark test. Fig. 1 shows that light in general is beneficial in improving the selectivity of reaction. Studies are in progress to understand the role of structure and composition of support in optimizing a significant LSPR effect at lower temperature.

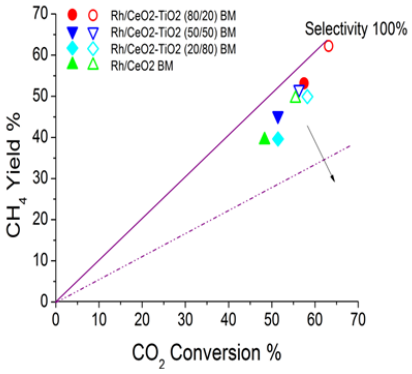

Fig. 1 Yield-Conversion - plot at 300°C isotherm. Solid and empty symbols represent dark and light experimental condition respectively; 33 ml/min gas mixture 28% He / 61% $H_2$ /11% $CO_2$.

**Introduction.** Decreasing anthropogenic $CO_2$ emissions is compulsory to mitigate the problematic effects of global warming. In that sense, shifting the paradigm from a linear carbon economy to a circular one is a good step in this direction. [1] The Sabatier and the Reverse Water Gas Shift reactions are paradigmatic examples of this strategy. [2] Nonetheless, they imply the need for a catalyst due to the stability of the $CO_2$ molecule. Being so, magnetic induction heating or "magnetically-assisted catalysis" is an already proven feasible technique that helps achieve the required temperature at the active centres using an external magnetic field. This avoids undesired secondary reactions and increases the efficiency of the process while heating and cooling velocity are drastically improved. [3] Under this context, the chemical storage of energy from renewable intermittent sources would be facilitated. In this work, nickel and cobalt ferrites have been synthesized and studied as bifunctional materials. They combine a catalytic activity for $CO_2$ reduction to CO and $CH_4$ and the necessary heating ability for magnetically-assisted catalysis.

**Experimental/methodology.** Nickel ($NiFe_2O_4$) and cobalt ($CoFe_2O_4$) ferrites were synthesized using different synthesis methods: autocombustion sol-gel, Pechini and template-directed approach employing a MOF (Fe-BTC). Afterwards, 2.3%Ni/$CoFe_2O_4$ and 4%Ru/$CoFe_2O_4$ were obtained through impregnation. The materials' heating ability was studied by evaluating the required field intensity to reach the reaction temperature in the magnetically-assisted catalytic reactor. Magnetic methanation was performed using a glass tubular reactor that was placed inside a 100 kHz coil. The catalytic bed was composed of the selected ferrite and SiC. Gases from the outlet were quantified by gas chromatography. Finally, ferrites were characterized by X-ray Diffraction, BET area, vibrating sample magnetometry and temperature programmed reduction.

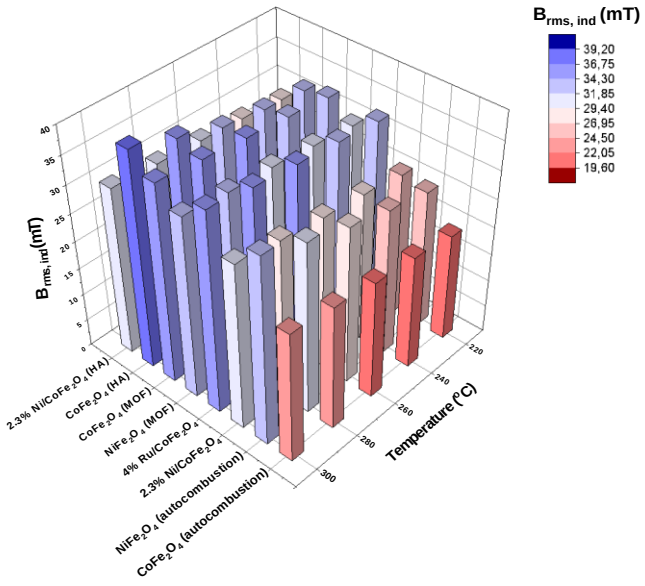

**Figure 1**. **Required magnetic field intensity to reach the reaction temperatures for each ferrite.**

**Results and discussion.**

**a. Heating ability of the ferrites.** $CoFe_2O_4$ (sol-gel) results in the most promising heating agent for magnetically-assisted methanation. Ni-Fe and Co-Fe alloys are formed during the pretreatment of the catalyst, specially in the case of $CoFe_2O_4$.

**b. Methanation tests.** Low to moderate conversions were achieved. $CoFe_2O_4$ (sol-gel) is extremely selective for the production of CO ($S_{CO,\ 300\ ºC}$ = 95%), while showing moderate conversions ($X_{CO2,300\ ºC}$ = 60%). Regardless of the synthesis method, $NiFe_2O_4$ exhibits a higher $s_{CH4}$, but lower conversions. Increasing the surface area of $CoFe_2O_4$ and impregnating active metals like Ni also result in higher $S_{CH4}$.

**c. Characterization.** $H_2$ consumption peaks were identified and assigned. Magnetization curves were obtained. The materials are soft ferrimagnets with higher saturation values than those reported on the literature. Differences in synthesis method translate into different BET areas.

**Keywords:** CO2 methanation, plasma catalysis, single atom catalyst

**Introduction.** $CO_2$ valorisation is one of the players for the de-fossilization of energy production and industrial manufacturing, it comprises of different strategies of $CO_2$ capture and utilization (CCU) [1] and it requires fundamental research and engineering to efficiently break the $CO_2$ molecule and have it react to form added-value chemicals. One of the possible reactions is the reduction of $CO_2$ to methane, a.k.a. Sabatier's reaction. This reaction between $CO_2$ and $H_2$ has been widely studied in conventional catalysis: it is known to be exothermic but kinetically hindered, therefore happening with the aid of a catalyst typically between 200 °C and 450 °C, at pressures between atmospheric and 100 bar [2]. The use of non-thermal plasmas is promising for energy efficient $CO_2$ conversion exploiting the dissociation happening in plasma via electron impact and vibrational excitation. Additionally, the synergy between the plasma and the catalytic material can further enhance the reaction performance, as it has been demonstrated for Ni-containing catalysts resulting in an enhanced reaction yield even at atmospheric pressure and mild reaction temperatures (around 200 °C) [3].

Ru and Ir on $CeO_2$ single-atom catalysts have been previously used for thermal $CO_2$ methanation, reporting effects on strong metal-support interaction, metal dispersion, cerium oxide crystalline structure and hydrogen spill over that affect differently the catalyst activity and $CH_4$ selectivity [4,5].

**Experimental/methodology.** A one-pot hydrothermal method was used for the synthesis of Ni-Ru single atom $Ni_xRu_yCe_{(1-x-y)}O_2$ materials with x = 0.05, 0.025, 0 and y = 0, 0.025, and 0.05. The relative metal salts were dissolved in a 6 M NaOH solution, poured in an autoclave and placed in an oven at 120 °C for 24 h. The material recovered via filtration was dried, calcined at 400 °C, and reduced before the reaction [6]. The catalysts were characterized by means of XRD, $N_2$ physisorption, XPS, $H_2$-TPR, $CO_2$-TPD, and TEM. Plasma-assisted $CO_2$ methanation was carried out in a non-thermal Dielectric Barrier Discharge (DBD) plasma reactor. The high voltage electrode of the cylindrical DBD fixed-bed reactor was supplied by a high-voltage, alternating current source with frequency 27 kHz and voltage 20-25 kV.

**Results and discussion.** The morphology of the doped ceria structures is needle-like and the crystallite size of the cerianite phase does not vary drastically with the introduction of the metal sites from 7 to 9 nm. Regarding the physicochemical properties of the single-atom catalysts, we report that for low %mol. Ni and Ru clusters are well dispersed in the ceria crystalline structure as the diffraction peaks are not detectable in XRD [6]. Furthermore, the reducibility of the materials is improved at low temperatures compared to $Ni/CeO_2$ materials obtained via wet impregnation. The low amount of metal sites does not allow reaching a high activity for plasma-assisted $CO_2$ methanation compared to previous tests carried out with 15 %wt. Ni catalysts; however, it is still relevant if normalized by $mol_{metal}$. The catalyst with both Ni and Ru sites, $Ni_{0.025}Ru_{0.025}Ce_{0.95}O_2$, results in an enhanced $CO_2$ conversion, indicating synergy between the two metals in the catalytic methanation reaction assisted with plasma.

**Keywords:** Supported Au catalysts, $CO_2$ hydrogenation, Methanol

**Introduction.**

Catalytic conversion of $CO_2$ to value-added chemicals using green $H_2$ derived from renewable energy is essential to develop a carbon-neutral society[1]. Among $CO_2$ hydrogenation products, methanol ($CH_3OH$) as a primary chemical has attracted much attention. Recently, direct $CH_3OH$ synthesis from $CO_2/H_2$ has been developed using Cu-based catalysts. This reaction is exothermic; therefore, the lower temperature is thermodynamically more favorable. In this study, various metal oxides-supported Au catalysts were prepared, and the activity for $CO_2$ hydrogenation at low temperatures (< 473 K) was investigated.

**Experimental/methodology.**

Supported Au catalysts were prepared by the deposition-precipitation with urea[2]. Catalytic tests were carried out in a fixed-bed flow reactor. The diameter of Au was estimated by HAADF-TEM.

**Results and discussion.**

The catalytic performance of various supported Au catalysts was evaluated in $CO_2$ hydrogenation at 473 K. Among the Au catalysts tested, $Au/ZrO_2$ showed the highest $CH_3OH$ formation rate. However, CO was mainly formed. Au/ZnO exhibited the highest $CH_3OH$ selectivity (75%) without unfavoured $CH_4$ formation.

Fig.1 shows the turnover frequencies (TOFs) for the formation of $CH_3OH$ at 473 K as a function of the mean diameter of Au NPs on supported Au catalysts. To determine whether the active sites for the $CO_2$ hydrogenation to $CH_3OH$ were exposed Au atoms on the Au NPs or perimeter sites at the Au-support interfacial perimeter, we calculated the TOFs in two ways: 1) by normalizing the number of $CH_3OH$ molecules formed per hour to the total number of exposed Au atoms at the Au NPs (TOF-S) and 2) by normalizing the number of $CH_3OH$ molecules formed per hour to the total number of Au atoms at the Au-support interfacial perimeter (TOF-P). TOF-S decreased with increasing mean Au NPs diameter, whereas TOF-P remained nearly constant. These results suggest that the active sites for $CO_2$ hydrogenation to $CH_3OH$ are the Au-support interfacial perimeter, and $CH_3OH$ is generated by the reaction between $CO_2$ adsorbed on the Au-support interface and $H_2$ dissociatively adsorbed on the Au NPs.

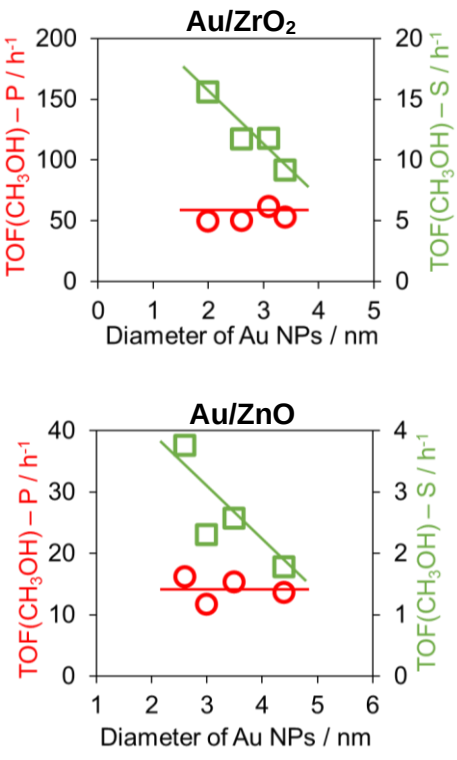

Fig.1 Relationship between diameter of Au NPs and TOF-P (○) and TOF-S (□) for $CH_3OH$ formation.
Pretreatment: $H_2$ reduction at 473 K
Reaction: 473 K, $CO_2/H_2$ = 1/3, 4 MPa

**Introduction.** $CO_2$ hydrogenation is a hot topic, being a relevant step to satisfy future energy demand and supply building blocks for the petrochemical industry while mitigating $CO_2$ emissions. 10% $LaNiO_3/CeO_2$ formulation has emerged as a promising precursor of highly active, selective and estable catalysts for $CO_2$ methanation [1]. However, the role of the active sites and the main reaction intermediates is still unclear. The aim of the current study is to monitor the behavior of the different Ni, La and Ce species as well as reaction intermediates during $CO_2$ methanation reaction using NAP-XPS and in-stu FTIR techniques.
**Experimental/methodology.** The surface of the sample, prepared as reported elsewhere [1], has been monitored during the exposure to pure $H_2$, pure $CO_2$ and $CO_2$ methanation (20% $CO_2$ + 80% $H_2$) atmospheres at increasing temperatures by Near Ambient Pressure-XPS (NAP-XPS) using synchrotron radiation at the CIRCE beamline, ALBA Synchrotron Light Source. Ni3p, Ce3d, La3d and C1s regions were monitored with 320, 375 and 1125 eV photon energies. Meanwhile, the role of the different active sites and reaction intermediates in the $CO_2$ methanation mechanism was evaluated by *In-situ* FTIR anlaysis. For that, a Cary 600 Series FTIR spectrometer (Agilent) coupled with a high temperature cell equipped with ZnSe windows (Specac) was used.
**Results and discussion.** After subjecting the 10% $LaNiO_3/CeO_2$ sample to controlled reduction step (500 °C), small $Ni^0$ nanoparticles and a $La_2O_3$ phase in close contact with ceria support are conformed. As a result of these strong interactions, a certain proportion of nickel always remains oxidized under reaction conditions. Among them, the species involved in the redox processes taking place during the $CO_2$ methanation mechanism are the $Ni^{2+}$-$CeO_2$/$Ni^0$ and $Ce^{4+}$/$Ce^{3+}$ pairs, which tend to be oxidized under $CO_2$ methanation conditions at increasing temperatures.
*In-situ* FTIR experiments allow indetifying the participation of formates, bicarbonates as well as mono-, bi-dentate carbonates intermediates during $CO_2$ methanation (Figure 1). It is worth to mention that formate intermediate disappears as long as $CH_4$ production increases, in line with the identification of the formate peaks made in the C1s region during NAP-XPS experiments. Thus, the formate route, with assistance of the oxygen vacancy of ceria support and $La_2O_3$ basic sites, is expected as the most feasible mechanism for $CO_2$ methanation over this novel material. Based on these results, the high activity of the 10% $LaNiO_3/CeO_2$–derived catalyst is tentatively attributed to the simultaneous presence of $Ni^{2+}$-$La_2O_3$, $Ni^{2+}$-$CeO_2$ and $Ni^0$ active sites, where $CO_2$ and $H_2$ can be associatively and dissociatively adsorbed, respectively.

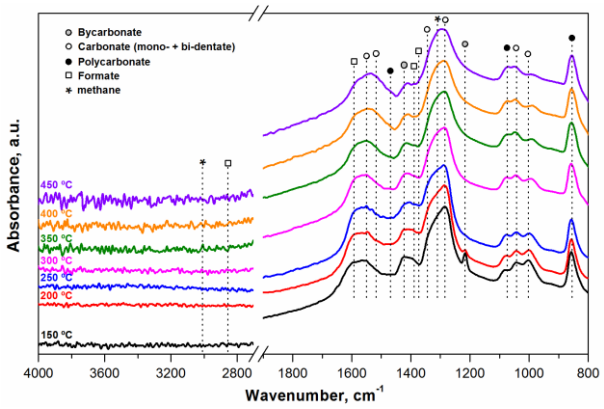

**Figure 1.** *In-situ* FTIR spectra for the pre-reduced 10% $LaNiO_3/CeO_2$ sample during $CO_2$ methanation at different temperatures.

# Enhancement the $CO_2$ adsorption and hydrogenation to $CH_4$ capacity of Ru-Na-Ca/$\gamma$-$Al_2O_3$ dual function material by controlling the structure under different calcination atmosphere

A. Bermejo-López, B. Pereda-Ayo., J. A. Onrubia-Calvo, J. A. González-Marcos, J. R. González-Velasco*

**Keywords:** integrated $CO_2$ capture and utilization, methanation, dual function material, calcination atmosphere.

**Introduction.** Integrated $CO_2$ capture and utilization (ICCU) technology requires the implementation of dual function materials (DFMs) to carry out the process in a single reaction system[1]. In this work, the possibility of improving the activity of a previously optimised DFM formulation[2] (4% Ru-8%$Na_2CO_3$-8%CaO/$\gamma$-$Al_2O_3$) by modifying the calcination atmosphere is studied.

**Experimental.** A single batch of DFM was prepared by sequential wetness impregnation, which was splitted into four alliquotes. One of them was calcined in static air inside a muffle (RuNaCa-air), whereas the remaining three were calcined in a horizontal furnace under different gas mixtures. Two of them under reducing atmosphere (RuNaCa-10$H_2$ and RuNaCa-50$H_2$) and the last one in an inert atmosphere (RuNaCa-$N_2$). The four DFMs were deeply characterized by XRD, TG, $N_2$ adsorption-desorption, $H_2$ chemisorption, TEM, $H_2$-TPD, $H_2$-TPR, $CO_2$-TPD and TPSR. The catalytic behavior was evaluated, in cycles of $CO_2$ adsorption and hydrogenation to $CH_4$, and the temporal evolution of the concentration of reactants and products was analyzed.

**Results and discussion.** DFMs with high metallic dispersion are obtained in all cases, and it was confirmed that the reduction pretreatment prior to the activity tests reduced completly the ruthenium phase. The calcination atmosphere did not alter significantly the basicity of the DFMs; however, a stronger effect on the reactivity of the adsorbed $CO_2$ was identified for the samples prepared under different calcination atmosphere. In the TPSR experiments, RuNaCa-$N_2$ and RuNaCa-air DFMs produced a significantly higher amount of $CH_4$. It is proposed that the DFMs calcined ubder an inert flow and muffle have a better arrangement between the adsorbed carbonates and the metal sites; in fact, they present the highest surface area values, especially DFM RuNaCa-$N_2$ (134 $m^2$ $g^{-1}$).

Figure 1 shows the catalytic activity in $CO_2$ adsorption and hydrogenation to $CH_4$ sucessive cycles. For all DFMs the same general trend is observed. Note that the formulation of the four DFMs is the same and only the calcination atmosphere is varied. However, differences in production of $CH_4$ ($Y_{CH4}$) can be observed. RuNaCa-$N_2$ DFM presents the highest $Y_{CH4}$=449 µmol $g^{-1}$ at 370 °C. Therefore, it is concluded that calcination atmosphere significantly influences the physico-chemical properties and, consequently, the activity of each DFM. The DFM RuNaCa-$N_2$ is proposed as the optimum of this study; and therefore, calcination in flow of $N_2$ is selected as optimal for presenting the best arrangement conformed between ruthenium and the adsorbent phases to enhance activity in ICCU.

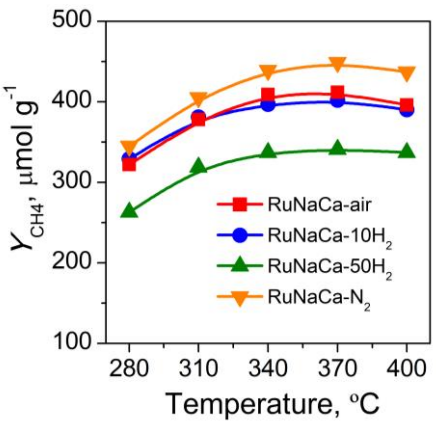

**Figure 1.** Evolution of $CH_4$ productions with operating temperature for the DFMs.

**Keywords:** ZSM-5 zeolite; bifunctional catalysts; renewable methane production; gas phase reaction

**Introduction.** The ongoing intensive use of conventional fuels is associated with increasing carbon emissions and their serious impact on the climate. The European Green Deal, as part of the EU's long-term strategy, aims to address climate change issues by eliminating net greenhouse gas emissions by 2050, most notably $CO_2$, whose emissions reach a record amount of 420 ppm in 2020 [1]. In recent years, technologies have been developed and industrialized to capture $CO_2$ from outgoing gas streams or directly from the atmosphere, after which it can be utilized via transformation processes to chemical substances and fuels [2]. This can be achieved by carboxylation reactions, where the $CO_2$ molecule is used as a precursor for organic compounds, such as carbonates, acrylates and polymers, or in reduction reactions to produce methane, methanol, synthesis gas, urea or formic acid [3].

**In this study**, template-free micro-mesoporous ZSM-5 zeolite was synthesized and modified with Ni and/or Ru. The obtained catalysts were investigated in the $CO_2$ hydrogenation to renewable methane.

**Experimental.** The obtained materials were characterized by X-ray powder diffraction, $N_2$ physisorption, temperature-programmed reduction (TPR-TGA), TEM and XPS spectroscopy. Hydrogenation of methane was studied at an atmospheric pressure using a fixed-bed flow reactor in the temperature range 250–400 °C with a flow rate of 90 mL/min $H_2$, $CO_2$ and $N_2$ (50%) ($H_2/CO_2$ is 4/1).

**Results and discussion.** Mono- and bimetallic Ni- and Ru-modified micro-mesoporous ZSM-5 catalysts were prepared by wet impregnation. Formation of finely dispersed nickel and/or ruthenium oxide species was observed on the external surface and in the pores of zeolite support. It was found that the peculiarity of the used zeolite structure and the modification procedure determine the type of formed metal oxides, their dispersion and reducibility. The applied Ni content, the addition of Ru as a second metal and the sequence of the modification by two metals are of key importance for the preparation of bimetallic catalysts with appropriate physico-chemical characteristics. XPS study revealed that the surface became rich in nickel and poorer in ruthenium for bimetallic catalysts. However, surface density of ruthenium is lower in bimetallic preparations compared to the monometallic one. TPR study confirmed the facilitated reducibility of nickel oxide particles in the presence of noble metal. Among the studied catalysts, 10Ni5Ru/ZSM-5 composition shows the highest activity and high selectivity for methane formation, reaching the equilibrium conversion and 100% selectivity at 400 °C. High stability and good reusability were found for the bimetallic 10Ni5Ru/ZSM-5 catalyst.

**Keywords:** reverse water-gas-shift, Cerium Oxide, Copper, $CO_2$ utilization, Zirconium Oxide

**Introduction**

Reverse water gas shift (RWGS) have received recently attention as a way to utilize $CO_2$ to produce syngas. Among RWGS catalysts, inexpensive Cu-based materials are of interest because they have shown high activity and selectivity .[1] However, it has also been demonstrated that the nature of the support can affect the catalytic performance. In particular, reducible oxides are regarded as good supports for RWGS, because their reducible properties can be modulated to improve the catalytic performance.[1] $CeO_2$ as catalyst support has been used to investigate the RWGS reaction because of its ability to form oxygen vacancies and its oxygen storage and release capacity, which have been demonstrated to assist in the conversion of $CO_2$ to CO.[2, 3] $ZrO_2$ is known to enhance oxygen mobility when added to $CeO_2$. [4] In this work we study the effect of adding adding $ZrO_2$ on the activity in RWGS of $Cu/CeO_2$ catalysts with different metal loadings.

**Experimental**

The $CeO_2$-$ZrO_2$ supports have been synthetized by co-precipitation, with loadings of $ZrO_2$ between 15%wt to 50%wt. The Cu was then introduced in a range of loadings between 5%wt and 28%wt by impregnation of the supports with Cu nitrate solutions, followed by calcination at 500°C for 4 hours. Activity tests were performed in a 3 mm diameter quarz reactor, after reduction of the catalyst at 300°C to generate Cu particles, at differential conditions in the lower temperature range (250°C to 350°C) in order to obtain the kinetics parameters. The gases were analyzed by gas chromatography.

The characterization of the catalysts have been performed by XRD and X-ray absorption spectroscopy, as well as temperature-programmed reduction.

**Results and discussion**

The results show that among the catalysts tested, Cu supported on $CeO_2$ has the highest activity at the 250°C - 350°C temperature range. On the other hand, the apparent energy of activation was similar for all the materials studied, indicating same reaction mechanism for all the catalyst formulations tested. The addition of $ZrO_2$ to $CeO_2$ achieved and increase in the CO yields, while carbon deposition is detected for the $CeO_2$ support. The characterization of these catalysts shows an increase in the Cu particle size upon reduction when $CeO_2$ is used as support. In contrast, $ZrO_2CeO_2$ supports stabilize Cu particles in sizes of ca. 30 nm. Further studies on the $CeO_2ZrO_2$ support will lead to insights on the role of support on the activity of Cu particles for RWGS.

**Keywords:** Hydrogen Production,Chemical looping Technologies, Nickel based mixed oxides, like-hydrotalcites materials

**Introduction.** Hydrogen is an energy vector with attractive attributes, such as lightness, storability, reactivity, high energy content per unit mass, and ease production on industrial scale. Furthermore, hydrogen can be used without direct emissions of air pollutants or greenhouse gases and can be produced from a diverse range of low-carbon energy sources. Chemical looping technologies can be used as a valuable approach for hydrogen production, due to the high energy efficiency and inherent $CO_2$ capture ability[1]. This study deals with the investigation of five type of nickel- based oxygen carrier materials active in methane reforming for hydrogen production through chemical looping technologies.

**Experimental/methodology.** Five catalysts with Nickel in different environments were prepared: Nickel supported on Ceria (**Ni/Ce**), Ni coprecipitated with cerium oxide (**NiCe**), **NiAlMg** or **NiAlCa** mixed oxide prepared by like-hidrotalcites materials, thermal decomposition and Ni in **$LaNi_{0.8}Co_{0.2}O_3$** perovskites structure. All samples were characterized by X-ray diffraction (XRD), Nitrogen physisorption, temperature programmed reduction (TPR) with diluted $H_2$ or $CH_4$ and temperature programmed oxidation (TPO) techniques. The Redox stability was checked with multiple REDOX cycles and chemical looping experiments were carried out isothermally alternating the gas composition every 10 minutes from 15 vol% of $CH_4$ in $N_2$ to air. The reaction temperature was chosen for each sample based on temperature programmed reduction measurements with methane.

**Results and discussion.** Characterizations of nickel based materials confirmed very different nickel enviroments whose redox stability, checked by two cycles of $H_2$-TPR/$O_2$-TPO, was very high for NiAlMg and $LaNi_{0.8}Co_{0.2}O_3$, and lower for the other trhee structures. Looking at the $CH_4$-TPR the best perfomances , in terms of hydrogen production, is given by NiCaAl and NiCe catalysts with a peak of activity at 600°C. The same behaviour was found in the reduction/oxidation cucles with $CH_4$/air mixtures, with the sample NiCaAl having the highest hydrogen yield. This sample suffered of a deactivation along the cycles, due to structural modifications, while NiCe showed a stable activity along ten redox cycles (see Fig. 1).

**Keywords:** Carbon dioxide hydrogenation, Particle size effect, Indium oxide, Green Methanol

**Introduction.** To combat global warming, liberation of fossil $CO_2$ should be avoided. However, some processes require carbon as a raw material, which could instead be taken from the atmosphere or $CO_2$ emissions from industry.
One important reaction for this is the production of methanol from $CO_2$, either as a stand-alone process or coupled with e.g. MTO to produce methanol.
For $CO_2$ hydrogenation, Cu-based catalysts similar to those used for CO hydrogenation were used, but to overcome their drawbacks many new catalysts based e.g. on $In_2O_3$-$ZrO_2$, PdZn, ZrZn systems are being researched. Two main factors are identified that influence the selectivity and yield of the $In_2O_3$ system: As shown by Chen et al [1], CO formation mainly depends on the indium loading, or more precisely the particle size of the indium particles, as intermediates are suspected to spill over to the zirconia surface and decompose to CO and $H_2O$ if the particles are too small. Additionally, the lattice spacing of m-$ZrO_2$ is almost half of the spacing of $In_2O_3$, which leads to high strain when an Indium layer is deposited on zirconia, improving the methanol activity [2]. Using a modified, green catalyst preparation method involving alginate as a template [3], highly dispersed $In_2O_3$ particles can be obtained at high loadings, demonstrating the importance of particle size instead of loading.
**Experimental/methodology.** Catalysts were prepared by mixing a Na-alginate gel with zirconia powder. Next, the alginate was ion-exchanged with indium, after which indium is finely dispersed in a matrix of alginate gel. During calcination, the alginate is burned off, thereby depositing indium particles on the zirconia powder. By varying the calcination duration and thus the degree of sintering, different particle sizes were prepared. In addition, impregnation catalysts were prepared by wetness impregnation as described by Martin et al [4]. For catalyst characterization, BET was used to measure the extent of sintering, while XRD and SEM were used to obtain particle size and changes in lattice parameters.
**Results and discussion.** Most of the current literature concentrates on the loading, even though already Chen et el. assumed the particle size is key. To understand the influence of the particle size, it is first required to synthesize catalysts with varying particle sizes without changing any other parameter. E.g., during the study of Chen et al., the particle size was changed indirectly by loading. However, preliminary results show that it is possible to deposit indium nanoparticles of a chosen size using the alginate method onto zirconia at a loading of 20 wt-% $In_2O_3$ (minimum size: 4 nm, after 8h sintering: 14 nm). As expected from the literature, the methanol selectivity was negatively correlated to the particle size. According to XRD results, the strain of the lattice is also negatively correlated.
An impregnation catalyst resulted in a particle size of 6 nm and an intermediate selectivity.
With additional data from alginate and impregnation catalysts with different particle sizes, more insight into the effects of the particle size for both the activity towards methanol and the selectivity will be obtained and presented.

# Electrified $CO_2$ reforming of methane and reverse-water gas shift driven by Joule heating

L. Zheng, M. Ambrosetti, F. Nicolini, A. Beretta, G. Groppi, E. Tronconi*
*Dipartimento di Energia, Politecnico di Milano, Via Lambruschini 4, 20156, Milano, Italy*
**enrico.tronconi@polimi.it*

**Introduction.** The $CO_2$ reforming of methane (dry reforming of methane, DRM) and the reverse water-gas shift (RWGS) reactions are interesting alternatives for syngas production from captured $CO_2$ [1]. To allow significant conversion, heat should be supplied to the reactor at relatively high temperature (700-800°C). Instead of using conventional fuel combustion which reduces the $CO_2$ valorization potential, we report here the catalytic $CO_2$ activation in a structured reactor driven by Joule heating, which paves a new path to the synthesis of low carbon chemicals utilizing captured $CO_2$ and excess renewable electricity.

**Experimental/methodology.** Like in our previous works on electrified methane steam reforming [2, 3], a SiSiC foam washcoated with $Rh/Al_2O_3$ catalyst was prepared and connected to an AC generator to provide efficient Joule heating combined with optimal heat and mass transfer properties for the catalytic $CO_2$ conversion (Fig. 1(a)). eDRM: $CO_2/CH_4$=4, eRWGS: $H_2/CO_2$=2.25, GHSV=100 kNl/$kg_{cat}$/h, ambient pressure.

**Results and discussion.** As shown in Fig. 1(b), the structured catalyst could be heated by the Joule effect up to temperatures needed for DRM and RWGS reactions. An almost linear correlation was observed between the input power and the measured outlet foam temperature, $T_{cap}$. As a result of its higher endothermic nature, the eDRM (ΔH=247 kJ/mol) require more power to reach the same temperature in comparison to eRWGS (ΔH=41 kJ/mol) at same GHSV. $CO_2$ conversions approaching equilibrium were measured across a wide range of conditions for both reactions (Fig. 1(c)). The eRWGS process was highly selective, as hardly any $CH_4$ could be detected for the investigated conditions. We ascribe these results to the high activity of Rh catalyts for both DRM and RWGS reactions, to the excellent external mass transfer properties combined with the intimate contact between catalyst and electrified foam support. The overall energy efficiency of the system was evaluated from the ratio of process heat duty ($H_{out}$-$H_{in}$) to input power ($W_{el}$). An energy efficiency of approx. 25% was obtained for eRWGS, while a higher value of approx. 53 % was achieved for eDRM. The heat dissipation is the primary source of energy loss in our system and, once the reactor geometry is fixed, it is mainly governed by the reactor temperature. We could demonstrate that losses are in a similar range for the two reactions, while the net process heat demand at the same GHSV is higher for eDRM, leading to a higher thermal efficiency. Noteworthy, such a dissipation mechanism can be minimized when scaling up the reactor. Moreover, the proposed electrified reactor concept is proven to ensure remarkably low specific energy demand for $CO_2$ valorization (approx. 0.7 kWh/$Nm^3_{CO2}$ for eRWGS, considering an overall adiabacity of 95% and a recovery of 90% sensible heat).

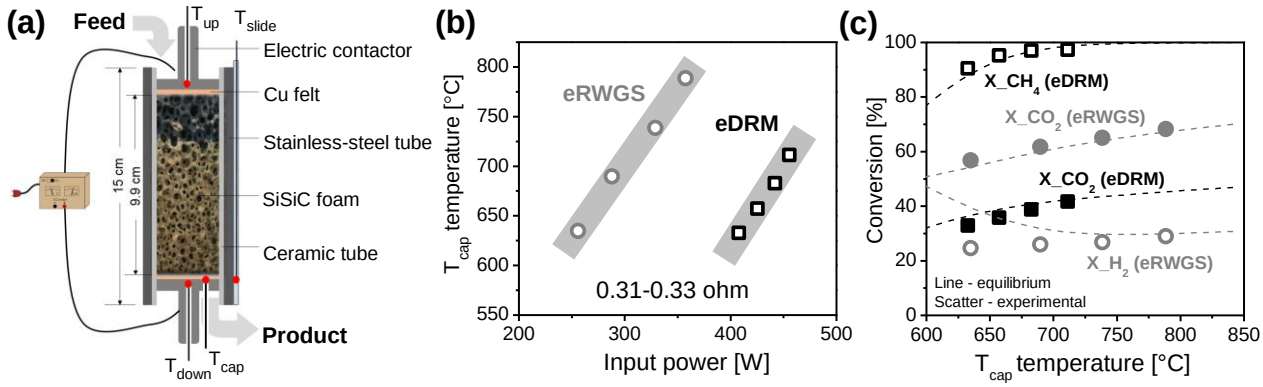

**Fig. 1** (a) Electrified reactor layout, (b) $T_{cap}$ vs. input power, (c) $CO_2$ conversion vs. $T_{cap}$ during eDRM and eRWGS runs.

**Keywords:** $CO_2$ hydrogenation, Fischer-Tropsch synthesis, kinetic modeling, parameter estimation

**Introduction.** $CO_2$ hydrogenation via Fischer-Tropsch synthesis (FTS) is one of the ways to convert $CO_2$ to a high-value-added product, and hydrocarbon synthesis over Fe catalysts prepared by co-precipitation was shown to be promising in our previous work [1]. This work addresses the development of kinetic rate equations for $CO_2$ hydrogenation over K/Fe-Cu-Al catalyst to analyze the contribution of two different pathways and quantitatively evaluate the effects of operating conditions on the catalytic performance.

**Experimental/methodology.** Details about catalyst preparation and characterization can be referred to in our previous work [1]. Kinetic data were produced in the experiments (0.5 g of catalyst and 2 g of $Al_2O_3$) under various temperatures (270–330 °C), space velocities (1000–5000 mL/$g_{cat}$/h), and feed compositions ($H_2/CO_2/CO/Ar$ = 72/24/0/4 and 72/20/4/4), while pressure was fixed at 21 bar. The $CO_2$ conversion and the yields of methane, ethane, ethene, propane, propene, butane, butene, $C_{5+}$, and $C_{5+}$= were measured.

**Results and discussion.** The two different pathways were considered in this work; direct $CO_2$ hydrogenation to hydrocarbon products and reverse-water-gas-shift reaction followed by CO-FTS reaction. The Langmuir-Hinshelwood type rate equations were assumed for overall reactions, where CO, $CO_2$, $H_2$, and $H_2O$ were considered in the site-balance equation. Kinetic parameters were estimated by fitting experimental data, in which lsqcurvefit function in Matlab (MathWorks Inc.) was used to apply the Levenberg-Marquardt method for the minimization of the objective function. The means of absolute relative residuals for the objective elements (conversion and yields) were less than 20%, and the model could satisfactorily describe the catalytic behaviors of $CO_2$ hydrogenation. Further analysis will be conducted to evaluate the effects of operating conditions and determine the optimal condition for high productivity of light olefins and stable thermal behavior in the reactor.

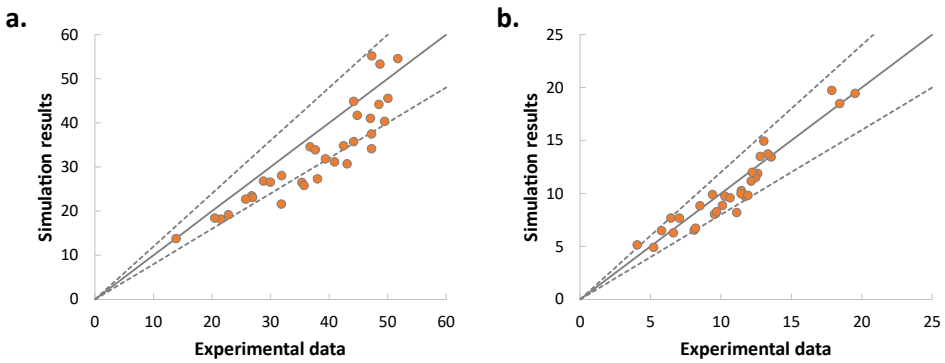

**Figure 1.** The comparison of **(a)** $CO_2$ conversion [%] and **(b)** $C_{5+}$ yield [%] between experimental data and simulation results. The solid and dashed lines represent the diagonal and ±20% error lines, respectively.

**Keywords:** CFD, membrane reactor, reactor optimization

**Introduction.** Despite technological maturity, understanding reaction mechanism and the interplay of the surface properties is still ongoing topic among researchers. Thus, the exact mechanism of the reaction pathway and the interplay of the catalytic surface have received much attention in academia in recent years [2,3]. While multi-scale hierarchical approach was already successfully applied to a compelling industrial process, where catalytic heterogenous system is captured from micro to macro level, it is hard to believe that this will become a main stream of solving industrial processes due to high computational cost of the methods.

**Experimental/methodology.** On the other hand, correlation equations (CE) have a long history of use in chemical engineering. They are collection of dimensionless numbers and coefficients that gives fast and meaningful prediction of mass and heat transfer. The advantage of CE is that they project three dimensional phenomena to one dimension by averaging physiochemical properties which can be used in much simpler continuum fluid dynamic models such as plug flow reactor (PFR). However, they have to be experimentally determined for each specific system which in case of industrial scale reactors is prohibitively expensive. Moreover, CE validity is strictly bonded to the specific range of the operational conditions of the system.

**Results and discussion.** Herein we captured all the local phenomena which can be used to calculate CE with aid of CFD. The goal was to develop workflow for model order reduction (MOR) of computational demanding CFD model. Thus, mass and heat transfer obtained with CFD simulation was linked to pseudo-homogeneous and heterogeneous continuum models. With this technique we created modules for fast and targeted optimization of industrial processes.

**Keywords:** Photo-thermalcatalys, Bimetallic MOFs, $CO_2$ hydrogenation

**Introduction:** The use of Metal-organic frameworks (MOF) as hard templates for the preparation of heterogeneous catalysts have attracted great attention in last years, due to the excellent features (high surface area or porosity) and the good and uniform distribution of metallic clusters in the derived structure [1,2]. Herein, we have prepared via calcination and pyrolisis several bimetallic MOF-based catalysts (Zr-BDC in combination with Ru and Ni) and we have tested for the photo-termal hydrogenation of $CO_2$.

**Experimental/methodology:** Bimetallic MOF were synthesized following published protocols for the monometallic UiO-66 MOF (Zr-BDC) [3] (BDC = terephthalic acid) with a metal to organic ligand ratio of 1 : 2 (metal : organic ligand). Guest specie Ru or Ni were introduced by interchanging 3 % or 10 % of the initial Zr precursor by the respecting salt ($RuCl_3$ or $NiCl_2$). Bimetallic MOFs were treated from 400 ºC to 600 ºC for 3 h in air atmosphere or in dry $N_2$. Physicochemical properties were characterized by XRD, TEM, TEM-EDX, TGA and ICP. Catalytic activity was evaluated by $CO_2$ photothermal hydrogenation (1 $CO_2$ : 4 $H_2$) in a Harrick chamber under 3 Suns of irradiance. The outlet gas was analyzed with an Agilent microGC.

**Results and discussion:** Figure 1 shows some examples of the $CO_2$ hydrogenation under some calcination treatments. The $CO_2$ conversion increased with increasing calcination temperature. The selectivity of Ru0.10ZrO2 treated at 600ºC was close to 100% at temperature of 300ºC. Under pyrolysis, MOF derived-carbons present high selectivity to CO formation.

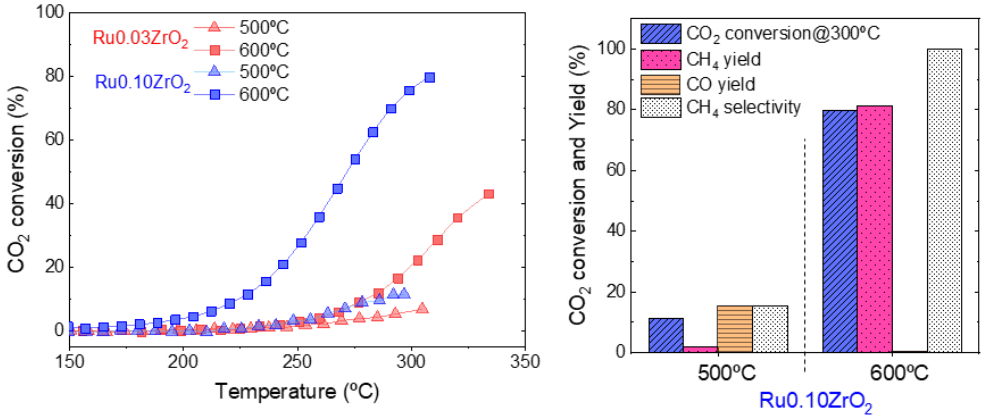

Figure 1. (a) $CO_2$ conversion of $Ru0.03ZrO_2$ and $Ru0.10ZrO_2$ catalysts calcinated at 500 °C and 600 °C at different reaction temperatures. (b) $CO_2$ hydrogenation activity of $Ru0.10ZrO_2$ catalysts calcinated at different temperatures under 300 °C reaction temperature.

**Keywords:** Electrocatalytic reduction of $CO_2$, Zeolite Templated Carbons, oxygen functionalities in ZTC

**Introduction.**

In the last years, the rapid increase of greenhouse gas emissions and sudden climate change is becoming one of the most critical issues to be addressed. The electrocatalytic conversion of $CO_2$ into high added value products such as formic acid (FA) represents a very promising technology to address this issues. From this perspective, the greatest challenge facing the scientific community is the development of new stable and low-cost materials to achieve this technology at industrial level. Zeolite templated carbons (ZTC) thanks to their high conductivity, high surface area and chemical stability can be considered promising candidates as electrocatalysts for the $CO_2$ valorization [1, 2].

**Experimental/methodology.**

Two different ZTCs were synthesized starting from a home made and a commercial Na-BEA zeolites (ZTC_01 and ZTC_02) through Chemical Vapour Deposition using ethylene as a carbon source at high temperature. A combination of a chemical and thermal treatment was carried out in order to modify the nature and the amount of the oxygen functionalities on the ZTCs surface. The effect of the surface modification was in depth investigated using different techniques as XRD, $N_2$ adsorption, TGA/DTA, SEM/EDS analysis, FT-IR and Raman spectroscopy. The electrocatalytic behavior of the electrocatalysts was evaluated in the electrocatalytic reduction of $CO_2$ in a three-electrode flow cell configuration (-1.6 and -1.8V vs Ag/AgCl ) using 0.5 M $KHCO_3$ as catholyte and 0.5M $H_2SO_4$ as anolyte. The liquid and gas products were identified by HPCL and micro GC in line.

**Results and discussion.**

ZTCs were synthesised and further modified by a deoxygenation procedure using combined thermal and $NaBH_4$ treatment. Through a deep characterization was possible to observe how the combined treatments lead to a reduction of oxygen content obtaining a more ordered structures. From the electrocatalytic results was possible to assess how the induced surface modification of ZTCs coherently affects the electrocatalytic activity. The best electrocatalytic performances was obtained by using the treated sample (rZTC0_1) derived from the home made zeolite which reaches a 40% of faradaic efficiency to FA at -1.8V. Analising the obtained results it is highlited a direct correlation between the degree of order ($I_D/I_G$) of the structure calculated by Raman spectroscopy and the catalytic performances as well as a linear correlation with the amount of oxygen content. These results highlights how the surface modification of ZTCs represents a promising strategy for the development of efficient electrocatalysts for the $CO_2$ valorization.

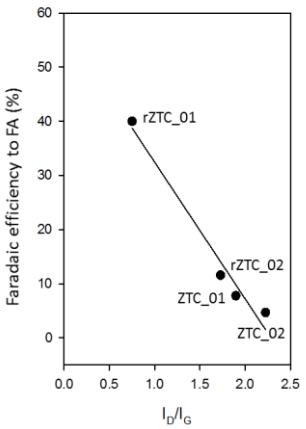

***Fig.1: Correlation between the Faradaic efficiency and ZTCs order degree***

**Keywords:** $CO_2$ hydrogenation, alkane dehydrogenation, heterogeneous catalyst

**Introduction.** In the recent years, an increasing attention has been paid to the sustainable development of cutting-edge technologies and processes with an increasingly reduced environmental impact, accounting also for the EU target of net zero emission by 2050 [1]. In principle, these technologies would make it possible to avoid emitting $CO_2$ into the atmosphere [2], through carbon capture and storage processes (CCS) or even by reusing it (CCU, Carbon Capture and Utilization) as a feedstock in the energy, chemical and building industries. In this complex scenario, different key-challenges need to be undertaken. Therefore, the aim of this work is to develop efficient catalysts in processes involving $CO_2$ as a reactant.

As a starting point of the study, a catalytic system that was already at the state of the art (heterogeneous Ni-, Fe-based and bimetallic catalysts [3,4]) was chosen, by focusing on different reactions, i.e. methanation, reverse Water Gas Shift (rWGS) and so-call tandem reaction (light alkanes oxidative dehydrogenation) in order to evaluate their performances. The great advantage of coupling light alkanes dehydrogenation to rWGS is that a process can be carried out without introducing hydrogen into the system, using $CO_2$ as a soft oxidant. This results in great benefits in terms of energy efficiency, process simplification, and costs.

**Experimental/methodology.** Ni-, Fe- and (Ni, Fe)-catalysts supported on $CeO_2$ have been prepared through Incipient Wetness Impregnation (IWI) technique using an aqueous solution of metal precursor salts and then calcined. In order to evaluate their morphology and structure, the catalysts have been characterized through XRD and FE-SEM analysis before and after the catalytic tests. Moreover, catalytic materials have been characterized by FT-IR and UV-vis techniques.

The catalysts have been tested in a laboratory-scale plant equipped with a fixed bed tubular reactor by evaluating the catalytic performances in $CO_2$ hydrogenation to methane and by attempting more challenging $CO_2$ conversion processes as well by the so-call tandem reactions, accounting for a complex mix of alkanes. Moreover, a thermodynamic equilibrium analysis of the catalytic system was carried out using AVEVA PRO II software® [5].

**Results and discussion.** All catalysts resulted to be active in the proposed reactions, despite the metal loadings. Therefore, it is possible to develop cutting-edge catalysts based on abundant, non-critical, and cheap transition metals by finely tuning composition.

Ni-based catalyst promotes rWGS reaction at low temperature ($T < 623$ K), while Fe-based at high temperature ($T > 623$ K). Ni addition into Fe-based catalysts increases catalytic stability and activity to rWGS, reaching CO yields close to the equilibrium one.

Considering the tandem reaction system, higher catalytic activity to rWGS and dehydrogenation reactions has been obtained using the bimetallic catalyst compared to the Ni-based one, even though the first undergoes faster deactivation.The phenomena underlying this behavior are not known to date and work is in progress to clarify this important issue.

# Synergetic Activity of Ag and Zn in $CO_2$ Hydrogenation to Methanol

S. Phadke[1,2], C. Copéret[2], O. V. Safonova[1]

[1] *Paul Scherrer Institut, CH-5232 Villigen, Switzerland*
[2] *ETH Zürich, Laboratory of Inorganic Chemistry, CH-8093 Zürich, Switzerland*

**Keywords:** silver, zinc, $CO_2$ hydrogenation, methanol

**Introduction:** The search for a highly-efficient $CO_2$-to-methanol hydrogenation catalyst has led scientists to screen different bimetallic compositions, mainly consisting of Cu, Pd, Ni and Au nanoparticles promoted with various promoters such as Zn, Ga, Zr, etc. However, Ag, the element sandwiched between Cu and Au, has been much less considered among the coinage metals. In this work, we attempt to uncover the activity of Ag in combination with Zn for the selective hydrogenation of $CO_2$ to methanol.

**Experimental/Methodology:** In contrast to Cu-Zn bimetallic system, very little is known about the synergy of zinc and silver. We synthesized a series of Ag-Zn catalysts supported on silica with constant Ag and varied Zn loading. The catalysts were tested in a flow reactor at 40 bar $CO_2$:$H_2$:Ar = 1:3:1 at 250°C. Quasi *in situ* XAS analysis was performed at Zn and Ag K-edges for the calcined and $H_2$ activated (at 350°C) catalysts. (S)TEM and EDX mapping were implemented to visualize the distribution of Ag and Zn.

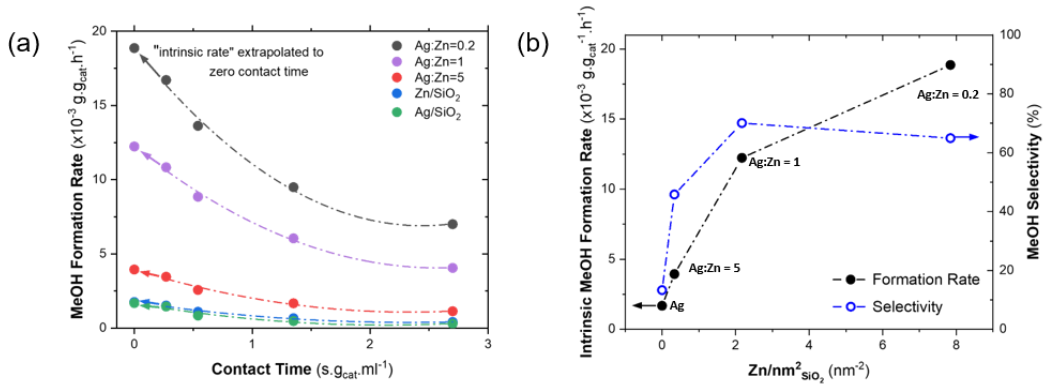

**Figure 1: Methanol (MeOH) formation rate for the series of Ag-Zn/$SiO_2$ catalysts as a function of contact time (arrows indicate intrinsic methanol formation rate at zero contact time obtained by a second-order polynomial fit of formation rates); (b) Intrinsic MeOH formation rate and MeOH selectivity as a function of nominal Zn surface coverage. The samples are denoted by Ag:Zn molar ratios; Ag concentration is ca. 7wt%.**

**Results and Discussion:** Neither Ag nor Zn are very active in $CO_2$ hydrogenation and selective for the formation of methanol. Adding Zn to Ag/$SiO_2$ steadily increases the methanol formation rates. The methanol selectivity, the other product being CO, seems to plateau after 2 Zn/nm$^2$ support coverage. According to XAS and TEM, Ag is easily reducible and forms Ag nanoparticles of ca. 2.8 nm without evidence of alloying with Zn. From XAS, it is also apparent that Zn exists only in a cationic $Zn^{II}$ state, even after $H_2$ activation at 350°C. This cationic $Zn^{II}$ is composed of a mixture of isolated $Zn^{II}$ sites on silica and highly dispersed ZnO oligomers with an incomplete second Zn-O-Zn coordination shell. The latter is visible in HAADF-STEM images of the catalyst with the highest Zn loading (Ag:Zn = 0.2), and its location coincides with the Ag nanoparticles. For the lower Zn loading (Ag:Zn = 1), crystalline domains of ZnO are not detectable. We hypothesize that the ZnO phase presenting at higher Zn loading and its characteristic interface with the Ag nanoparticles are crucial for catalyzing the hydrogenation of $CO_2$ and the formation of methanol. We are currently probing the structure of the Ag-Zn system using *in situ* XAS and IR spectroscopy to further elucidate the specific function of each phase, clarify the reaction mechanism of methanol formation, and compare the reactivity of Ag-Zn and Cu-Zn systems.

**Introduction**

Currently, conventional $Cu/ZnO/Al_2O_3$ catalysts for methanol synthesis from syngas are employed for commercial-scale $CO_2$ hydrogenation to methanol, under conditions of 200-300 °C and 10-100 bar [1]. According to Le Châtelier's principle, lower temperatures are more favorable to achieving almost full $CO_2$ conversion and $CH_3OH$ selectivity [2]. However, the major challenge is overcoming the sluggish kinetics, thus leading to the exploration of highly active and selective catalysts below 200 °C. $Re/TiO_2$ was the most promising in reactivity under a batch condition (44 TON, $S_{CH3OH}$ = 82%, $H_2/CO_2$ =5, 150 °C, and 60 bar) among various supported metals (e.g. Pt, Pd, Rh, Ir, Ru, Ni, Co, Ag, and Cu), supports (e.g. $ZrO_2$, $SiO_2$, $Al_2O_3$, $CeO_2$, etc.), and the conventional $Cu/ZnO/Al_2O_3$ catalyst, because the subnanometer size Re with multi-oxidation states between $Re^0$ and $Re^{4+}$ served as active sites for methanol formation [3].

**Experimental**

The catalyst synthesis of Cu, Rh, Pd, Ag, Re, Pt, and Au supported on $TiO_2$ was prepared via the wet impregnation method, as reported elsewhere [3]. The catalysts were reduced *in situ* under $H_2$ at 500 °C, tested in a fixed-bed reactor at $H_2/CO_2$ = 3, 125-200 °C, 60 bar, and characterized by XRD, $H_2$-TPR, TEM, STEM-EDS, *Ex situ* XAS, and *operando* DRIFTS.

**Results and discussion**

Among various $M/TiO_2$ (M = Cu, Rh, Pd, Ag, Re, Pt, or Au), $Re/TiO_2$ remained the most active and selective catalyst for $CH_3OH$. The origin of the unique reactivity of $Re/TiO_2$ was elucidated previously as the coexistence of cationic highly-dispersed Re including single atoms, driving the formation of monodentate formate, and metallic Re clusters in the vicinity, activating the hydrogenation of the formate to methanol. The ability to stabilize formate species against its decomposition to CO was reflected in a high methyl formate selectivity at low temperatures over $Re/TiO_2$ and $Cu/ZnO/Al_2O_3$; (125 °C), which was found over $Ag/TiO_2$ at increasing temperatures (175 °C). The addition of a small amount of Ag to $Re/TiO_2$ improved the methanol selectivity significantly by suppressing methane formation. STEM-EDS showed that Re clusters migrated and distributed around the Ag nanoparticles over $Re\text{-}Ag/TiO_2$ after the reaction. *Ex situ* XAS reveals no alloy formation between Re-Ag after reduction. After $CO_2$ hydrogenation, Ag remained metallic while Re was oxidized creating cationic Re species. *Operando* DRIFTS studies confirm that the reaction mechanism over $Re\text{-}Ag/TiO_2$ is identical to that of $Re/TiO_2$ but metallic Ag addition helps boost forming surface formate species while suppressing carbonyl species which is the intermediate for methane formation. Metallic Re species act as $H_2$ activators, leading to H-spillover and importantly to hydrogenation of active formate intermediate present over cationic Re species. The role of metallic Ag is ascribed to complementarily activate $CO_2$ to formate and supply it to cationic Re species via spillover, driving forward the hydrogenation of the formate to methanol. $Re\text{-}Ag/TiO_2$ showed high stability in $CO_2$-to-methanol and improved catalytic performance over time on stream up to 40 h. This work has important implications for other bifunctional systems where the balance between different catalytic functions determines the rates and product distribution.

**Keywords:** $CO_2$ hydrogenation, methanol synthesis, Au/$ZrO_2$, *in-situ* DRIFTS, $CO_2$ utilization

**Introduction.** Carbon pollutants production via the utilization of carbon-based fuels has enormously increased since the industrial revolution. These carbon effluents released into the atmosphere are among the main factors responsible for global warming through the greenhouse effect. The global temperature rise due to global warming drives the scientific community to find strategies to reduce $CO_2$ emissions and the level of $CO_2$ in the atmosphere. In this regard, $CO_2$ is considered as an abundant C1 source that can be used as a raw material to produce vital value-added products, such as syngas, dimethyl ether, formic acid, methane, higher hydrocarbons, methanol, etc. The use of $CO_2$ as a feedstock can be seen as advantageous from both environmental and economic points of view to achieve carbon neutrality, contributing to global climate change mitigation. $CO_2$ conversion has several advantages and challenges; therefore, it is necessary to discover new concepts and opportunities for catalytic and industrial development. Among all the $CO_2$ conversion routes, most studies in recent years have been focused on $CO_2$ hydrogenation to methanol [1].

**Experimental/methodology.** Amorphous $ZrO_2$ supported 0.5-1 wt.% Au catalysts were synthesized in the present work by two preparation methods, namely deposition precipitation (DP) and impregnation (IMP), characterized by a variety of techniques and examined in the process of $CO_2$ hydrogenation to methanol.

**Results and discussion.** The use of nanometric gold nanoparticles supported on $ZrO_2$ enables efficient hydrogenation of $CO_2$ to methanol even at low temperatures. Au deposition decreased specific surface area due to pore blockage; this decrease was considerably low in the case of DP method. TEM analysis revealed that Au particle size distribution depends on the preparation method and Au loading, with the DP technique resulting in the formation of Au ensembles with 1 nm in size. TPD measurements illustrated a change in the strength and number of surface acidic and basic sites with the deposition of Au; these changes were strongly influenced by the method of preparation, where the catalysts synthesized by the DP technique showed strong acidic sites and a high number of basic sites (i.e. $Zr^{4+}/O^{2-}$ centres). Variations in surface sites due to different preparation methods exhibited a huge impact on the formation of intermediates and their fast hydrogenation to methanol. Important surface intermediates were identified by *in-situ* DRIFTS analysis, i.e. formate, dioxymethylene and methoxy species, which helped to establish a possible reaction mechanism via the formate route [2]. Here, time resolved FTIR profiles of both 0.5 wt.% Au loaded catalysts showed large differences in the hydrogenation of formate and methoxy intermediates with respect to the catalyst preparation method. High $CO_2$ uptake and the presence of small Au nanoparticles enabled fast hydrogenation of intermediate species to methanol over DP-based catalysts, whereas low $CO_2$ uptake and the presence of bulk Au clusters on the catalyst surface leads to slow hydrogenation of intermediate species to products, as observed in the case of IMP-based catalyst. Au/$ZrO_2$ catalysts synthesized by the DP method were advantageous in the process of $CO_2$ hydrogenation to methanol, compared to the IMP-based catalyst. Finally, the rate of formation of methanol was enhanced with increased synergy between the metal and support, and exceptionally high space-time yields of methanol (up to 2.0 $g_{MeOH}\ h^{-1}\ g_{cat}^{-1}$) were obtained in the presence of DP-based Au/$ZrO_2$ catalysts.

**Keywords:** $CO_2$ methanation, Ni-based catalyst, Alkaline-earth metal carbonates

**Introduction.** The continuous increase in the world energy demand has increased greenhouse gases mainly $CO_2$ into the atmosphere. There is a pressing demand across the globe to develop materials and processes to reduce the harmful emission[1]. $CO_2$ methanation using a catalyst obtained from earth-abundant materials offers a promising option to economically reduce anthropogenic $CO_2$. Alkaline earth metal carbonates are interesting and relevant candidates with respect to $CO_2$ methantion as it is available in large quantities in the form of low-cost natural mineral resourses[2]. In this work, we have explored the use of supported Ni catalysts derived from alkaline earth metal carbonate. We obtained the catalysts from the thermal decomposition of respective carbonate precursors under $H_2$ stream and studied its catalytic activity and stability in $CO_2$ methantion reaction.

**Experimental/methodology.** $NiMgCaCO_3$ with different Ni:Mg:Ca ratios (NMC) were synthesized via a simple co -precipitation method using $Na_2CO_3$ as the carbonating agent. Under $H_2$ reduction condition, $NiCaMgCO_3$ decomposed to $Ni/Ca(OH)_2$-$CaO/MgO$ and formed an active catalyst for $CO_2$ methanation. Under reaction condition hydroxide/oxide phase adsorbs $CO_2$ and formed a carbonate phase, which cyclically converted into oxide with the release of $CH_4$ in the presence of $H_2$ and metallic Ni.

**Results and discussions.** Screening of catalysts revealed that the active Ni catalyst originating from the decomposition of $MgCaCO_3$ exhibited good activity for $CO_2$ methanation. At 340 °C, NMC-154 showed 84% $CO_2$ conversion and 99.7% $CH_4$ selectivity. The developed catalytic system operated efficiently over 100 h on a stream without catalyst deactivation. Detailed structural characterization of these catalysts showed the phase-dependent generation of active species. From XRD and BET analysis it is revealed that, an increasing concentration of Mg in carbonates improves the textural properties and dispersion of Ni nanoparticles. The local reducing environment generated by the formation of $CH_4$ from the decomposition of alkaline metal carbonates maintains the reducibility of the catalyst. However, more detailed characterization studies must understand the structure-activity correlation of catalysts.

**Keywords:** Photocatalysis, $CO_2$, $CH_4$, flow reactor, heterojunction

**Introduction.**

One of the key strategies identified in the scientific literature to alleviate climate change is the exploration of new catalytic reactions in which wastes may be converted into useful products [1-2]. In this respect, the reduction of $CO_2$ into useful chemicals appears as an ideal solution, and given the high amount of energy provided by the Sun, photocatalysis stands out as an ideal candidate to its application in energy-related research.

While titanium dioxide ($TiO_2$) is one of the most widely studied catalysts due to its numerous advantages, it is not without drawbacks, being perhaps the most grievous the fact that its light absorption capacity in the visible range is very limited due to its relatively large band gap (3.2 eV). For this reason, substantial efforts have been dedicated to the development of novel photocatalysts with enhanced visible light adsorption by the use of different dopants such as noble metals or transition metal oxides [3].

The objective of the present work is to prepare a series of photocatalysts based on the combination of $TiO_2$ and $Cu_xO$, in order to develop high-performance heterojunction systems. The photocatalysts were tested in the photoreduction of $CO_2$ in a flow reactor that uses a thin layer of the photocatalyst, thus being considered as a 2-dimensional flow reactor designed to irradiate the sample with UV LED lights during the experiments.

**Experimental/methodology.**

The impregnation of a transition metal (Cu) on the surface of $TiO_2$ (P25 Degussa) was carried out by a modification of a standard impregnation protocol followed by a reduction step with $NaBH_4$ [4]. The performance of the prepared photocatalysts in the reduction of $CO_2$ in the presence of water vapor to yield $CH_4$ using a flow reactor was evaluated under ambient conditions [3].

**Results and discussion.**

The first results obtained in our study were already promising considering those reported in the literature for such a process using similar reactor configurations (over 1 $\mu molCH_4 \cdot g\ cat^{-1} \cdot h^{-1}$), but the selection of a proper hole scavenger and the subsequent optimization of its concentration has allowed us to reach $CH_4$ production rates which are among the best reported irrespective of the reactor and/or conditions (117 $\mu molCH_4 \cdot g\ cat^{-1} \cdot h^{-1}$) and using low power LED lighting, which shows the outstanding relevance of our results. The effect of Cu loading and particle size has also been studied.

**Keywords:** $CO_2$ reduction, methane production, Photocatalyst, Substrate's conductivity, Charge transfer, SPR.

**Introduction.** Recycling accumulated $CO_2$ in the atmosphere into value-added chemicals via a photocatalytic process is an ambitious strategy for mitigating both global warming and the energy crisis[1]. while supported photocatalysts on various soft or hard substrates for enhanced practicality have been successfully developed, the activity of the catalyst is attributed to the catalytic layer and the substrate's contribution to the catalyst's activity is less studied. When the thickness of the catalytic film is within the thin film domains, the substrate's role becomes more pronounced. Conductive substrates can function as electron collectors [2] in a multistep, complex reaction like the $CO_2$ photocatalytic reduction to decrease the recombination of charge carriers and to supply electrons to energy levels above or below the conduction band of the overlay catalyst (each intermediate of $CO_2$ reduction reaction has a different reaction potentials). Moreover, surface plasmon resonance (SPR) in certain conductive substrates [3] may improve the light-harvesting capability and catalyst's activity when thin film structure is used.

**Experimental/methodology.** Silica-modified amorphous and crystallized $TiO_2$ photocatalysts were spin coated on Ti sheet, indium tin oxide coated polyethylene terephthalate (ITO-PET), and PET substrates. The prepared films were employed in photocatalytic $CO_2$ reduction in vapor-phase and batch reactor. Optical and photo-electrochemical analyses, as well as simulations based on density functional theory (DFT), were used to investigate the effect of substrate conductivity on catalyst activity.

**Results and discussion.** On Ti sheet, photocatalysts' activity for $CO_2$ reduction to $CH_4$ and CO were significantly higher than on two other substrates. The photoluminescence (PL) analysis demonstrated that the substrate can significantly affect both the energy levels from which radiative recombination occurs and the recombination of charge carriers. The excitation of electrons to higher energy states can provide greater driving force in $CO_2$ reduction reaction and increase the catalyst's activity. Additionally, a study of the open circuit potential decay (OCPD) of the silica-modified crystalline $TiO_2$ revealed the function of the Ti substrate in electron collection. Moreover, the density of states (DOSs) modeling of the Ti substrate revealed the presence of intense energy states in the middle of the band gap of photocatalysts, which can facilitate electron transfer between the catalysts and substrate. By emphasizing on the substrate's effect in thin film photocatalysts, this study proposes a straightforward and effective approach for enhancing the photocatalytic activity for $CO_2$ reduction in water vapor.

# Atomic layer deposited zinc over metal oxide supported copper for carbon dioxide hydrogenation to methanol: Comparison of supports

Ahmed Sajid[1], Aitor Arandia[1], Jihong Yim[1], Ashish Chahal[1], Hua Jiang[1], Reetta Karinen[1], Riikka L. Puurunen[1*]

[1]*Aalto University, 02150 Espoo, Finland*
[*]*Riikka.puurunen@aalto.fi*

**Keywords:** Atomic layer deposition, metal oxide supports, zinc copper catalysts.

**Introduction.** Zinc-copper-based heterogeneous catalysts are well-known for carbon dioxide hydrogenation to methanol (CHM). Metal oxide supports can influence the activity of zinc-copper catalysts e.g. by affecting the reducibility of Cu and the $CO_2$ adsorption capacity [1]. In a recent work, adding zinc by atomic layer deposition (ALD) [2] on top of zirconia-supported copper to make "inverse" ZnCu catalysts was found beneficial for activity and selectivity in CHM [3]. In this work, continuing from the earlier work, we investigated the effect of support on heterogeneous inverse ZnCu catalysts for CHM.

**Experimental.** Copper was impregnated on metal oxide supports (alumina, ceria-zirconia, lanthana-ceria-zirconia, niobia, titania, zirconia) by incipient wetness impregnation and zinc was added by ALD. Catalysts were designed to have a Cu/Zn atomic ratio of 2, with ~2 Zn/nm$^2$ added by ALD [3]. This gave catalysts with 1.5-5.7 wt-% of Cu, depending on the support's surface area. Samples were characterized by $N_2$ physisorption, inductively coupled plasma-optical emission spectroscopy, hydrogen temperature programmed reduction, carbon dioxide temperature programmed desorptionand scanning transmission electron microscopy. Conversion, selectivity and methanol space time yield (STY) were measured in a continuous flow fixed bed reactor.

**Results and discussion.** The catalytic activity was influenced by the support. In terms of methanol STY, the metal oxide suppports gave highest activity in the order: zirconia > 17%ceria-zirconia > 25%ceria-zirconia > lanthana-ceria-zirconia > alumina > niobia > titania (Figure 1a). Addition of zinc on copper increased the activity in varying degrees: for example, on zirconia, the effect was minor whereas on niobia it was significant (Figure 1b). The highest methanol STY calculated per grams of copper was obtained on zirconica-supported ZnCu catalysts (124 mmol $g_{Cu}^{-1}$ $h^{-1}$, at 550 K).

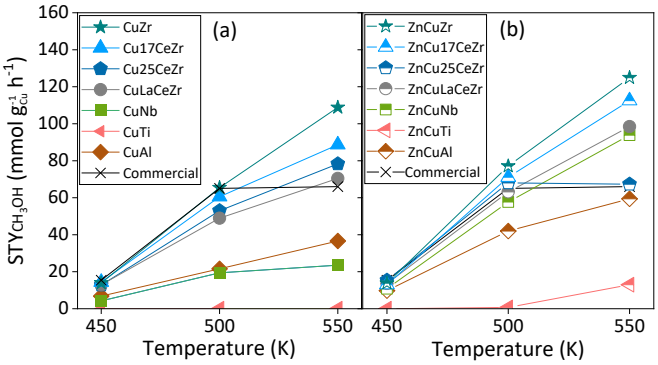

**Figure 11: Methanol STY over supported (a) Cu and (b) ZnCu catalysts. Reaction conditions: *T* = 450, 500, 550 K, *P* = 3.0 MPa, $H_2/CO_2/N_2$ = 71/23/6 V/V/V%, space velocity = 8900 l $g_{cat}^{-1}$ $h^{-1}$ and $m_{cat}$ = 1.0 g. The reaction was carried out for 90 minutes at each temperature.**

# $CO_2$ activation *via* oxidative dehydrogenation and dry reforming of ethane over $Fe_3Ni_1$ nanoalloys influenced by supports

Shaine Raseale[1], Gonzalo Prieto[2], Michael Claeys[1] and Nico Fischer[1]*

[1]*Catalysis Institute and DSI-NRF Centre of Excellence in Catalysis c*change, University of Cape Town, Cape Town, South Africa.*
[2]*Instituto de Technología Química (ITQ), Av. de los Naranjos, 46022, Valencia, Spain.*
[*]*nico.fischer@uct.ac.za*

**Introduction.** The $CO_2$-mediated oxidative dehydrogenation of ethane ($CO_2$-ODHE) is an alternative route for producing the high-demand ethylene while simultaneously serving as a carbon capture and utilization (CCU) route co-activating $CO_2$ to CO. It has been extensively investigated on metal-oxides (MOx) with those based on Cr, V and Ga exhibiting promising selectivity towards ethylene but deactivate rapidly due to their low $CO_2$ activation ability [1]. The reaction proceeds *via* a Mars van Krevelen mechanism where the $MO_x$ is reduced upon ethane activation and subsequently re-oxidized *via* $CO_2$ activation. Thus, desirable catalysts should possess suitable redox properties [2]. Since redox properties are interlinked with the Lewis acidity and in turn depend on the nature of $MO_x$, variation of Lewis acidity should influence activity (re-oxidation rate) under $CO_2$-ODHE. Recent studies identified supported $Fe_xNi_y$ alloys as potential catalysts which depending on x:y ratio and support can promote either $CO_2$-ODHE or ethane dry-reforming (DR) with enhanced $CO_2$ activation [3-4]. However, not enough supports were explored to explicitly underpin their catalytic role. In this study, monodisperse $Fe_3Ni_1$ nanoalloys anchored on $MO_x$ overlayers with varying Lewis acid strength were synthesized and tested for $CO_2$-ODHE.

**Experimental/methodology.** The nanoalloys were supported on $MO_x$ overlayers which were coated on γ-$Al_2O_3$ using incipient wetness impregnation to impose uniform textural properties (surface area, pore volume and diameter) across different catalysts thereby decoupling their catalytic influences. To encourage effective alloying upon reduction, oxidic Ni-ferrite nanoparticles, in which Fe and Ni are closely associated, were prepared and used as alloy precursors. A benzyl alcohol solvothermal synthesis was employed to prepare the precursor nanoparticles before deposition onto the supports [4].

**Results and discussion**. Our results reveal that the initial activity of the bare overlayers increases with the Lewis acid strength and reducibility but is lost fast due to their low $CO_2$ conversion. The deposition of the $Fe_3Ni_1$ nanoalloys to the overlayers enhances the activity and stability due a significantly enhanced $CO_2$ conversion ability while the acidity vs activity trend is maintained. However, due to the significantly enhanced $CO_2$ conversion, the CO-forming DR reaction is prominent on the strongly acidic and reducible $VO_x$ and $CrO_x$ while $CO_2$-ODHE is predominant on the irreducible, $GaO_x$, $TiO_x$ and $SmO_x$ with intermediate to weaker Lewis acid sites. Thus, acidity and reducibility of $MO_x$ supports play a key role.

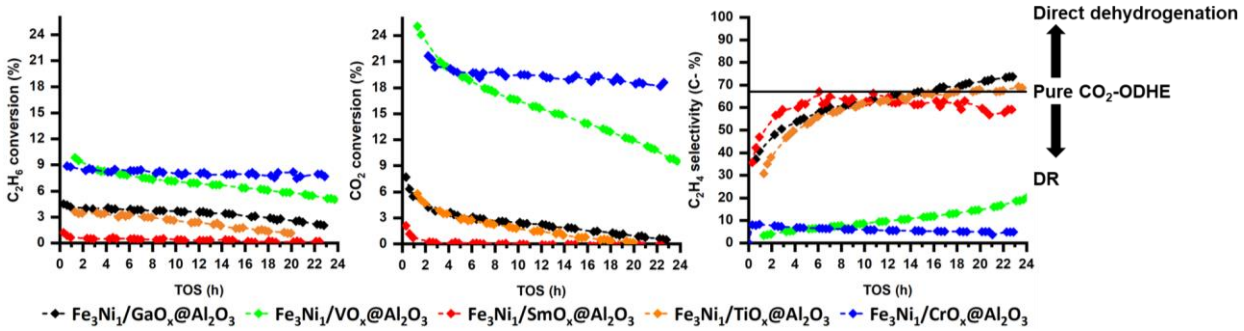

*Figure 11: $C_2H_6$ (left) and $CO_2$ (middle) conversions and carbon based $C_2H_4$ selectivity of materials tested. Conditions: T = 600 °C, P = 1 atm, total space velocity = 15 $L \cdot h^{-1} \cdot g_{cat}^{-1}$, $CO_2$ : $C_2H_6$ ratio = 1 (6.25 mL/min each) with inert dilution.*

# Carbon dioxide reduction *via* the reverse Water Gas Shift reaction over iron-nickel nanoalloy-based catalysts

Shaine Raseale, Karina De Kock, Michael Claeys and Nico Fischer*

*Catalysis Institute and DSI-NRF Centre of Excellence in Catalysis c*change, University of Cape Town, Cape Town, South Africa*
**nico.fischer@uct.ac.za*

**Introduction.** $CO_2$ emissions, primarily due to anthropogenic activities, have led to its increased atmospheric concentration (< 415 ppm currently) [1]. Currently, it is majorly accepted as a greenhouse gas linked to global warming, climate change and ocean acidification. Thus, multiple treaties such as the Paris agreement aiming to significantly reduce the global net $CO_2$ emission in the next decades to curb the global temperature increase to below 2 °C have been established. Some of the ways to realize this are $CO_2$ capture and storage (CCS), use of gas over coal and adoption of renewable energy sources. Another alternative with potential economic benefits is carbon capture and utilization which leverages on $CO_2$ as a carbon source for value-added chemical production. Several CCU processes such the Solvay method, methanol and urea synthesis, salicylic acid and cyclic carbonates production are already in industrial application but utilize a negligible fraction of the $CO_2$ emitted [2, 3]. Thus, the development of more CCU processes remain a necessity. Power-to-Liquid (PtL), which targets the production of liquid fuels using captured $CO_2$ with green $H_2$ *via* routes like the reverse Water-Gas Shift (rWGS) linked with the Fischer-Tropsch synthesis (FTS) reactions, can serve this purpose. However, the rWGS reaction is thermodynamically limited. Supported $Fe_xNi_y$ alloys have shown potential for application as rWGS catalysts with the performance being metal composition dependent [4]. To extent the scope and understanding of their catalytic roles for future catalysts design, this study investigates the influence of metallic composition and support on the performance of $Fe_xNi_y$ nanoalloys in the rWGS reaction.

**Experimental/methodology.** The nanoalloys are supported on a series of metal oxide ($MO_x$) ovelayers prepared by incipient wetness impregnation and are compared to commercial bulk oxides. To encourage effective alloying upon reduction, oxidic Ni-ferrite nanoparticles in which Fe and Ni are closely associated, were prepared and used as alloy precursors. A solvothermal synthesis in benzyl alcohol was employed to prepare the precursor nanopaticles before deposition onto the supports and reduced in situ before testing.

**Results and discussion**. Our results reveal a composition and support dependent tandem effect between the $Fe_xNi_y$ alloy and reducible supports, significantly influencing the rWGS activity and stability of the catalysts. On the unreducible and inert $SiO_2$, the alloys deactivate fast with an overall low activity. However, the rWGS activity and stability increase slightly with increasing Fe-content. On $GaO_x$ which has a high intrinsic activity and stability, the same trend with iron content is observed with a high stability maintained. However, the trend is reversed on the reducible $CrO_x$. The bare support shows some initial activity but is significantly more stable in the presence of the alloy, especially at an Fe:Ni ratio of 3. When studied on a larger library of supports, $Fe_3Ni_1$ shows a high rWGS activity and stability on the reducible overlayers (due to the tandem effect). However, poor stability/activity are observed on the unreducible supports. For all materials, a close to 100 C-% CO selectivity was obtained confirming the kinetic suppression of the methanation reaction.

**Introduction.** There is an ever-increasing need for sustainable fuels and chemicals. Many of the technologies such as the Fischer–Tropsch synthesis suffer from poor selectivity and, consequently, bad profitability. Isosynthesis, the highly selective process for the manufacture of isobutene and -butane, was discovered already in the 1940s [1], but it has not received very much attention. Over the decades, the extreme reaction conditions and harmful catalysts, about 300 bar and $ThO_2$-catalysts, have been replaced by more feasible and practical alternatives, while having better catalytic performance [2]. Due to these developments and recent demand for renewable feedstock conversion routes, isosynthesis has again become an interesting topic. This paper reports experimental work using syngas produced from $CO_2$ via reverse-WGS as well as computational results of isosynthesis reaction over a range of zirconia-based catalysts.

**Experimental/methodology.** Monoclinic and tetragonal $ZrO_2$, as well as Ce-, La- and Y-doped $ZrO_2$ were tested for isosynthesis reaction in a tubular fixed bed reactor. Reaction conditions varied between 400–450 °C, 20–45 bar and GHSV 2000–3000 $h^{-1}$. CO conversion and product selectivities were analyzed by on-line GC. In order to better understand the reaction mechanism and parameters affecting catalyst activity, the isosynthesis reaction network was also explored computationally using vdW-corrected DFT. Monoclinic $ZrO_2$(−212) was chosen as the model surface to account for the possible role of edge sites.

**Results and discussion.** Monoclinic $ZrO_2$ (450 °C, 45 bar, GHSV = 2000 $h^{-1}$) performed best out of the tested catalysts and iso-C4-hydrocarbons could be produced with a high selectivity of 33–40 mol-% and up to 75 % CO conversion, while tetragonal $ZrO_2$ was much less active and selective. The computational results for monoclinic $ZrO_2$ are in agreement with the good experimental CO conversion, as the modeled surface was found active for both $H_2$ dissociation and CO activation. Hydrogen was found to preferentially dissociate on the step edge, indicating that the conversion may be enhanced by the presence of such undercoordinated reaction sites. An interesting and unusual shift in the share of iso-C4 occurred after 23–112 h on stream with all catalysts: while CO conversion remained constant, the selectivity of i-C4/HC decreased, and the selectivity of methane increased correspondingly, Figure 1. We are currently studying the cause of this finding via catalyst characterization and modeling.

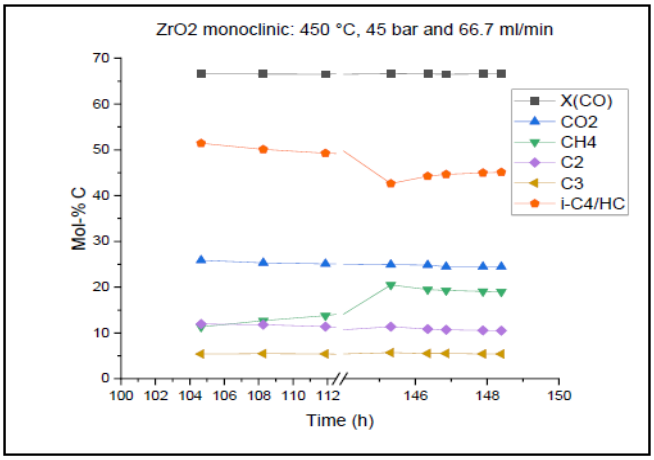

Figure 1. Catalytic performance of monoclinic $ZrO_2$ at 450 °C, 45 bar and GHSV = 2000 $h^{-1}$.

# Upgrading of Solvent-Free Acetone-Butanol Mixtures to Aviation Fuels over Heterogeneous Metal Catalysts

K. J. Betsy[1], P. Doménech[1], A. Riisager[1*]

[1]*Technical University of Denmark, Centre for Catalysis and Sustainable Chemistry, Department of Chemistry, 2800 Kgs. Lyngby, Denmark*
**ar@kemi.dtu.dk*

**Introduction.** Systematically designed production of renewable transportation fuels and chemicals from the green house gas $CO_2$ has attracted interest in both industry and academy. Currently about 3 % of the global $CO_2$ emission is originating from the aviation sector by the use of fossil fuels [1]. This dependence can be diminshed by the replacement with sustainable aviation fuels (SAF) produced from $CO_2$ as the raw material. The strategy to upgrade fermentation mixtures from $CO_2$ to long-chain aliphatic ketones and alcohols ($C_7$-$C_{11}$) for liquid fuels using heterogeneous metal catalysis is attractive from the standpoint of sustainable and green chemistry but underexplored [2]. The α-alkylation of ketones with alcohols through a borrowing-hydrogen route over transition metal catalysts is an efficient methodology to obtain SAFs as water is the only liquid byproduct [3]. Use of recyclable heterogeneous catalysts is a preferred approach for the α-alkylation, and Pd nanoparticles (NPs) supported on carbon has been widely used for the reaction with moderate product yield [4]. In this study, alternative Pd-$MgSiO_2$ catalysts have been examined for upgrading of acetone/1-butanol mixtures to produce ($C_7$-$C_{11}$) ketones and alcohols under solvent free and benign reaction conditions (Figure 1).

**Experimental/methodology.** Catalysts with Pd NPs supported on ultra-high surface area Mg-modified silica ($MgSiO_2$) were prepared by wet impregnation and applied in batch reactions with acetone/1-butanol mixtures. With aid of various characterization techniques structure-activity correlations established.

**Results and discussion.** A modified Pd-$MgSiO_2$ catalyst showed 75 % conversion and high selectivity for $C_7$-$C_{11}$ aliphatic ketones (78 %) under solvent free conditions at relative low temperature (150 °C). The utilization of the inherent basicity from the modified support made only a catalytic amount of base required for catalysis, and a heterogeneous behaviour without Pd leaching was found under the reaction conditions. The high surface area (> 1000 $m^2/g$) of the Mg-modified support not only helped to obatin a high dispersion of Pd NPs, but facilitated also synergy through strong metal-support interaction enhancing the catalysis with high selectivity for long-chain aliphatic ketones.

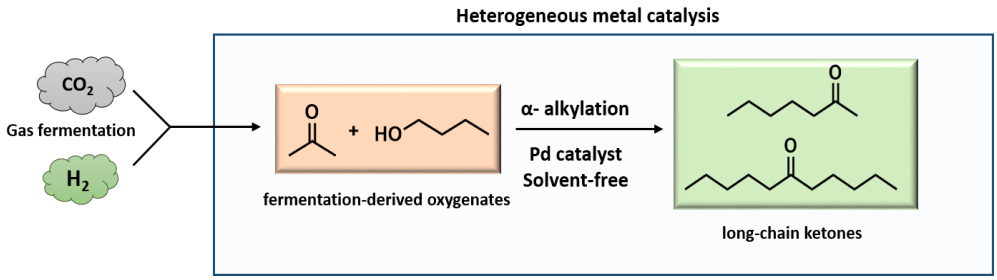

**Figure 1:** Schematic illustration of the synthesis of long-chain aliphatic ketones through Pd catalyzed α- alkylation

**Keywords:** metal-free *N*-doped carbons chitin chitosan shrimp shells $CO_2$ insertion cyclic carbonates continuous flow

**Introduction.** High anthropogenic $CO_2$ emissions are among the main causes of climate change. Herein, we investigate the use of $CO_2$ for the synthesis of organic cyclic carbonates on metal-free *N*-doped carbon catalysts obtained from chitosan, chitin, and shrimp shell (SSs) wastes, both in batch and in continuous flow (CF). Shrimp shells have been considered as a source of chitin suitable to synthesize *N*-doped carbonaceous materials with built-in basic properties. A procedure to convert SSs or chitin and chitosan into slightly basic solids has been coupled to the use of such materials as heterogenous catalysts for the $CO_2$ fixation into epoxides.

**Experimental/methodology.** The catalysts were characterized by a multitechnique approach and reactivity tests were run in the absence of solvents, under batch and continuous flow conditions, in the conversion of epichlorohydrin (selected as a model epoxide), into the corresponding cyclic carbonate. Also, additional batch experiments proved that the catalysts were successful on different terminal and internal epoxides.

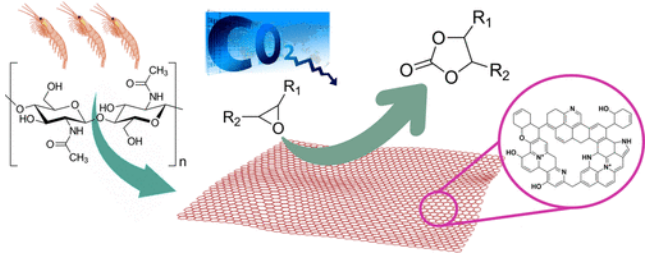

Figure 1. Schematic representation of the preparation and utilization of metal-free *N*-doped carbons.

**Results and discussion.** The here reported work has been aimed at achieving multiple objectives, from the design of a simple and sustainable method to obtained metal-free *N*-doped carbons to the use of such solids as catalysts for the activation and incorporation of $CO_2$ in the synthesis of durable chemicals/materials, and, finally, to the implementation of $CO_2$ cycloaddition reactions in a continuous mode to improve productivity and process intensification.[1] In particular: (i) a (small) library of catalysts with built-in basicity has been prepared from chitosan, chitin, and SS wastes through a thermal treatment carried out in the absence of additional reagents and solvents; (ii) a variety of batch experiments have demonstrated that the *N*-doped carbons, mostly those derived from chitin and SSs, were excellent catalysts for the cycloaddition of $CO_2$ to internal epoxides with quantitative conversion and selectivity to cyclic carbonate products up to 95–97%; and (iii) albeit investigated only for the model case of epichlorohydrin, the setup of a continuous solvent-free protocol for the $CO_2$ cycloaddition has confirmed that the same *N*-doped carbons allowed not only to scale-up the reaction with a productivity up to 15.0 mmol $gcat^{-1}$ $h^{-1}$, but they were outstandingly stable materials which did not undergo deactivation over time, at least in the explored time frame (8 h). Compared to the very recent literature of the sector, the CF procedure proved to be a robust and competitive option for the synthesis of cyclic organic carbonates.

**Keywords:** $CO_2$ reduction, power-to-gas, Ni metallic catalysts, Cs promoter, Ba promoter

**Introduction.** In order to meet the Paris Agreement, anthropogenic $CO_2$ emissions need to be critically diminished in a more time-consistent way. A potential solution is the so-called Power-to-Gas technology. This concept refers to the idea of storing spare electric energy as chemical energy[1]. Metallic Ni nanoparticles are among the most used catalysts for both the hydrogenation of $CO_2$ to methane or the reverse water gas shift (RWGS) reaction combining remarkable catalytic properties (activity and selectivity) with the fact that it is an abundant non-precious element. Understanding the role that different promoters and supports play in both the selectivity and stability of the catalyst seems to be a straightforward approach to developing efficient catalytic systems for conversion of $CO_2$ to CO (an intermediate for many existing processes in chemical industry such as, alcohol or Fischer-Tropsch fuels synthesis). Usually, promoters improve the catalytic performance by activating $H_2$ and/or $CO_2$, as well as increasing nickel´s reducibility and dispersion[2]. In this work, Cs and Ba have been chosen as promoters. While the first one is considered an electronic promoter, Ba has been reported to be a structural one[3].

**Experimental/methodology.** Catalysts were synthesized by a common incipient wetness impregnation method using nitrates as precursors. Prior to that, high-surface-area graphite (HSAG400) was chosen as support due to its open porosity and inertness which facilitates metal-promoter interaction. Activation of the catalysts was performed with hydrogen in the reactor, a U-shaped glass tube, before the catalytic tests. Outlet gases were analyzed with a Bruker CP-3380 gas chromatograph coupled with a thermal conductivity detector. Finally, the materials were studied through common characterization techniques: temperature programmed reduction, X-ray photoelectron spectrosocopy and scanning electronic microscopy, among others.

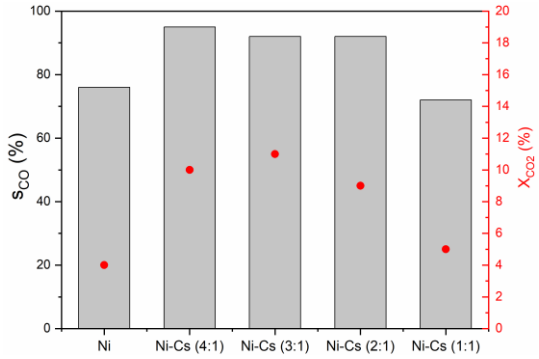

**Figure 1:** Catalytic performance of Ni-Cs catalysts in the $CO_2$ hydrogenation reaction.

**Results and discussion.** Kinetic regime conditions were stablished on the first place (WHSV = 36000 ml · $h^{-1}$ · $g^{-1}$; $H_2/CO_2$ ratio = 4, granular particle size ≈ 0.25-0.35 mm). Subsequently, the catalytic properties towards $CO_2$ reduction of two series of promoter (Cs or Ba) Ni catalysts were analyzed and compared to the monometallic Ni/HSAG catalyst. In each series, different stoichiometric ratios between Ni and the promoter were tested. In the case of Ni-Ba catalysts, an optimal 2:1 Ni/Ba ratio allowed increasing $CO_2$ conversion from 4% to 15%, while selectivity towards $CH_4$ rose from 24% to 38%. Higher Ba-loadings resulted in lower increments of activities or selectivity values, probably due to the covering of the most suitable adsorption centers of Ni. Ni-Cs catalysts display different catalytic behavior. When catalysts are promoted using an equimolar relationship, both CO and $CH_4$ productions are slightly increased. The diminishment of the amount of impregnated Cs entails the complete shifting of the selectivity towards CO. A paradigmatic example of this effect can be appreciated in the case of the 4:1 Ni/Cs-containing catalyst, where $s_{CO}$ = 95%. The conversion was also improved, producing three times more CO than our monometallic catalyst.

**Keywords:** $CO_2$, hydrogenation, $CH_4$, Ru, O-vacancies, in-situ spectroscopy

**Introduction.** Since metal-support electronic interactions determine the stability of key intermediates [1], efficient catalysts can be designed by the modification of electronic properties. Hydrogenation of $CO_2$ to $CH_4$ with renewable hydrogen is an attractive option for energy storage [2], yet, more efficient catalysts are still required. Therefore, a strategy such as the enhancement of defects is explored in this investigation. We demonstrate by different in-situ spectroscopic techniques how MgO incorporation in $ZrO_2$ boosts the $CH_4$ activity of $Ru/ZrO_2$ by changing the electronic Ru-support interactions.

**Experimental/methodology.** 0.4 wt.% Ru catalysts were prepared by wet impregnation over $ZrO_2$ and $ZrO_2$-MgO supports, which were prepared by precipitation and co-precipitation, respectively. The catalytic performance was determined at 1 atm at different temperatures with $H_2$:$CO_2$ ratio 4:1. In-situ EPR and dynamic in-situ DRIFT spectra were collected at similar conditions.

**Results and discussion.** From the catalyst screening, we found that $CO_2$ conversion increased by ca. 1.60 times on $Ru/ZrO_2$-MgO and even improved at 300 °C by ca. 1.80 times (Fig. 1a). Evidence for the involvement of paramagnetic species in the structure-reactivity behavior was provided by in-situ EPR (Fig. 1b). After reaction, a signal at g = 2.008 attributed to bicarbonate radical [3], evidenced more facile interaction between MgO-modified support and entities at the interface. Moreover, absence of $Zr^{3+}$ signal ($g_\perp$ = 1.974) on $Ru/ZrO_2$-MgO suggested electron delocalization from this center probably to Ru. In-situ DRIFTS indicated that the key intermediate species (Ru-CO) was found to be less stable in presence of MgO. During a dynamic experiment, the signal 2064-2050 $cm^{-1}$ required ca. 10 min to disappear together with that of $CH_4$ on $Ru/ZrO_2$, while for $Ru/ZrO_2$-MgO only 5 min were needed. Such destabilization is attributed to electron transfer from support to Ru sites. In summary, enhanced Ru-support electronic interactions induced by MgO allowed the generation of a more efficient methanation catalyst.

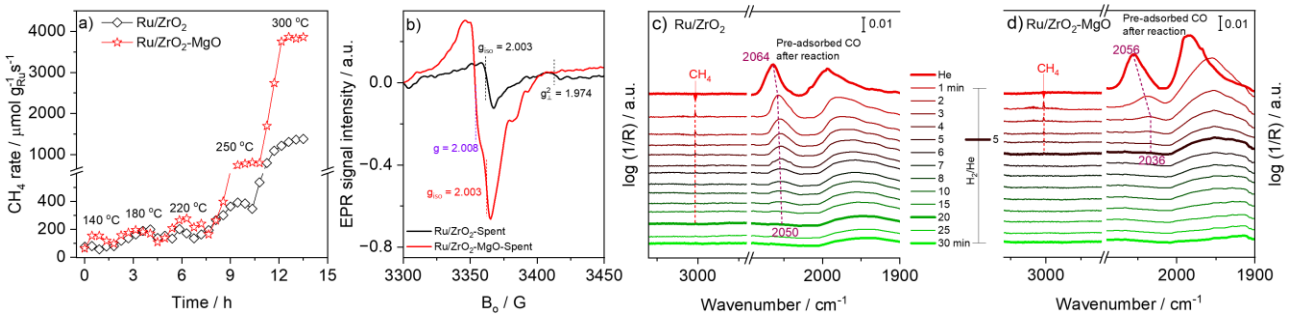

**Figure 1. a) Kinetic assessments, b) in-situ EPR spectra, c-d) dynamic in-situ DRIFTS**

**Keywords:** ethane, dehydrogenation, carbon dioxide, catalysis.

**Introduction.** The large supply of ethane from shale gas has increased the interest on the study of its catalytic conversion to valuable products [1]. Ethane is converted to ethylene through the dehydrogenation reaction (EDH), the addition of $CO_2$ favors this reaction [2]. By consuming the $H_2$ through the reverse water gas shift reaction, $CO_2$ can shift the EDH reaction equilibrium leading to higher ethane conversion; in addition, $CO_2$ reacts with solid carbon by the reverse Boudouard reaction, producing CO and avoiding catalyst deactivation by coke deposition. In this study, catalysts with gallium (Ga) and zinc (Zn) over $SiO_2$ were prepared, characterized, and tested in the $CO_2$-assisted EDH reaction.

**Experimental/methodology.** The catalysts were prepared by traditional wet impregnation method over $SiO_2$. The samples were calcined at 600 °C for 4 hours (10 °C/min ramp) in 50 mL/min air flow to obtain the metal oxide form. The catalysts were characterized by thermogravimetric analysis, X-ray diffraction (XRD), Raman spectroscopy (pre and post reaction) and temperature-programed reduction (TPR-$H_2$).

The catalytic tests were performed in an automated PID Eng&Tech system in a tubular reactor with online analysis in a GC-2010 Plus chromatograph (Shimadzu) using a thermal conductivity detector (TCD) and a flame ionization detector (FID). The catalysts were tested at different temperatures and different feed gas ratios in order to identify their influence on the ethane conversion and ethylene selectivity.

**Results and discussion.** Catalyst characterization evidence the presence of metal oxide ZnO and β-$Ga_2O_3$. Both catalysts are active for the EDH reaction, as shown in Figure 1, however the gallium catalyst showed higher $CO_2$ conversion. In reactions with different $C_2H_6/CO_2$ feed ratios, both catalysts presented an increase in ethane conversion with increasing $CO_2$ content, indicating that $CO_2$ indeed assists the ethane dehydrogenation reaction. The Raman spectroscopy analysis performed after reaction identified coke deposition on the samples, suggesting possible catalytic deactivation.

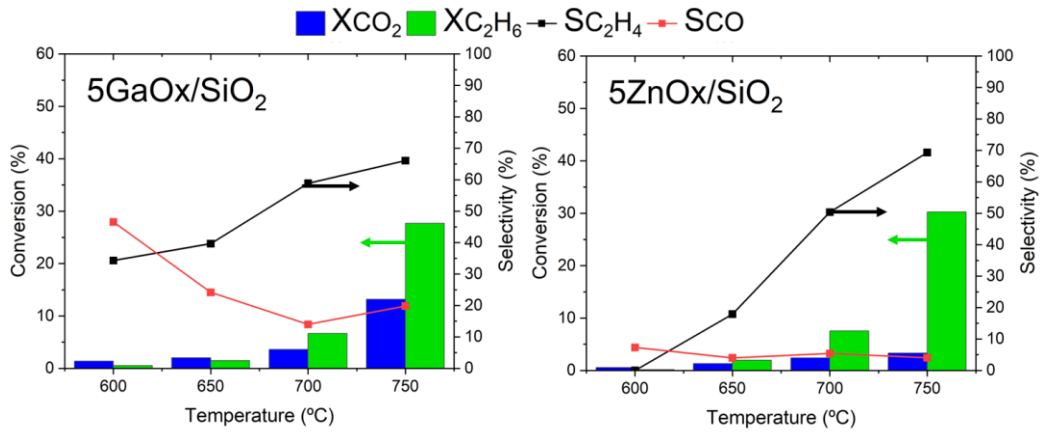

Figure 1. Temperature screening for the catalysts in the $CO_2$-EDH. Reaction conditions: $C_2H_6/CO_2/N_2$ = 1/1/4, total flow of 60 mL/min, WGSV = 12000 mL $g^{-1}$ $h^{-1}$.

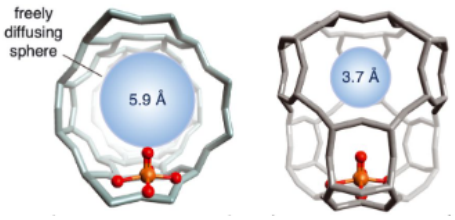
**Keywords:** spectroscopy, cage-effects, coordination chemsitry, catalysis, structure-activity relationships

**Introduction.** Catalytic decomposition of $CH_4$ and $N_2O$ are tantalizing but fundamentally challenging goals. Current technologies based on zeolites deactivate too rapidly for practical application. We found that similar active sites hosted in different zeolite lattices can exhibit markedly different reactivity with $N_2O$ and $CH_4$, depending on the size of the zeolite pore apertures and on the shape of the framework rings. These can be chosen through zeolite framework selection. The structure function relations are derived and demonstrated.



**Experimental/methodology.** Fe active sites were synthesised in different zeolite frameworks (BEA, ZSM-5, FER, MOR, CHA) and their reactivity with N2O and CH4 was investigated. Intermediates were identified with advanced spectroscopy (UV-Vis, FTIR, Mössbauer, NRVS, MCD, rRaman, EPR) and reaction kinetics were measured with operando UV-vis spectroscopy coupled with mass spectrometry. The results were interpreted and explained using spoctroscopically validated comutational models.

**Results and discussion.** Different zeolite framework have differently shaped of the 6-membered rings that host the active alpha-Fe sites.[1] This influences their ability for oxygen atom abstraction from $N_2O$ to form highy reactive alpha-O sites.[4] The underlying property is revealed to be a geometric distortion imposed by the zeolite lattice. At the same time this disctortion influences the binding energy of the Fe ion in the exchange site,[1,3] and also the reactivity of the alpha-O site in hydrogen atom abstraction from $CH_4$.[2] This creates a trade-off triangle of properties steered by the 6-ring symmetry, that must be optimised to the intended application and reaction conditions.

**6-membered ring shape and coordination distrorion of the alpha-Fe site**

Also the window size controls reactivity of alpha-O with $CH_4$. Known alpha-Fe zeolite with large pore apertures deactivate completely after a single turnover. New materials with small apertures were found to regenerate 40% of active sites in zeolite after single turnover, enabling a catalytic cycle.[5] Detailed spectroscopic characterization of reaction intermediates and density functional theory calculations show that hindered diffusion through small pore apertures disfavors premature release of CH3 radicals from the active site after C-H activation, thereby promoting radi cal recombination to form methanol rather than deactivated Fe-OCH3 centers elsewhere in the lattice.

# Single-atom Ru on zeolite catalyst for the valorisation of muconic acid via isomerization and hydrogenation reactions

Ibrahim Khalil[1], Lisa De Vriendt[1], Michiel Dusselier[1*]

[1]*Center for Sustainable Catalysis and Engineering, Celestijnenlaan 200F, KU Leuven, 3000 Leuven, Belgium*

[*]*Michiel.dusselier@kuleuven.be*

**Keywords:** Muconic acid, metal on zeolites, heterogeneous catalysis, single-atom.

**Introduction:** Muconic acid (MA) can be present in 3 isomeric forms: *cis,cis* (*cc*), *cis,trans* (*ct*), and *trans,trans* (*tt*). Its added-value is attributed to its potential as a starting material for the synthesis of value-added derivatives such as **(1)** adipic acid via hydrogenation reaction, **(2)** hexenedioic acid via mono-hydrogenation, and **(3)** terephthalic acid via Diels-Alder cyclo-addition (Figure 1).[1] To access these products, the *tt*-isomer is preferred either for its stability against the intramolecular lactonization reaction or to its geometry to perform Diels-Alder cycloaddition. The biotechnological synthesis of MA produces *cc*MA and *ct*MA, thus, an isomerization step leading to *tt*-isomer must be developed. In this work, we present a single-atom Ru on Beta zeolite catalysts to investigate the isomerization of *ct*-muconates. In addition, the single-atom Ru on Beta catalysts is used for the mono-hydrogenation of MA to produce **(2)**.

**Experimental/methodology:** To achieve atomic dispersed Ru on Beta zeolites (12.5 < Si/Al < 250), Ru was loaded via a cation exchange method using the $Ru^{III}(NH_3)_6Cl_3$ precursor. The activation conditions were primordial to achieve both isomerization and hydrogenation activities. In that sense, the thermal dissociation of the $NH_3$ ligands was followed and optimized activation temperatures were found between 300 and 350°C, where only 1-2 out of the 6 $NH_3$ ligands remain linked to Ru (EXAFS confirmation).[2]

**Results and discussion:**

**Isomerization:** 95% selectivity towards the *tt*-isomers could be achieved together with high productivity values (up to 85 g/L.h) and TON >2500 mol/mol. In addition, deep characterization were performed (EXAFS, ICP, $H_2$-TPR, FT-IR, BET) to confirm the atomic distribution of Ru and elucidate the reaction mechanism. Finally, one-pot isomerization/Diels-Alder reaction was conducted to produce **(3)** after a full conversion of *ct*-muconates. This reaction was proven to be applicable to various di-alkyl muconates.

**Hydrogenation:** To date, the synthesis of **(2)** was only reported using electrochemical methods.[3] **(2)** can serve as a co-monomer in the synthesis of nylon-6,6 polymer, which opens routes for the functionalization of the produced polymer with chemical reactions on the C=C bonds. The difficulty in making **(2)** remain in the control of the hydrogenation step which usually end up with the formation of **(1)** after excessive hydrogenation. In this part, we present a new method to access **(2)** from MA and muconates using Ru-Beta catalysts in an $H_2$-free system using ethanol (solvent) as a hydrogen source. The desired product **(2)** was obtained in yields surpassing the 50% and selectivity around 70%. The optimization of the reaction conditions to achieve will be discussed in this communication.

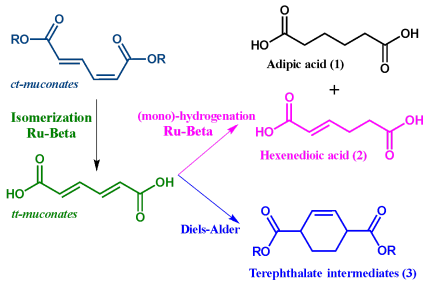

**Figure 1:** Reactions scheme for the isomerization of *ct*-muconates using Ru-Beta zeolites followed by the valorization of the *tt*-isomer via hydrogenation and Diels-Alder reactions.

**Keywords:** transition metal sulfides, hydrogen activation, operando spectroscopy, DFT

**Introduction.** Transition metal sulfides (TMS) have played an important role in industrial catalysis for over a century. Being ubiquitously utilized for heteroatom removal from petroleum feedstock, these catalysts have made their way into a multitude of other processes such as upgradation of bio-derived feedstock, reverse water gas shift reaction, $CO_2$ conversion, and more recently in electrocatalytic $H_2$ evolution. Such is the importance of these TMS phases that nature has also found a way to incorporate these active phases into its own catalysts: the enzymes. The active site in the nitrogenase enzyme, commonly referred to as the FeMo cofactor, has been identified as a Fe-Mo sulfide cluster. Industrial TMS catalysts, typically composed of sulfides of Mo or W, are often promoted with other 3d transition metals (most prominently Ni and Co). These mixed metal sulfide catalysts exceed the activity of monometallic sulfide catalysts by a wide margin. Interestingly, different mixtures of base and promotor metals result in a particular enhancement of individual reaction types. As a large fraction of reactions investigated on these TMS catalysts involve $H_2$ as a reactant, a significant amount of effort has been put into understanding the $H_2$ activation on these materials. It is widely accepted that $H_2$ activation on these catalysts occurs via dissociative adsorption followed by stabilization of hydrogen as either –SH groups or as hydride species. With the aim of improving the fundamental understanding the hydrogen activation in zeolite-encapsulated mixed TMS clusters, we have combined kinetic studies with *operando* spectroscopy and theoretical calculations to understand the mode of hydrogen activation on the zeolite-encapsulated TMS clusters.

**Experimental/methodology.** Mo was incorporated in the pores of NaY zeolite *via* chemical vapor deposition (CVD) using $Mo(CO)_6$. These precursors were sulfided at 673 K to form dimeric $Mo_2S_4$ species within the zeolite framework. *In situ* X-ray absorption and emission spectra (XAS/XES) were measured at P65 beamline of the German electron synchrotron (DESY) and the ID26 beamline of the European Synchrotron Radiation Facility (ESRF), respectively. DFT calculations were performed using the ORCA quantum chemistry package. All catalytic reactions were carried out in a lab-scale plug flow reactor. Ethene hydrogenation was performed at 473 K at ambient pressure with a $H_2/C_2H_4$ volumetric ratio of 20/1.

**Results and discussion.** Zeolites are ideal supports for forming well-defined TMS clusters due to their stable and structurally well-defined porous framework. We have recently synthesized homogeneously distributed molybdenum sulfide clusters encapsulated in the micropores of NaY.[1] The tetrameric $Mo_4S_4$ clusters structurally resemble the cubane motifs of the FeMo-cofactor and exhibited remarkable stability for ethene hydrogenation, while the classic layered $MoS_2$ catalyst deactivated significantly under the same conditions.[1] These promising results motivated us to address, how these clusters activate and stabilize $H_2$. Combining IR spectroscopy with kinetic measurements and DFT calculations we showed that the zeolite-encapsulated $Mo_xS_y$ clusters primarily activate and stabilize hydrogen as hydride species on Mo atoms while the bulk TMS phase stabilizes hydrogen primarily as sulfhydryl (–SH) groups.[2] With the aim of further improving the molecular understanding the $H_2$ activation in these zeolite-encapsulated TMS clusters, we have investigated how the mode of $H_2$ activation varies based on their composition. Partially ion-exchanging the NaY zeolite with $Ni^{2+}$ or $Co^{2+}$ resulted in the formation of interconnected mixed TMS phases. Their structure was elucidated *via* a combination of XAS and DFT calculations. Further combining theory with IR spectroscopy, we could show that the S-atoms bridging the two sulfide phases provide a new site for hydrogen stabilization as –SH groups, in addition to the formation of hydride species. This additional path for hydrogen activation resulted in improved activity of these mixed TMS clusters for ethene hydrogenation.

**Keywords:** Activation of $N_2O$, $CH_4$ conversion, Zeolite, Framework Al distribution

**Introduction.** The use of $CH_4$ as the carbon source for producing value-added chemicals has attracted much attention in the last decade. The development of a catalytic process that can directly convert $CH_4$ into useful chemical feedstocks such as $CH_3OH$ and C2-C4 hydrocarbons has extensively been pursuedwe report a novel catalytic process for the selective and effective production of hydrocarbons from $CH_4$ under mild conditions. Beside, nitrous oxide ($N_2O$) is a greenhouse gas and participates in the destruction of stratospheric ozone, and is also produced through $NH_3$ combustion process. Our strategy is based on the activation of $N_2O$ and $CH_4$ over metal-exchanged zeolite to effectively produce $CH_3OH$, and produced $CH_3OH$ from $CH_4$ is immediately converted to hydrocarbons by methanol to olefins (MTO) reaction before over-oxidation of $CH_3OH$. Recently, we have found that the importance of Al distribution in zeolite framework for physicochemical and catalytic properties for $CH_4$ activation [1]. Here, we report the design and synthesis of the zeolite catalyst enabling the production of lower olefins from $CH_4$ under oxidative atmosphere through the optimization of the Al distribution and the creation of both active sites for the MTM and MTO reaction in single zeolite catalyst.

**Experimental/methodology.** To investigate the impact of the Al distribution, aluminosilicate-type CHA zeolite with the Al distribution controlled were synthesized from different starting materials under the organic structure-directing agent (OSDA)-free conditions; the details were described in Supporting Information. Here, the CHA zeolites synthesized from amorphous silica-alumina and FAU were designated as CHA-Am and CHA-FAU, respectively. Cu species were introduced into the NH4+-form zeolites ($NH^{4+}$/CHA) by ion-exchange method (Cu-H/CHA-Am and Cu-H/CHA-FAU).

**Results and discussion.** Through various types of structural characterizations, CHA-FAU gave a significantly lower $Q^4$(2Al) proportion than CHA-Am, where "$Q^4$(*n*Al)" is $Si(OSi)_{4-n}(OAl)_n$; CHA-FAU contained more isolated Al atoms compared to CHA-Am. Catalytic conversion of $CH_4$ with $N_2O$ were carried out by using Cu-H/CHA-Am and Cu-H/CHA-FAU. For both catalysts, the conversions of $CH_4$ and $N_2O$ were decreased along with time on stream (TOS), while Cu-H/CHA-FAU gave a higher $CH_4$ conversion than Cu-H/CHA-Am. Note, there were clear differences in the products' distribution. Interestingly, for Cu-H/CHA-FAU, in addition to $CH_3OH$, hydrocarbons were produced. On the other hand, Cu-H/CHA-Am mainly produced $CH_3OH$ and CO, and hardly produced the hydrocarbons. For Cu-H/CHA-FAU, the selectivity to $CH_3OH$ was decreased but that to hydrocarbons was increased along with time on stream (TOS), suggesting that the $CH_4$ is converted to the hydrocarbons *via* $CH_3OH$ and/or $CH_3OH$ derivates. The distribution of the hydrocarbons indicats that lower hydrocarbons such as C2-C4 were selectively produced; the main products were ethylene followed by propylene. This is a typical feature of the MTO reaction over CHA-type zeolite. Hence, these results strongly suggest a new route to the production of the hydrocarbons from $CH_3OH$. In conclusion, we have successfully found the Al distribution greatly affected the state of the Cu species, and the catalytic performance in oxidative conversion of $CH_4$ and that "isolated Al atoms" would be advantageous for producing $CH_3OH$. In addition, the acid sites played an important role in the production of hydrocarbons; the $CH_3OH$ produced from $CH_4$ is converted into hydrocarbons over the acid sites [2].

**Keywords:** Transfer Hydrogenation, Hydrogen Borrowing, Green Chemistry, Amination

**Introduction.** Transfer hydrogenation has attracted significant attenstion since Anastas and Warner published their green chemistry guidelines back in 1998. These strategies offer alternative reaction pathways which are more atom economical than conventional methods and produce less waste. While significant research has been conducted on the use of these strategies for the hydrogenation of carbonyl compounds, their application for the production of amines is significatnly less explored. With this in mind, we set out to establish what catalytic properties might facilitate this chemistry. Pt/$CeO_2$ materials were used as model catalysts for this study and a reaction between cyclopentanol (CPL) and cyclopenylamine (CPA) were selected as our model reaction (**Figure 1**); dicyclpentylamine (DCPA) is produced in reaction cascade involved alcohol dehydrogenation, coupling and reduction. Importantly, hydrogen atoms generated from the dehydrogenation of CPL are utilized for the subsequent reduction of the coupled product, further improving atom efficiency.

**Experimental/methodology.** Several 1 *wt.*% Pt/$CeO_2$ catalysts were prepared by impregnation and reduced thermally to yield the final catalysts. The Pt precursor ($H_2PtCl_6$ or $Pt(NH_3)_4(NO_3)_2$) and $CeO_2$ source (Sigma Aldrich, Alfa Aesar and $CeO_2$ produced from $Ce(NO_3)_3.6H_2O$ decomposition) were varied to produce analagous materials, but with differing physicochemical properties. These were subsequently probed using an extensive range of characterisation methods (AC-STEM and SEM, $N_2$ Physisorption, CO chemisorption, CO-DRIFTS, XAS, $CO_2/NH_3$-TPD, INS). The catalytic performance of the materials towards hydrogen-borrowing amination was subsequently assessed in a glass batch reactor, operated under $N_2$.

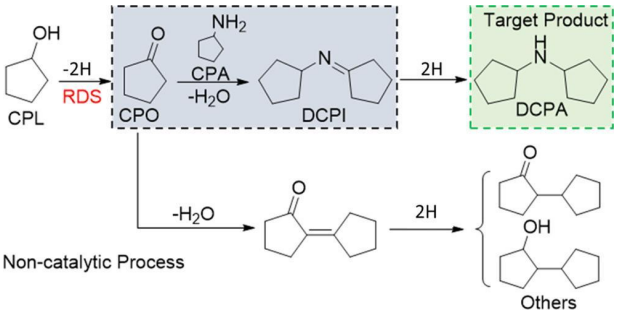

**Figure 1. Schematic representation of the cascade reaction under investigation. KEY: Cyclopentanol (CPL); Cyclopentylamine (CPL); Dicylcopentylamine (DCPA); N-cyclopentylcylcopentanamine (DCPI).**

**Results and discussion.** Both the Pt salt and the $CeO_2$ support used had a profound effect on the morphology of the supported Pt species. Two dimensional (2D) Pt rafts, cationic Pt species and Pt nanoparticles were all observed in these materials, but their relative quantities changed depending on the Pt precursor and $CeO_2$ support that was used. Importantly, the Pt morphology served as an activity indicator for alcohol dehydrogenation (rate determining). This was confirmed by subsequent density functional theorey calculations, which evidenced that the 2D Pt rafts were more effective towards alcohol dehydrogenation than the Pt nanoparticles and cationic Pt, respectively. This was supported by *quasi* in-situ INS experiments, which confirmed the existence of a Pt hydride intermediate. $NH_3/CO_2$-TPD experiments demonstrated that redox properties of the materials had a significant impact on the overall reaction selectivity; residual $Cl^-$ ions were proposed to inhibit undesireable condensation reactions in favour of the desired amine, DCPA.

# From Mechanism Study to Catalyst Design: Exsolved Ru Nanocatalysts on Proton Conducting Oxide for Efficient Ammonia Synthesis

H.-I. Ji[1,2*], J. Kim[1], H. Kim[1], S. Yang[1,2*]

[1] *Korea Institute of Science and Technology (KIST), Seoul, Republic of Korea*
[2] *Korea University of Science and Technology (UST) KIST Campus, Seoul, Republic of Korea*
[*] *hiji@kist.re.kr (H.-I. Ji), syang@kist.re.kr (S. Yang)*

**Introduction.** Since it was revealed that the ammonia synthesis reaction is associated with the nitrogen adsorption energy, represented by a volcano plot, the catalysts placed near the peak of volcano plot, particularly ruthenium (Ru), have been actively investigated [1,2]. For high efficiency of ammonia synthesis under mild conditions, the requirements of supported Ru catalysts are i) electron donating ability of supports (as promoters) that weakens the N≡N bond, ii) hydrogen absorption/desorption capability of supports to suppress $H_2$ poisoning on Ru surface [3], iii) refractory property for maintaining high specific surface area of supports [1], and iv) the structurally robust and uniformly distributed Ru nanoparticles [4]. However, the supported Ru catalyst that simultaneously fulfills all requirements above has yet been developed. Here we report a highly active exsolved Ru nanocatalyst supported on perovskite proton conducting oxide, $BaCe_{0.55}Zr_{0.3}Y_{0.15}O_{3-\delta}$ (BCZY), for ammonia synthesis at atmospheric pressure based on the understanding of exsolution mechanism.

**Experimental/methodology.** The supported catalyst, 5mol% Ru-added BCZY, $BaCe_{0.5}Zr_{0.3}Y_{0.15}Ru_{0.05}O_{3-\delta}$, was synthesized via solid state reaction using appropriate amount of oxide precursors. Analyses of XRD for crystal structure, TEM for microstructure observation, TGA for measurement of mass change against temperature, XPS for determination of oxidation state, BET for surface area measurement, and catalytic activity for quantifying ammonia synthesis rate were carried out.

**Results and discussion.** The exsolution is basically driven by reduction of oxide support, corresponding to the mass loss owing to the oxygen release. Thus, the decrease in mass directly associated with the Ru exsolution in a form of metal. Based on in situ TG profile at 1000°C under reducing atmosphere, it was verified that the Ru exsolution process is controlled by size-related strain, and the degree of exsolution can be effectively enhanced as the reduction time increases, e.g., from 1h to 20h. The exsolved Ru nanoparticles on proton-conducting oxide support formed by 20h reduction treatment at 1000°C had diameter of ~6 nm, and exhibited higher catalytic activity for ammonia synthesis reaction compared to exsolved Ru via 1h reduction treatment as well as the previously reported catalysts. The use of proton conducting oxide support, which has electron donating capability, structurally refractory property, and hydrogen absorption/desoprtion capability, could possibly be synergistic to boost the catalytic activity of exsolved Ru nanocatalyst. In this presentation, the details on exsolved Ru catalyst as a function of temperature, probable exsolution mechanism, and role of proton conducting oxide support will be further discussed.

**Keywords:** $N_2O$, $NH_3$-SCR of NO, Mn single atom.

**Introduction.** Nitrogen oxides have emerged as one of the main sources of air pollution from stationary and mobile sources, which can cause serious damage to the environment and human health. Selective catalytic reduction (SCR) of NO with $NH_3$ has been the predominant technology for deNOx in industry. [1] To date, manganese oxides are reported to be one of the most promising catalysts for mobile source emissions at low temperatures. However, a large amount of $N_2O$ could be produced on the MnOx in the $NH_3$-SCR reaction, which is the main byproduct and has a strong greenhouse effect as well as severe hazards towards human health. How to further suppress the formation of $N_2O$ remains a challenge. Based on our previous work, we hypothesized that spacing the MnOx active sites could produce less $N_2O$. [2] Single-atom catalyst (SAC) has been widely used in heterogeneous catalysis due to its high dispersion and maximized atom utilization efficiency. Hence, one of the efficient approaches for clarifying $N_2O$ species formation on MnOx-$TiO_2$ is to prepare single Mn-atom catalysts which by definition results in a complete dispersion and spacing of the metal over the support.

**Experimental/methodology.** To achieve this goal, a series of highly dispersed MnOx/$TiO_2$ catalysts were prepared via strong electrostatic adsorption, which was involved with anchoring Mn atom on the surface of defected-$TiO_2$ for different Mn loadings (1.2 to 6.0 wt.%). The sample containing Mn nanoparticles (Mn NP) with the same metal loading was prepared for comparison. The NO conversion and $N_2O$ concentration were measured by online-FTIR and the structural properties of these catalysts were investigated by ICP, $N_2$-physisorption, EPR, XRD, $H_2$-TPR, UV-Vis, $NH_3$-TPD, STEM/EDX, TEM/EELS, XPS and XAS.

**Results and discussion.** Atomically dispersed Mn structures (Mn SA) can be confirmed using HAADF-STM and XAS whereas MnOx nanoparticles were observed in the control samples (Figure a-d). The $N_2O$ formation rate in a wide temperature range (150-400 °C) was much lower compared to Mn NP during $NH_3$-SCR reaction at similar conversion ranges and at different concentrations of $NH_3$ and NO (Fig. e and Fig. f). Besides, more $N_2O$ were also observed during $NH_3$ oxidation, NO-TPD and $NH_3$-TPD process, thus further verifying that atomically dispersed Mn species can suppress the $N_2O$ formation while providing a good NOx abatement compared to samples having MnOx nanoparticles.

**Keywords:** Divergent bond activation, Adaptive systems, Homogeneous Catalysis, Cooperativity

Traditionally, catalytic protocols are designed to convert substrates into a single product, preferably or even exclusively. As an alternative, the catalyst can be viewed as a system whose activity can be comprehensively adjusted by fine-tuning the reaction conditions in order to convey distinct product platforms. Such dynamic catalytic systems support the idea of molecularly controlled catalysis.[1] Understanding and designing catalytic systems in their full complexity is crucial to this approach. This can result in responsive or adaptive catalysts that enable precise control and regulation of catalytic activity. The main aim of such systems is to advance the understanding of how to control different chemical transformation sequences, ultimately producing selectively different products from a large panel of building blocks.

This lecture will provide an update on our ongoing research on the development of molecular control over bond-making and -breaking processes using adaptive transition metal systems.[2] In these systems, we demonstrate how to manipulate primary functional groups by targeting their intrinsic chemical bonds to open divergent reaction pathways. Our attention will be focused on (1) an iron-based catalyst that controls C=O versus C–H bond activation in aldehydes to open two divergent pathways and convert a wide range of substrates to the desired amides and nitriles (figure, panel A);[3] and (2) an adaptive rhodium-based catalytic system that controls the hydrogenation network of nitro-containing substrates to produce anilines and hydroxylamines (figure, panel B).[4]

*ali.abdelmageed@catalysis.de

**Introduction:** The synthesis of heterogeneous catalysts with well-defined active sites is essential for elucidating reaction mechanisms and further development of catalytic materials.[1] Metal-organic frameworks are excellent platforms for the achitecture of molecularly well-defined active sites.[2] This proved efficient for supporting individual metal atoms or smal metal clusters. As an example, we reported recently a Cu single-atom catalysts supported by Zr-based UiO-66 frameworks which proved highly active and stable for CO oxidation reaction.[3] Based on this approach, we expanded on our investigations to the selective oxidation of methane to methanol. Inspired by the enzyme soluble methane monooxygenase which utilizes iron-oxo species to transform methane to methanol under mild conditions,[4] we dsigned a synthetic Fe complex supported by UiO-66 framewor as an active site for this reaction.

**Experimental** Fe/UiO-66 catalysts were prepared by covalent attachment of $Fe^{3+}$ ions on UiO-66 defects (see Ref.[3]). $CH_4$ oxidation ($CH_4$:$O_2$:$H_2O$ = 2:1:0.2) was studied in flow-reactor at 5 bar and at T= 140-200°C. Catalysts were characterized under operando or "quasi" in-situ conditions using diffuse reflectance UV-vis, FTIR, X-ray absorption (XANS / EXAFS) , electron-paramagnetic resonance (EPR) and $^{57}$Fe Mössbauer spectroscopic methods, in addition to high-resolution electron microscopy / EDS mapping.

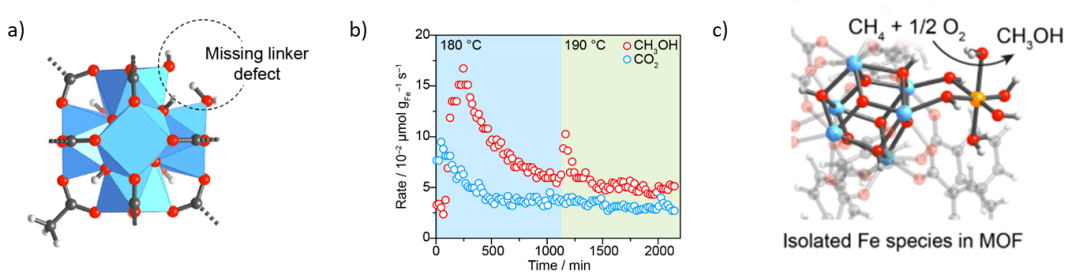

**Figure1. a) $Zr_6$ cluster of UiO-66 with missing terephthalate linker, b) methanol and $CO_2$ formation rates on stream at 180°C and 190°C, c) DFT optimized strucutre of Fe-single sites where methane oxidaiton is proposed to occur.**

**Results and discussion:** Coordination of Fe to the terephthalate defect sites (see Figure 1a) was evidenced by elemental analysis, SCXRD, PXRD and in-situ FTIR measurements. Activity measurements done at 180-190 °C indicate an initial activation phase up 250 min on-stream followed by catalyst deactivation for 500 min (Figure 1b) and reaching a steady-state production of methanol at a reaction rate of $5.9 \times 10^{-2}$ µmolMeOH gFe–1 s–1 at. By monitoring the total oxidation of methane to $CO_2$ we estimated a selectivity for methanol and $CO_2$ formation under steady state of 62% and 38% respectively. The catalytic turnover for methanol formation was verified by following the rate of buildup / decay of methanol isotopomers ($^{13}CH_3OH$ and $^{12}CH_3OH$) during a transient isotope scrambling experiment using $^{12}CH_4$ and $^{13}CH_4$ isotopomers. Based on in-situ / operando spectroscopic measurements (Fe K-edge XANES / EXAFS, EPR, $^{57}$Fe Mössbauer spectroscopy) and density functional theory (DFT) calculations we concluded the reaction relevant structure of Fe-active site as electron-deficient isolated Fe single sites coordinated by the UiO-66 MOF support (Figure 1c). Both the formation and depletion of these species, either by loading different Fe concnetrations or during activation/deactivation phase could be correlated with the activity of these catalysts for the selective oxidation of methane to methanol under relevant reaction conditions.

# Sub–nanometric metal species supported in MOFs for organic synthesis

Marta Mon*, Antonio Leyva-Pérez

*Instituto de Tecnología Química, Universitat Politècnica de València–Consejo Superior de Investigaciones Científicas (ITQ, UPV-CSIC), Valencia, Spain*
**marmoco@itq.upv.es*

**Keywords:** heterogeneous catalysis, MOFs, organic reactions.

**Introduction.** Ligand–free single metal atoms and clusters can be easily prepared in solution and catalyze relatively complex organic reactions with extremely high turnovers, >1 million in many cases, with just parts per million (ppm) of metal. This catalytic approach is very convenient for industrial purposes, where the amount of expensive metal catalysts must be minimized. Besides, if desired, the sub–nanometric metal species can be prepared in nanostructured solid materials, which allows easy recovery, reuse and implementation in continuous processes. Nanostructured solids have been traditionally used in fields somewhat away of organic synthesis, such as petrochemistry and water treatment, since spatial restrictions have been viewed as an unsurmountable issue when dealing with relatively big molecules. However, we will show here that this view can be incorrect in many cases, and that Metal-Organic Frameworks (MOFs) can be used as suitable supports for sub-nanosized metals, obtaining solid catalysts capable of carrying out complex organic reactions.[1]

**Experimental/methodology.** In this communication, the strategy followed to prepare and stabilize ligand–free clusters or single metal atom will be presented, which consists in the use of MOFs channels as chemical nanoreactors.

**Results and discussion.** Key industrial reactions such as the $NH_4CN$ formation, $CO_2$ methanation, olefin hydrogenation,[2] the low-temperature water–gas shift reaction,[3] and the oxidation of alcohols[4] will be shown. Other reactions of interest in organic synthesis such the Büchner reaction,[5,6] and carbon–carbon cross–coupling reactions,[8] will be also described.

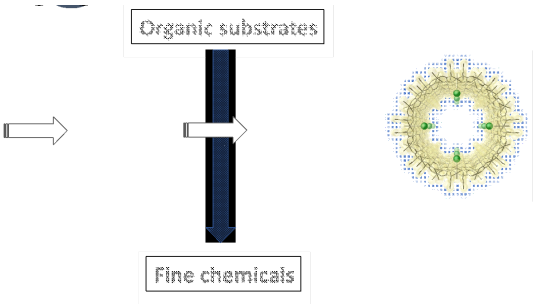

**Figure 1**. Ligand–free sub–nanometric metal species supported in MOFs as catalysts for organic reactions.

# Design of Metal-Organic Frameworks for Photocatalytic $H_2O_2$ Production

Hiromi Yamashita[1*], Yoshifumi Kondo[1], Yasutaka Kuwahara[1], Kohsuke Mori[1]

[1]*Osaka University, Suita, Japan*
[*]*yamashita@mat.eng.osaka-u.ac.jp*

**Keywords:** MOF Photocatalyst, $H_2O_2$ production,

**Introduction.** $H_2O_2$ has attracted much attention as an environmentally friendly oxidant as well as a promising liquid fuel. Photocatalytic process is a potentially sustainable method for $H_2O_2$ production alternative to the current anthraquinone oxidation process. Our group demonstrated that application of metal-organic framework (MOF) for photocatalytic $H_2O_2$ production via oxygen reduction [1]. Thanks to the advantages of the unprecedented design flexibility of MOFs, we developed the MOFs to improve the photocatalytic activity for $H_2O_2$ production by the linker functionalization and the missing-linker defects in the MOF framework, and the utilization of a two-phase reaction system using hydrophobic MOF [1-6].

**Results and discussion.** Ni/MIL-125-$NH_2$: Co-catalyst deposition is an efficient approach to improve photoctalytic $H_2O_2$ production. Ti-based MIL-125-$NH_2$ was synthesized using titanium isopropoxide and 2-aminoterephthalic acid and deposited with Ni nanoparticles (Ni/MiL-125-$NH_2$). Catalysts were dispersed in an $O_2$-saturated acetonitrile solution of benzylalcohol (BA) and irradiated with visible light (λ> 420 nm). Ni nanoparticles improved the selectivity for the two-electron reduction of oxygen to $H_2O_2$.

UiO-66-$NH_2$ with missing-linker: Defect engineering for MOFs is a promising process that can modulate their electronic structure, surface chemical properties and porosity. UiO-66-$NH_2$ consisting Zr-oxo clusters and 2-amino-terephtalate linkers was prepared and the missing-linker defects terminated by acetate ligands were introduced by adding acetic acid. Addition of missing-linker defects in UiO-66-$NH_2$ framework improved photocatalytic $H_2O_2$ production due to the promotion of linker-to-cluster charge transfer.

Two-phase reaction system with hydrophobic MOF: One critical issue of the above single-phase reaction system needs an energy-consuming separation process after the $H_2O_2$ production. Our group developed a two-phase reaction system, which is composed of water and benzyl alcohol, for photocatalytic $H_2O_2$ production utilizing hydrophobic MOF. The alkylated hydrophobic MOF was prepared by modification of the clusters in MIL-125-$NH_2$ with octadecylphosphonic acid (OPA). The hydrophobic MOF was dispersed in an $O_2$-saturated two-phase system composed of water and BA, and irradiated with visible light (λ > 420 nm). This two-phase reaction system realized spontaneous spatial separation of formed $H_2O_2$ to the aqueous phase and photocatalytst in BA improved the yield of $H_2O_2$ by preventing the $H_2O_2$ decomposition.

**Keywords:** Multifunctional catalyst, hybrid inorganic-polymeric materials,

**Introduction.** Multifunctional inorganic−organic hybrid materials, having both organic and inorganic components, have been recently widely investigated for their potential application in many fields. Various approaches exist for the preparation of these composites and their properties can be tuned by modification of the intimate composition. In the catalysis fields their activity is strongly correlated with the efficiency of the method of synthesis. An effective approach to develop a one-step synthesis of organic-inorganic materials with well-controlled compositions and porous textures can be the use of spray technique applied to single nanophase precursors.

**Experimental/methodology.** In this study, we use heterocoagulation and spray-freeze-drying (SFD) of sols containing the active phase precursors - oxides such as $SiO_2$, $TiO_2$ and $ZrO_2$ and polymers - to design hybrid catalysts with multifunctional properties for application in biomass valorisation and wastewater treatment.

The used synthesis process integrates colloidal heterocoagulation - exploring the electrostatic self-assembly between the oxide colloidal phase and the polymer dispersion - with the aerosol spray management and the evaporation by lyophilization.

**Results and discussion.** Firstly, with this procedure, nano-oxides having different Lewis acidity were encapsulated in a superacid resin matrix (Aquivion) leading to the preparation of porous micro-granules characterised by a high homogeneity in the phase distribution, high surface area and different acidity.

The presence of Brønsted sites (-$SO_3H$ belonging to Aquivion polymer) and Lewis acid sites (belonging to inorganic supports) of the composite materials were characterized with $^{15}N$ isotopically labelled pyridine adsorption at 298K coupled with MAS NMR spectroscopy. The $^{15}N$ chemical shift of the adsorbed pyridine clearly allows to evidence the presence of Brønsted and Lewis sites and to evaluate their accessibility. The effect of acidity and of composite catalysts were studied and optimized for the gas phase dehydration of ethanol to ethylene in mild conditions [1] and for the one-pot domino reaction from furfural to γ-valerolactone. Moreover, with this procedure we coupled a microalga (*C. vulgaris*) with $TiO_2$ NPs exploring a new challenging frontier in the hybrid bio-nano material design [2]. Indeed, we develop a multifunction bio-nano catalyst able to combine heavy metal absorption with the photocatalytic action. With optimized synthesis we obtained a composite where $TiO_2$ was demonstrated to photodegrade organic compounds typical of the industrial effluents while contemporary the microalgae act as heavy metal sequestrant.

**Keywords:** Catalyst design, cascade reactions, biomass valorisation, hierarchical materials, core-shell.

**Introduction:** Cascade reactions are sequential chemical transformations in which the starting substrate undergoes a reaction whose product becomes the substrate for the next step, and so on, until a stable product is reached.[1] Cascades offer great advantages in respect of atom economy, and time, labour and resource efficiency management, whilst permitting the use of synthetically enabling intermediates that may be impractical to isolate. However, catalytic cascades, in which the product of a reaction catalysed by species A undergoes a subsequent distinct transformation catalysed by a second species B, are hindered by the possibility of undesired interactions between the initial substrate and the second active site, or indeed between the two catalytic species. Thus highly desirable 'one-pot' catalytic cascades necessitate the spatial separation of each catalytic step. Here we report generic routes to new classes of spatially orthogonal (i.e. mutually exclusive) bifunctional porous materials,[2] comprising hierarchal bimodal porous skeletons and porous core-shell architectures, both enabling the chemical environment of distinct pore regions to be independently tuned. The hierarchical nature of the pore networks, either bimodal or core-shell, regulates active site accessibility and communication between different spatially localised catalytic functionalities.

**Experimental:** Hierarchical porous architectures have been synthesised via either duel templating strategies or desilication of commercial microporous zeolites, while porous core-shell structures are produced by consecutive growth strategy employing a bi-phasic synthesis protocol. Controlled active site deposition, through either blocking of locations by pore templates or capping agents or through size limitations, allows for the coupling of complementary sites, including two distinct metal nanoparticles (NPs), an acid and a base, and an acid and metal NPs. These configurations are tuned for one-pot alcohol selective oxidation, transesterification and esterification, and hydrodeoxygenation (HDO) cascades.

**Results and discussion:** Spatial compartmentalisation of 2.4 nm Pt NPs and 5.5 nm Pd NPs within mesopores and macropores of a bimodal porous silica,[2] was verified by HAADF-STEM imaging (Fig. 1), electron tomography, and simultaneous surface (SEM) and bulk (DF-STEM) imaging. The subsequent material displays the catalytic advantage of spatially segregating Pt NPs within mesopores, accessible only through interconnected Pd containing macropores, for the cascade selective oxidation of cinnamyl alcohol → cinnamaldehyde → cinnamic acid (Fig. 1). Catalytic Biofuel production, via the combined transesterification and esterification, has been facilitated by the spatial separation of $Zr(SO_4)_2$ (acid), in macropores, and MgO (base), within mesopores, akin to the selective oxidation system.[3] In a similar fashion, Pd doped in mesopores and acid sites in micropores of hierarchical porous zeolite has shown excellent HDO performance for the cascade reduction → dehydration → hydrogenation of fatty acids into alkanes. Core-shell structures have also been developed for biofuels, via consecutive dehydration and hydrogenation, for the conversion of fructose into biofuels over acid and metal NP sites, respectively.

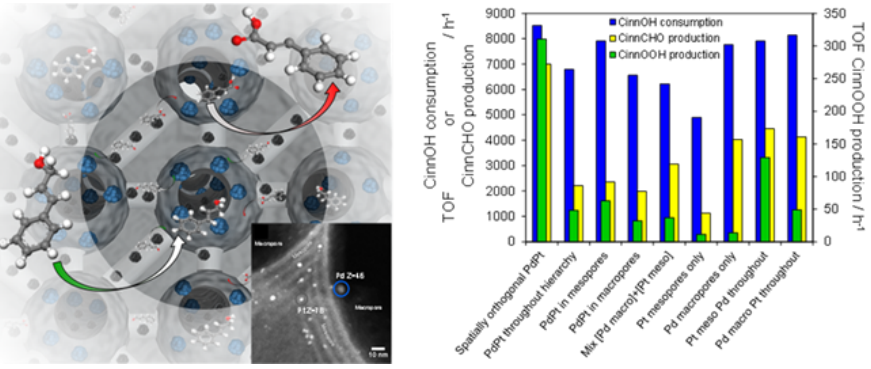

Figure 1. (left) Concept of spatially orthogonal selective oxidation catalysts, with inset HAADF-STEM image. (right) Catalytic cascade selective oxidation of cinnamyl alcohol.

**Keywords:** Sabatier reaction, Magentically-induced catalysis, Eddy current

**Introduction.** Recently, magnetically induced catalytic $CO_2$ hydrogenation has gained lots of attention due to its high energy efficiency and better heat management of exothermic processes as compared to thermal heating.[1] In particular, ferromagnetic nanoparticles (dual heating and catalytic agent) are shown to be active for this process, but the complex synthesis of such nanoparticles hinders their potential to be a commercial success.[2] Herein, a single macroscopic Fe based ($SiO_2$ and Ni coated) composite with dual functionality was realized and tested for magnetically induced gas-phase methanation and further proved to be active for the liquid phase model hydrogenation and hydrodeoxygenation reactions.

**Experimental/methodology.** The $SiO_2$ coating of the Fe wool was carried out using a simple sol-gel chemistry route involving hydrolysis and polycondensation of TEOS, followed by annealing. Subsequently, the Ni deposition was accomplished using an organometallic decomposition route in presence of the Fe wool and the Fe wool@$SiO_2$ (Fig. 1). All as-prepared samples were characterized using XRD, ICP-AES, VSM, SAR, XPS, SEM, SEM-EDS elemental mapping, and FIB-SEM techniques. The continuous gas phase $CO_2$ methanation was carried out in fixed bed reactor and liquid phase catalytic reaction in batch type reactor.

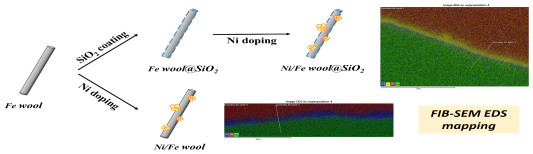

**Figure 1.** a) Schematic representation of Fe wool functionalization and the respective FIB-SEM EDS mappings.

**Results and discussion.** The enhanced catalytic activity (higher $CO_2$ conversion and $CH_4$ selectivity) of Ni deposited silica coated Fe wool as compared to the uncoated counterpart could be attributed to the presence of $SiO_2$ layers, providing more stability to the surface Ni species (Fig. 2a,b). An addition of a Siralox filler in the catalytic bed further improves the $CO_2$ conversion and $CH_4$ selectivity, and the stability of the catalyst (30 h on stream). Furthermore, this composite catalyst was demonstrated to be active for solution-phase model hydrogenation (styrene and nitrobenzene) and hydrodeoxygenation (acetophenone and diphenyl ether) reactions with 5mol% Ni loading (Fig. 2c). Herein, the combined XPS, FIB-SEM, and SAR measurements, signifies the judicious choice of $SiO_2$ coating and the utilization of eddy current mediated heating of Fe wool for the development of stable, energy efficicent, and inexpensive Fe based catalyst.

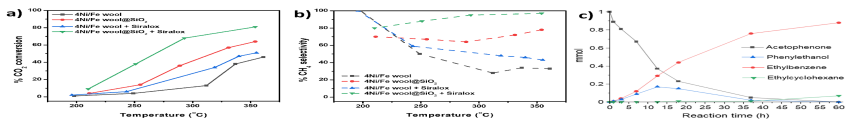

**Figure 2.** Plot of a) %$CO_2$ conversion as a function of temperature, and b) $CH_4$ selectivity as a function of temperature, c) solution phase kinetic data for acetophenone hydrodeoxygenation reaction using 4Ni/Fe wool@$SiO_2$ as a catalyst.

**Keywords:** Methanol-to-hydrocarbon, catalytic stability, zeolite, liquid metal, gallium

**Introduction.** Methanol-to-hydrocarbons (MTH) has been considered as one of the most practical approaches for producing high-valuable products.[1] However, the commonly used zeolite catalysts suffer from rapid deactivation due to coke deposition and require regular regeneration treatments. Inspired by the versatile roles of liquid metal for promoting the supported metal catalysts,[2] we demonstrate that the low-melting-point liquid metal can effectively promote more stable methanol conversion in MTH process by modifying acid sites of zeolite and accelerating the desorption of bulky products from zeolite surface. The ZSM-5 zeolite promoted with the liquid metal of gallium exhibited a more stable MTH lifetime of 32 h than the ZSM-5 alone (8 h) at the same conditions.

**Experimental/methodology.** HZSM-5 catalysts were prepared via calcination of $NH_4$-ZSM-5 (Zeolyst, CBV2314, $SiO_2/Al_2O_3$~23). The reference $Ga_2O_3$/ZSM-5 with a nominal 10% wt. Ga loading was prepared via incipient wetness impregnation. Ga/ZSM-5 was obtained by treating the HZSM-5 with metallic Ga (Sigma-Aldrich) under $N_2$ at 200 $^0$C with subsequent separation of zeolite. Ga+ZSM-5 is physically mixed HZSM-5 with Ga. The MTH reaction was performed in a fixed bed quartz tube reactor at 400 $^o$C at atmospheric pressure using $N_2$ flow saturated by methanol with GC analysis at the exit of the reactor.

**Results and discussion.** We have discovered that the MTH catalytic stability of ZSM-5 catalyst containing liquid metal Ga outperforms the ZSM-5 zeolite and $Ga_2O_3$-supported catalyst (**Figure**). Multiple characterizations of FTIR, TEM, XPS, TG and $N_2$ adsorption revealed that the liquid metal penetrates the pores of zeolite, interacts with acid sites and it favours the desorption of bulky molecules from the pores (**Figure**). It results in the suppression of coke formation and an increase in the stability of the catalyst 4 times from 8 to 32 h.

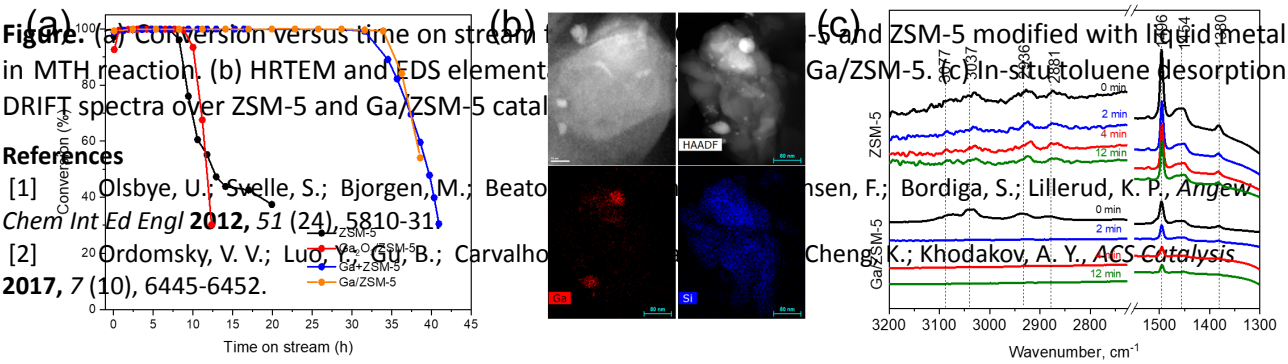

**Figure.** (a) Conversion versus time on stream f -5 and ZSM-5 modified with liquid metal in MTH reaction, (b) HRTEM and EDS element Ga/ZSM-5. (c) In-situ toluene desorption DRIFT spectra over ZSM-5 and Ga/ZSM-5 catal

**Keywords:** perovskite, rWGS, exsolution, doping, catalysis, high temperature

**Introduction.**

The utilization of $CO_2$ in chemical reactions could potentially provide a way to alleviate the impact of the industrial sector on climate change. As shown in previous works, perovskite type oxides (general formula $ABO_3$) have great properties to be used as catalysts for reactions – particularly the reverse water gas shift reaction (rWGS) – that mitigate $CO_2$ emission of the industrial sector [1]. The reason is the thermal stability of perovskites even under harsh reaction conditions and high T and their beneficial surface reactivity.

**Experimental/methodology.**

In this study we investigated the effects A- and B-site doping of the host latice on exsolution properties, oxygen surface chemistry and the corrsponding catalytic activity. Therefore, multiple series of catalysts were prepared utilizing a modified pechini synthesis route. The B-site undoped series $M_{0.6}Ca_{0.4}FeO_{3-\delta}$ (M = La, Nd, Pr) was compared to a series where the catalytically active metal X was doped on the B-site $M_{0.6}Ca_{0.4}Fe_{0.9}X_{0.1}O_{3-\delta}$ (X = Co, Ni). To obtain operando data on structural changes synchrotron based X-Ray Diffraction was applied. Additionally, to better understand the role of the A-site elements, Density Functional Theory (DFT) calculations were performed.

**Results and discussion.**

Catalytic results pictured in Figure 1 show that the Pr based perovskite is the most active one among the A-site variations. In total the activity of the catalyst could be doubled by the change of the A-site element from La to Pr. Also, in comparison to the Nd based catalyst the activity was increased by around 66 %. This different behavior can be explained by the different size of the exsolved nanoparticles and the modified surface chemistry of the host lattice, both observed by operando XRD. Altogether we could show that an increased redox activity of the A-site can be linked directly to improved redox chemistry of the surface which leads to better catalytic rWGS performance (i.e. the concentration of surface vacancies for $CO_2$ activation). Additionally, the variation of the B-site doping can further improve the catalytic performance.

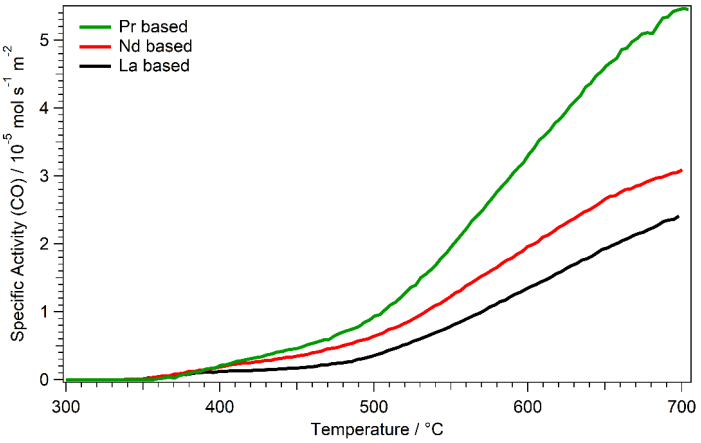

**Figure 1: Comparison of the catalytic rWGS tests of Co-doped perovskites with different A-site cations for increased surface reactivity. The Pr based catalyst proved to be the most active, followed by the Nd and La based.**

**Keywords:** Water Oxidation, Solar Fuels, Redox Catalysis, Molecular Anodes

The search for environmentally benign renewable energy sources as alternatives to the combustion of fossil fuels is a key target considering the continuously increasing energy demands and the consequences of the associated greenhouse gas emissions.[1],[2] Within this context, artificial photosynthesis is one of the most promising solutions. In particular, water splitting with sunlight (h*v*-WS), where sunlight drives the water oxidation to dioxygen (WO) and proton reduction (PR) to hydrogen is the most promising approach.[3] To achieve the design of an efficient and robust artificial device, a catalyst is needed for both processes.

Here, we show a new family of Ru-based oligomeric catalysts that can be anchored on the surfaces of graphitic materials through CH-π interactions between the auxiliary ligands bonded to Ru center and the hexagonal rings of the graphitic surfaces. A combination of spectroscopic, microscopic and electrochemical techniques allows an exquisite molecular control of the catalytic process. The resulting hybrid materials achieved current densities in the range of 0.2-0.3 A/cm$^2$ at neutral pH values, and remarkable long-term stabilities for more than 12 hours towards oxidation of water to dioxygen.[4],[5]

**Introduction.** Chemical transformations with molecular hydrogen ($H_2$) are fundamental pillars of the chemical industry and used across the whole value chain ranging from the production of fuels, fine chemicals, agrochemicals, and pharmaceuticals. Catalysts are essential to control the activation and transfer of hydrogen in particular for the selective conversion of biomass-derived substrates and intermediates. In this context, we have shown that the use of molecularly modified surfaces (MMS) as matrix for the synthesis and stabilization of metal nanoparticles is a versatile strategy to produce multifunctional NPs@MMS catalysts with tailor-made reactivity.[1] While these previously developed catalysts present often outstanding properties regarding their dedicated tasks, their performance is typically optimized to remain static. In a world where flexibility is becoming increasingly important, the design and development of adaptive catalysts - referring here to catalytic systems whose reactivity is reversibly modified upon changes in the reactive environment - is of great interest, but remains difficult.

**Experimental/methodology.** To tackle this challenge, a multifunctional hydrogenation catalyst composed of ruthenium nanoparticles immobilized on an amine-functionalized polymer-grafted silica (Ru@PGS, Figure 1) was prepared.

**Results and discussion.** Using the hydrogenation of biomass-derived furfuralacetone (**1**) as model reaction, we show that when the hydrogenation was performed under pure $H_2$, **1** was completely hydrogenated to give the corresponding saturated alcohol (**1a**). However, when a mixture of $H_2$ and $CO_2$ was used, a sharp change in selectivity was observed, and the ketone was conserved (product **1b**). The change in selectivity – which was not observed for a reference Ru@$SiO_2$ – is presumably due to the formation of alkylammonium formate species coming from the reaction between the amine functionality, $CO_2$ and $H_2$. This process is reversible, allowing switching the feed gas composition back and forth between $H_2$ and $CO_2$ + $H_2$ in continuous flow reactor to produce either the saturated alcohol **1a** or the saturated ketone **1b** in excellent selectivities and yields (Figure 1b-c).[2] This successful example of real-time selectivity switch shows how the combination of functional supports and metal NPs provides a versatile molecular approach to design and produce multifunctional catalytic systems with adaptive reactivity. Further examples and extension of this concept will be reported,[3] including other approaches to real-time and reversible switching of catalyst performance such as magnetically induced local heating.[4-5]

**Introduction.** Developing catalytic systems that combine the benefits of both heterogeneous and biocatalysts allows new approaches to perform highly selective oxidation and hydrogenation reactions. These approaches to combining catalytic systems can allow high regioselectivity, reaction at mild conditions and increased atom efficiency by removing sacrificial reagents or co-factor regeneration steps. Connecting these two different fields of catalysis can be achieved by either i) a tandem cascade system – where reactions happen independently on each type of catalyst at matched rates (Figure 1) or ii) a cooperative mechanism where both catalytic sites are electronically connected to provide sites of complimentary redox half reactions (Figure 2). This contribution will describe our progress in developing tandem systems which utilise *in situ* produced $H_2O_2$ and peroxygenase enzymes for selective C-H/C=C oxidaiton at mild conditions [1,2] and cooperative hydrogenase / metal nanoparticles systems for selective hydrogenation at conditions where traditional precious metal catalysts (Pd/C) become inactive.

**Experimental/methodology –** Heterogeneous catalysts were prepared by previously reported impregnation methods [2] or purchased commercially (e.g Pd/C). Bio-heterocatalytic tests were typically carried out in aqueous phosphate buffered solutions pH 6-8, with low gas pressures (1-3 bar) and substrate concentration 1- 10 mM in stirred glass reactor systems. Analysis was carried out by GC-MS and NMR methods.

**Results and Discussion. *C-H Activation* –** Continuous low-level supply or *in situ* generation of $H_2O_2$ is essential for the stability of unspecific peroxygenases, which are deemed ideal biocatalysts for the selective activation of C–H bonds. To envisage potential large-scale applications of combined catalytic systems the reactions need to be simple, efficient and produce minimal by-products. We show that gold-palladium nanoparticles supported on $TiO_2$ or carbon have sufficient activity at ambient temperature and pressure to generate $H_2O_2$ from $H_2$ and $O_2$ and supply the engineered unspecific heme-thiolate peroxygenase PaDa-I. This tandem catalyst combination facilitates efficient oxidation of a range of C-H bonds to hydroxylated products in one reaction vessel with high selectivity including substrates such as cyclohexane, ethylbenzene, tetralin, and styrene.

***Selective Hydrogenation* -** Here, we explore a new concept in catalytic hydrogenation by combining bio- and heterogeneous chemo-catalysts containing cooperative active sites electronically connected via a conductive carbon support. More specifically, we show how co-immobilising a hydrogenase enzyme with palladium nanoparticles on a carbon support leads to a significant rate enhancement in the hydrogenation of model alkynes. The effect is observed in different pH regimes and buffer systems. On top of increasing the rate, the presence of a hydrogenase was shown to alleviate substrate poisoning of the palladium catalyst and lead to a different product distribution. In this work we demonstrate the benefits of electronically coupling enzymatic active sites to a heterogenous chemo-catalyst via a carbon support to facilitate hydrogenation reactions under low hydrogen pressures.

**Introduction.**
Targeting the increase of activity and selectivity, the reduction in the use of critical raw materials and precious metals, the reduction of the water and carbon footprint of the catalyst production routes requires the exploration of novel catalyst morphologies[1] as well as the optimisation of more sustainable and rational synthesis approaches allowing size, shape and composition tuning.
In this talk, a broad toolbox[2,3] of different wet chemistry and colloidal routes to inorganic systems for heterogeneous catalysis will be presented, which are pooled by low or even room temperature of exercise and processing, use of water or other not harmful solvents, ease of implementation, high yields and polymorphs selectivity, high reprodicibility and potential scalability. Highly controlled synthesis of metal and metal sulphide/oxides nanoparticles, pure and doped oxide supports, supported catalysis can be pursued by these approaches. The exploration of the broad experimental parameters space can be profitably supported by rational approaches such as Design of Experiment[4], dramatically reducing time, raw materials and energy consumption. Examples of application of the prepared heterogeneous catalysts to photocatalysis and emission control catalysis will be presented.

**Keywords:** High-entropy oxides, high-entropy hydroxocarbonates, synthesis, Layered double hydroxide

**Introduction**

High-entropy materials (HEMs) are an emerging field that has expanded well beyond their origins in metal alloys and now include the materials like oxides[1] and carbides[2]. The driving concept for high-entropy materials is similar across all material classes, where the incorporation of multiple elements, their equimolar concentration, and their homogeneous distribution in the structure maximize configurational entropy. High-entropy oxides (HEOs), a subcategory of high-entropy ceramics, are becoming an enticing materials platform for a wide range of applications including catalysis, because of increased stability and unexpected properties arising from lattice distortions and cocktail effects between multiple cations.

Despite the recent interest in HEOs for catalysis,[3,4] HEOs are primarily synthesized by solid-state methods, where there is little control over morphology, porosity, and particle size.[5] As the field of high-entropy oxides is expanding into a wide range of applications like catalysis, synthesis strategies that can control its physical properties are needed.

**Experimental/methodology.**

Different synthesis strategies (hydrothermal and co-precipitation) have been utilized to adapt hydroxocarbonate structures to high-entropy forms, where systematic syntheses for chemistry containing 5 or more cations have been preformed. Special attention is given to cations that have particular interest for catalysis with varying combinations of Al, Mg, Cr, Fe, Co, Zn, Cu, Ni, Ga, In, Y, Ho, Er, Ce, and La cations. This material then serves as a precursor to high-entropy oxides when calcined.

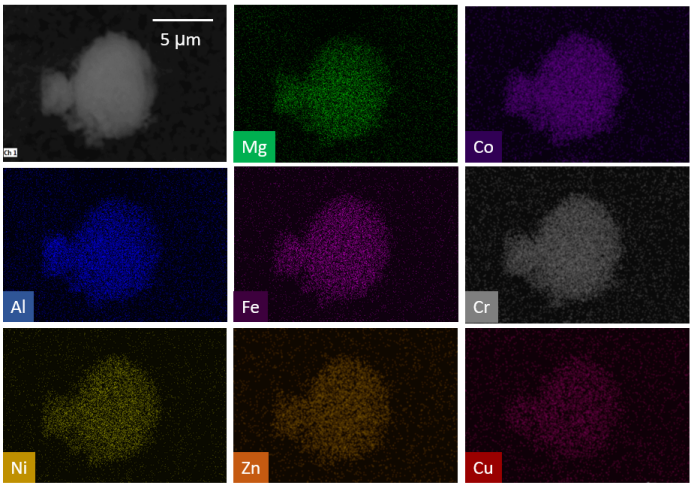

Figure 1: SEM micrograph of high-entropy layered double hydroxide

**Results and discussion.**

The chemistry of high-entropy precursor materials can be tailored by selecting a wide range of cations and cations sizes, and satisfies the criteria for high-entropy classification with 5 or more cations that are homogenously distributed in the structure (Figure 1).[6] High-entropy precursors are then calcined to a high-entropy spinel or rock salt oxide structure and maintain the chemistry, morphology, as well as, some porosity from their high-entropy precursors.

The expansion of high-entropy materials to include tailorable high-entropy precursors is an important step in the development of these materials' use in catalytic applications, thanks to their porosity as well as tailorable surface and bulk chemistry.

**Introduction.** The cobalt-catalysed Fischer-Tropsch synthesis typifies a conversion-efficient chemical process for the synthesis of liquid hydrocarbons from CO. However, the traditional Fischer-Tropsch synthesis is subjected to selectivity limitations for the major products[1]. Here we illustrate that almost atomically dispersed of $SiO_x$-moieties on the surface Co nanoparticles creates a $SiO_x$-Co interface which enhances activity in the Fischer-Tropsch and leads to chemical properties that tune the selectivity in favour of paraffins. Most of all, the inevitable by-production of methane is impeded resulting in a minimal amount of methane (< 4%). Moreover, this modification makes best use of cobalt and increase the turnover frequency (TOF). Such an increase in the TOF may provide the viability of practical applications of these catalytic systems in industry.

**Results and discussion.** Pseudo atomic deposition of silicon on cobalt oxide was performed by contacting cobalt oxide with trimethylchlorosilane (TMCS) in n-hexane at room temperature, followed by calcination at 873K yielding Si modified cobalt oxide. The resulting material was characterized using SEM-EDX, TEM, XRD, TPR, XPS, Raman spectroscopy, and FT-IR. SEM-EXD indicates the homogeneous dispersion of silicon over the oxide surface. Both FTIR and XPS suggest the dispersion of mononuclear Si surface species. Raman spectroscopy shows a low relative intensity of the silicate-sensitive peak which is indicative of the low degree formation of $SiO_2$ on the $Co_3O_4$ nanoparticles presumably due to low concentrations of $SiO_x$ moieties. We show that metal-oxide interface improves the catalytic activity and selectivity of the catalyst in the Fischer-Tropsch synthesis. Turnover frequency (TOF) increases by over 10 folds upon incorporation of $SiO_x$ on the cobalt surface. This change is due to electronic modifications at the $SiO_x$-Co interface which increases the heats of CO adsorption. The change on heat of adsorption favors the dissociation on CO as seen by the increase in the intensity of the high temperature CO-TPD peak.

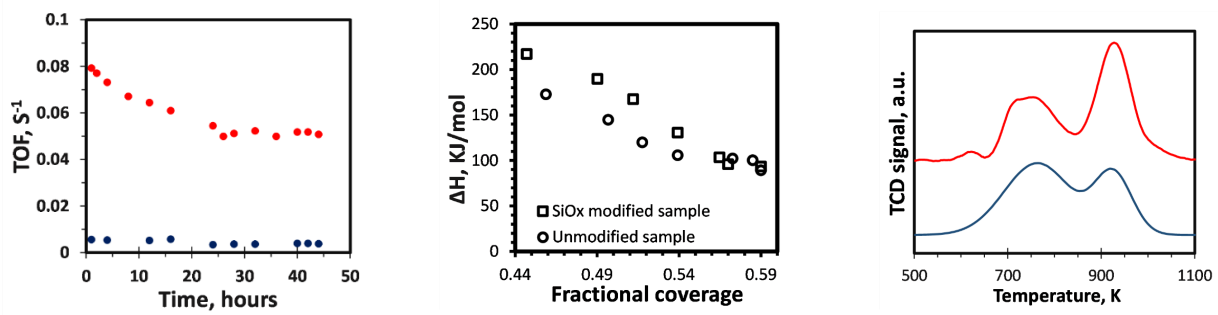

**Figure 1:** Effects of $SiO_x$-Co interface on a) catalytic activity of cobalt TOF as a fuction of time b) change of heat of adsorption of CO with fractional CO coverage and c) CO-TPD profile (red line- modified, blue line – sample)

**Introduction.** Syngas will play an important role during the energy transition to renewables, especially the transformation of $CO/CO_2$ + $H_2$ mixtures obtained either from biogas or $CO_2$ (RWGS). Here, rhodium catalysts are versatile benchmarks. In this work we present a strategy towards the preparation of Rh-containing solid catalysts, which consists in the low-temperature exsolution of Rh species from $ZnFe_{2-x}Rh_xO_4$ mixed oxides with a spinel structure. In a first step, hydroformylation of alkenes was used as a test reaction [1], which is also industrially relevant, but still carried out using Rh-phosphine/phosphite complexes in homogeneous phase [2]. In the recent years the effort has been focused on Rh-containing solids that can emulate the catalytic properties of their homogeneous counterparts [3].

**Experimental/methodology.** A series of nanosized $ZnFe_{2-x}Rh_xO_4$ (x=0-0.2) mixed metal oxides has been prepared by hydrothermal synthesis. Catalytic tests were carried out in stainless-steel batch reactors with a total volume of 12 mL and magnetic stirring ($m_{cat}$: 30 mg, 1.5 mL toluene, 1.5 mmol 1-hexene, 40 bar, $CO:H_2$ 1:1). The materials were activated in the reactor prior to the catalytic tests.

**Results and discussion.** The isomorphic substitution of $Rh^{3+}$ species for $Fe^{3+}$ in the octahedral positions of the $ZnFe_2O_4$ spinel has been successfully achieved by applying a hydrothermal synthesis protocol based on the decomposition of oxalates. Results derived from TPR-$H_2$, *in situ* Raman spectroscopy and *in situ* XRD experiments during activation of $ZnFe_{2-x}Rh_xO_4$ under reducing conditions indicate that activation temperature and time can be tuned to exsolve Rh species in the form of particles smaller than 1 nm, which remain anchored to a spinel-type metal oxide (Figure 1A). Interestingly, this exsolution process takes place at very low temperatures, in the 150-275 °C range. The reduced metal oxides have been tested in the hydroformylation of 1-hexene (Figure 1B). The materials present catalytic properties comparable to the Wilkinson $RhCl(PPh_3)_3$ homogeneous catalyst, especially at low temperatures, where undesired alkene isomerization can be minimized. No Rh leaching is detected, and the catalysts retain their catalytic properties up to 4 uses. The electronic properties of the metal particles were analyzed by DRIFT spectroscopy of adsorbed CO indicating that the spinel forms an unique functional interface.

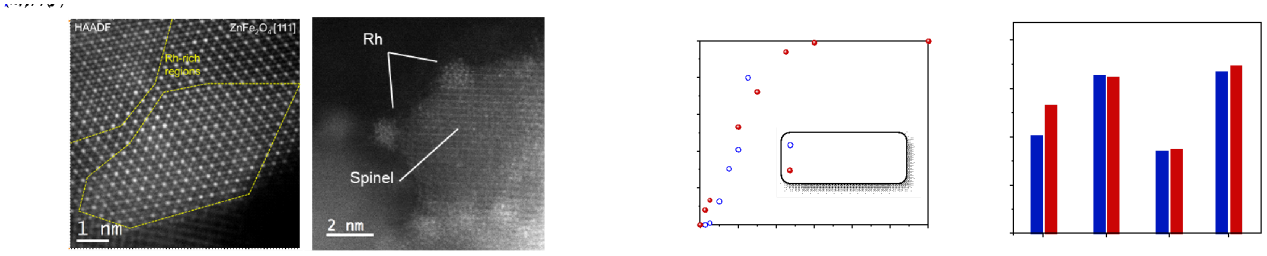

**Figure 1. A) High-Resolution HAADF-STEM images of $ZnFe_{1.8}Rh_{0.2}O_4$ activated in 5% $H_2$ at 275 °C for 1h. B) Catalytic properties in the hydroformylation of 1-hexene for $RhCl(PPh_3)_3$ and activated $ZnFe_{1.975}Rh_{0.025}O_4$ (Rh:1-hexene ratio of 1:500, T=60 °C, 40 bar, $CO:H_2$ 1:1).**

# How can we profit from merging catalysis with photocatalysis?

Wojciech Macyk,* Taymaz Tabari, Joanna Kuncewicz, Marcin Kobielusz, Zbigniew Sojka

*Faculty of Chemistry, Jagiellonian University, Gronostajowa 2, 30-387 Kraków, Poland*

**Keywords:** catalysis, photocatalysis, radical reactions, reactive oxygen species

A fundamental difference between photocatalytic oxidation of pollutants and photocatalytic production of solar fuels should be perceived. Similarly to combustion, oxidation of pollutants is an exergonic process, while water splitting or carbon dioxide reduction are endergonic reactions. In energy downhill processes absorbed light is utilized to overcome the activation energy of elemental steps, *e.g.*, activation of oxygen or C-H bond. The role of photons is therefore to "ignite" the energy downhill reaction. Production of hydrogen from water, or methanol from $CO_2$, are, however, highly endergonic reactions. Photocatalytic production of solar fuels is a process of solar quantum energy conversion to the energy of chemical bonds. In such processes photons can be considered as reagents. This differentiation is crucial to understand a theoretical limit of quantum efficiencies available in these types of processes. In the energy uphill reactions the energy gain (the energy of chemical bonds) originates from the energy of photons. One absorbed photon can generate one $e^-/h^+$ pair which can be used in single elemental reduction/oxidation reactions. Therefore, the limit of the overall quantum efficiency, defined as the number of $e^-/h^+$ redox steps divided by the number of absorbed photons, amounts 1. In the energy downhill reaction the energy evolved in the process can be dissipated as heat (and lost) or can be used to accelerate next elemental, catalytic steps. Taking this into account one can expect the overall quantum efficiency might exceed the unity. In order to facilitate it appropriate catalytic and redox conditions should be provided. A possibility of such reactions, including the design of appropriate catalytic/photocatalytic materials (Figure) will be illustrated and discussed.

**Keywords:** double-atom catalysis, ammonia borane, hydrogen storage

**Introduction.** Single-atom catalysis (SAC) has the advantage of 100% metal utilization and therefore the highest performance per price unit[1]. Besides an optimization in the surface-to-volume-ratio, another optimization is possible by changing the active site. Some chemical reactions are chemically hindered due to lack of potential binding sites. Double-atom catalysis (DAC) has therefore been a long-standing dream for bridging homogeneous and heterogeneous catalysis. Demonstrating the utilization of DAC is best performed in reactions where two reagents are activated. Ammonia borane hydrolysis is such a reaction which allows the activation of ammonia borane and water[2].

**Experimental/methodology.** The SACs and DACs were synthesized with following a wetness impregnation technique. $H_2PtCl_6{\cdot}6H_2O$ was used for the SAC and Di-μ-iodobis(ethylenediamine)diplatinum(II) nitrate (PIP) was used for synthesizing the DAC. They were supported on $CeO_2$ cubes, which were synthesized hydrothermally. The catalytic experiments were performed in a home-built set-up which is efficient in analyzing gas-ouput streams. Ammonia borane was dissolved in water and water was used both as substrate and as a solvent.

**Results and discussion.** Here we show the thermoconversion of ammoniaborane hydrolysis. The DAC showed a significant improvement in activity compared to the SAC. CO-DRIFTS measurements confirmed a quantitativly similar amount of platinum on the surface. Moreover, XPS measurements showed that the oxidation state of the platinum atoms was the same. This implies that other effects contribute as well to the higher turnover number. Surprisingly, the mechanism of the reaction is the same according to the Arrhenius plot. No discrepancies in the metal-support interactions for the SACs and DACs are possible as the surface structure of each $CeO_2$ particle is the same.

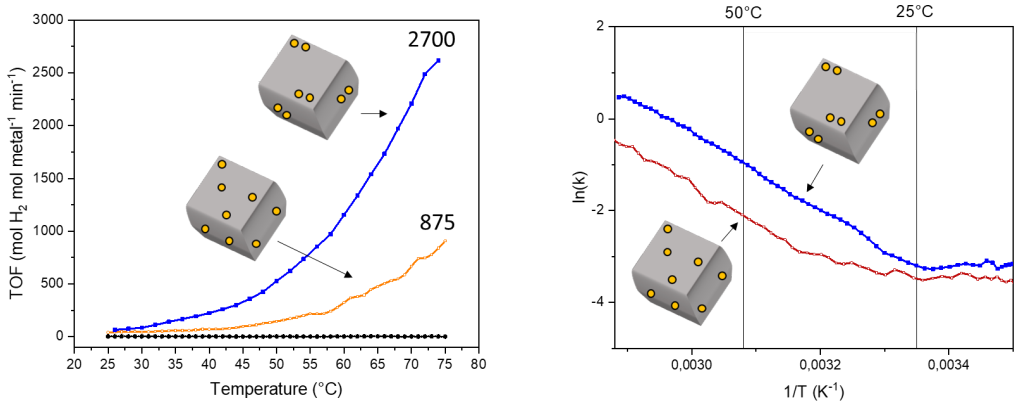

**Figure 1 – ammonia borane hydrolysis over SACs and DACs. An increased performance was observed for DACs, while the mechanism was the same.**

# Mn-promoted $MoS_2$ as a catalyst for $CO_2$ hydrogenation to methanol: Investigating the interaction between $MoS_2$ and Mn oxides

G. A. S. Alves*, G. Pacholik, T. Wagner, S. Pollitt, M. Latschka, R. Rameshan, C. Rameshan, K. Föttinger [1]

[1]*Institute of Materials Chemistry, Technische Universität Wien, Vienna, Austria*
**gustavo.alves@tuwien.ac.at*

**Introduction.** With the ongoing scenario of anthropogenic climate change, the capture and utilization of $CO_2$ has been increasingly considered as an alternative starting point for the production of a variety of value-added products, such as alcohols and hydrocarbons. In this context, the direct hydrogenation of $CO_2$ into methanol has been most effectively performed using $Cu/ZnO/Al_2O_3$ catalysts, but the applicability of this material at industrial scales is still limited by its low selectivity to methanol, instability of the active phase and surface poisoning in the presence of sulfur-containing gasses. [1]
Because of these constraints, non-metallic catalysts such as $MoS_2$ might offer a promising alternative due to their high stability and tolerance to sulfur. Pure $MoS_2$ is typically selective towards $CO_2$ hydrogenation to methane, although some promoters have been shown to induce CO production instead. [2] In this work, we demonstrate that Mn-promoted $MoS_2$ can work as a selective catalyst for methanol production from $CO_2$ hydrogenation as a result of the interaction between $MoS_2$ and Mn oxides.

**Experimental/methodology.** Mn-promoted $MoS_2$ was produced by a hydrothermal method. Ammonium heptamolybdate, thiourea and manganese sulfate were heated in an autoclave with water at 200 °C overnight. The precipitated sulfides were filtered and repeatedly washed with water and ethanol. The powder was dried in vacuum at room temperature, followed by calcination at 400 °C under inert gas.
Material characterization was carried out via X-ray diffraction (XRD), in-situ Near-Ambient Pressure X-ray Photoelectron Spectroscopy (NAP-XPS), Extended X-ray absorption fine structure (EXAFS) and Scanning Electron Microscopy (SEM). Catalytic testing took place with 1g of catalyst in a fixed bed reactor at 21 bar under flow of 1 mL/min $CO_2$, 3 mL/min $H_2$ and 1 mL/min He. Prior to each reaction, catalysts were activated at 400 °C under pure $H_2$. Reaction products were evaluated by gas chromatography.

**Results and discussion.** Mn-promoted $MoS_2$ produced via hydrothermal method was shown to present favorable properties as a catalyst for $CO_2$ hydrogenation to methanol. Although $MoS_2$ is typically selective towards methane in the presence of $H_2$ and $CO_2$ above 180 °C, the addition of Mn precursors to the hydrothermal synthesis of $MoS_2$ switches catalyst selectivity towards methanol. Interestingly, the highest methanol yield is achieved at temperatures below 200 °C. This enhanced activity under mild conditions may offer promising possibilities for industrial application, given the economical advantage of utilizing lower temperatures.
Material characterization by XRD, EXAFS and in-situ XPS shows that the manganese promoter is initially present as $MnCO_3$, which is converted to bulk MnO with a combination of surface Mn(II) and Mn(III) species after $H_2$ pretreatment. This composition is maintained at low temperature reaction conditions (< 200 °C), as higher reaction temperatures promote the carbonation of MnO into $MnCO_3$, compromising catalytic activity. Therefore, the results indicate that the synergy between $MoS_2$ and manganese oxides may be a key factor for the high methanol selectivity during $CO_2$ hydrogenation.

# Resolving the enhanced performance of Mn modified spinel based $CO_2$ methanation catalysts by combining *ex situ* and *operando* analysis

T. Franken[1*], D. Weber[1]

[1] *Friedrich-Alexander-Universität Erlangen-Nürnberg, Institute of Chemical Reaction Engineering, Group of Catalytic and Electrocatalytic Systems and Processes, 91058 Erlangen, Germany*

[*] *tanja.franken@fau.de*

**Keywords:** Spinel catalysts, *operando* Analysis, $CO_2$ methanation, $H_2$-spillover, selectivity enhancement

**Introduction.** $CO_2$ methanation with renewable $H_2$ from water splitting is a future relevant technology to limit $CO_2$ emission, close C-circles and enable chemical energy storage. Herein gaining high $CH_4$ selectivity is essential. Due to oxidation and deactivation Ni based catalysts tend to produce CO as an undesired by-product. This effect is even more pronounced if Co is used as the active sites. Within our contribution we resolve how Mn modified spinel based catalysts yield a superior performance over conventional supported $Ni/Al_2O_3$ catalysts and what properties lead to their strong improvement in $CH_4$ selectivity.

**Experimental/methodology.** Catalysts have been prepared by coprecipitation of the corresponding metal nitrates at a constant pH of 9 and were subsequently filtered, washed and calcined at 800 °C. The catalytic performance was investigated in fixbed flow reactors. Furthermore, catalysts were characterized by XRD, TPR, $CO_2$-TPD, $H_2$ & CO chemisorption, $CO_2$ DRIFTS and *operando* DRIFTS analysis.

**Results and discussion.** Dependent on the degree of Mn modification in both $NiMn_xAl_{2-x}O_4$[1] and $CoMn_xAl_{2x}O_4$[2] spinel systems a strong increase in activity and $CH_4$ selectivity was observed at intermediate Mn modification levels of x = 0.375 and x = 0.5, respectively. Both systems show good long term stability. The effect of enhanced $CH_4$ selectivity is much more pronounced for the Co-based system. By combing several *ex situ*, *in situ* and *operando* analytics we resolved the effect for the Co based spinel. *Operando* DRIFTS analysis suggests, that the reaction mechanism changes from a purely CO intermediate mechanism on Co based catalysts, towards a formate intermediate mechanism on the Mn modified catalysts. The change of reaction mechanism is the main reason for the strongly improved $CH_4$ selectivity. Obviously, due to Mn modification spillover of H from the metallic sites onto the surface of the full supporting spinel surface gets possible. Together with the stronger basic sites in the Mn modified spinels and the fine distribution of Co sites within the spinel $CO_2$ gets activated on the full surface of the supporting spinel. Therefore the catalytically active surface is enhanced from the metallic sites only towards the fully available specific surface area of the preactivated spinels. To conclude our contribution presents a novel approach to design catalysts based on mixed metal oxides, that can be tuned for high selectivity and activity thanks to cooperative effects and the high dispersion of elements within common crystalline structures.

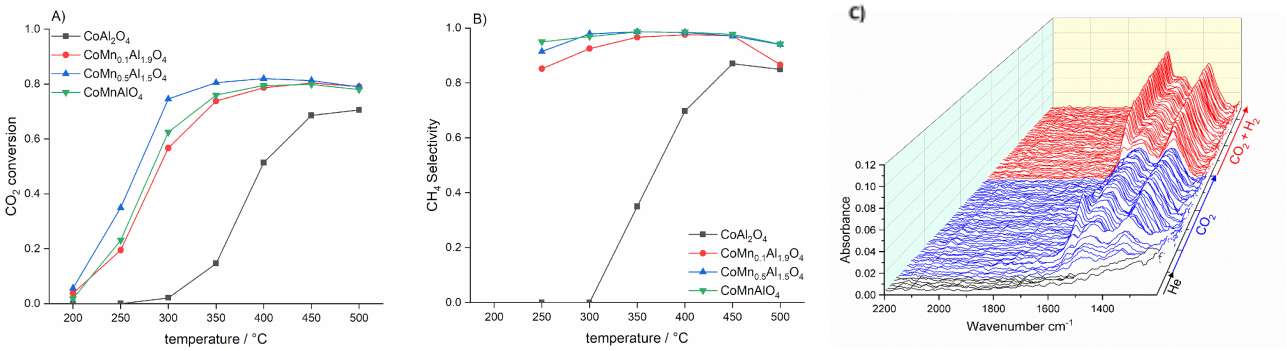

**Figure 1: A) Conversion and B) Selectivity of activated Mn modified CoAl-Spinels in the methanation of $CO_2$ C) Time resolved *operando* DRIFTS spectra under $CO_2$ Methanation conditions.**

**Keywords:** $CO_2$ Capture, Amine, Catalysis, $ZrO_xH_y$, Acid-base catalysis

**Abstract:**

$CO_2$ post-combustion with amine solution is one of the most "ready-to-use" $CO_2$ capture technics for the transition period from a traditional fossil-based society to a carbon-neutral society. However, the high energy cost of the primary amine regeneration process is one of the pain points for the application. Many catalysts have been developed to solve this problem. However, they are not efficient enough for real applications and are mostly tested in a batch reactor, which is very different from the continuous stripper used in the industry. Herein, we report a highly efficient $ZrO_xH_y$ catalyst, for $CO_2$ desorption from amine solution. Through the kinetic study results, $ZrO_xH_y$ shows a 2.5 times improvement on the $CO_2$ desorption rate constant ($k_{CAT}$) compared with blank in 30 wt% MEA solution in the batch reactor, with good recyclability. This great catalytic improvement is not especially for MEA solution but is also observed in other amines, like 2-Amino-2-methyl-1-propanol (AMP). By combining the kinetic study results and spectroscopic techniques, we found a volcano relationship between $k_{CAT}$ and the terminal /bridge hydroxyl group ratio, where $k_{CAT}$ reached the top at a terminal/ bridge hydroxyl group ratio close to 1. Based on that observation, an acid-base synergy mechanism is proposed in Figure 1. The mechanism is further proved through the operando ATR-FT-IR. To bring this work one step closer to the industrial condition, $ZrO_xH_y$ is also tested with a self-built fix-bed continuous reactor. By using $ZrO_xH_y$, a 3.5-fold $CO_2$ desorption rate is achieved under a much shorter (~1/4) contact time compared with blank, showing a more promising prospect for industrial applications.

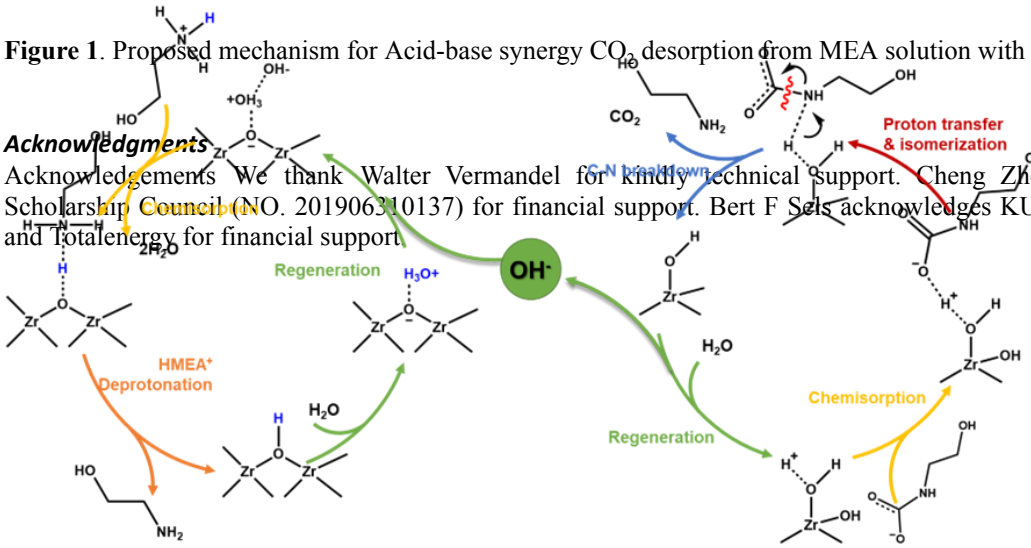

**Figure 1**. Proposed mechanism for Acid-base synergy $CO_2$ desorption from MEA solution with ZrOxHy.

**Keywords:** Catalysis, exsolution, $CO_2$ utilisation, light olefins

**Introduction:** Conversion of $CO_2$ into valuable chemicals and fuels provides a good solution to mitigate the ever-growing worldwide $CO_2$ emissions. Various approaches have been considered for $CO_2$ conversion, among which the thermocatalytic conversion of $CO_2$ by hydrogenation seems to be very promising due to the diversity of the products that can be produced.[1] However, challenges for this process include the design and preparation of catalysts that can promote activity and product selectivity without compromising stability. It is known that copper (Cu), cobalt (Co) and iron (Fe) are being used in industry to produce fuels and chemicals by $CO_2$ hydrogenation but easily get deactivated by agglomeration or poisoning.[2] Recent studies demonstrated that catalytically active transition metals substituted on B site of A-site deficient perovskite oxides ($A_{1-x}BO_3$) can emerge on the surface of the perovskite under reducing conditions in the form of metallic nanoparticles. This method is called exsolution and the particles produced are resilient to coking and agglomeration while having increased activity.[3] In this work, six perovskites with exsolved Fe-X (X= Cu, Co) metallic nanoparticles were explored for the $CO_2$ hydrogenation and show remarkable activity and stability as compared to their traditionally prepared analogues.

**Experimental:** A modified solid state synthesis method was used to synthesize two families of materials with high ($La_{0.5}Sr_{0.3}Ti_{0.7}Fe_{0.3}O_{3-\delta}$, $La_{0.6}Sr_{0.2}Ti_{0.7}Fe_{0.2}Co_{0.1}O_{3-\delta}$, $La_{0.6}Sr_{0.2}Ti_{0.7}Fe_{0.2}Cu_{0.1}O_{3-\delta}$) and low doping ($La_{0.43}Sr_{0.37}Ti_{0.94}Fe_{0.06}O_{3-\delta}$, $La_{0.43}Sr_{0.37}Ti_{0.94}Fe_{0.04}Co_{0.02}O_{3-\delta}$, $La_{0.43}Sr_{0.37}Ti_{0.94}Fe_{0.04}Cu_{0.02}O_{3-\delta}$), to investigate the effect of doping amount on the extent of exsolution and the amount of active sites on the surface.[4] To exsolve particles, reduction of the synthesized materials was carried out in a controlled atmosphere furnace, under continuous flow of pure $H_2$ at a range of temperatures (700- 900$^{o}$C) for 10h. The crystal structure and the purity of the exsolved samples were studied using powder X-ray diffraction (XRD). The morphology of the materials was obtained using scanning electron microscope (SEM, APREO 2). $CO_2$ hydrogenation was conducted in a continuous fixed bed quartz reactor using 0.25g of catalyst. The activity test was conducted at Weight Hourly Space Velocity (WHSV) 12 L/g.h with $H_2/CO_2$ ratio of 3:1 balanced in nitrogen. The reaction temperature varied between 250 $^{o}$C and 350 $^{o}$C in 10 $^{o}$C intervals for 30 min at each temperature. Reactants and products were monitored using gas chromatography (micro-GC equipped with thermal conductivity detector).

**Results and discussion.** The XRD patterns of the as-prepared materials clearly showed that both low and high doping of monometallic and bimetallic dopants were successfully incorporated into the perovskite structure. The particle size and distribution were analysed via ImageJ from the SEM images obtained at different temperatures. Catalytic results showed that the addition of a second metal (i.e. Co, Cu) has a strong influence in the selectivity of the materials owning to both the different exsolution characteristics and the chemistry of the active sites.

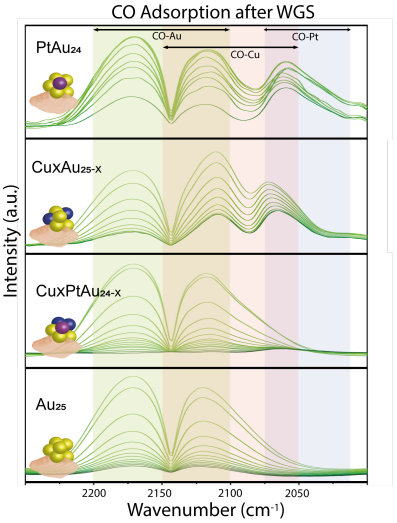
# Synergetic effect of Pt,Cu and Au in metal nanoclusters on $CeO_2$ as atomically precise active sites for WGS reaction: structural dynamics by *operando* XAFS and DRIFTS studies



Nicole Müller, Rareș Banu, Adea Loxha, Lorenz Lindenthal, Florian Schrenk, Noelia Barrabés*

*noelia.rabanal@tuwien.ac.at*

**Introduction.** A major route to obtain clean-energy hydrogen is the catalytic water-gas shift (WGS) reaction. Particle size/structure and metal-oxide interface have been shown to be critical for operation at mild conditions with high activity and selectivity in WGS. Therefore, understanding and controlling catalytic performance at the molecular level is essential for optimal catalyst design. Thiolate protected gold nanoclusters represents a new approach involving novel nanostructures with key atomically controllable parameters. Over the last years, we were able to develop mono- and bimetallic nanoclusters catalysts, tuning their properties with atomic precision and understanding the structure dynamics under reaction conditions by *operando* infrared (IR) and x-ray absorption spectroscopic (XAFS) studies [1-5]. The synergistic effect at the atomic level of Cu, Pt, and Au in terms of activity and selectivity in the WGS reaction was investigated using mono-, bi- and tri-metallic nanoclusters supported on $CeO_2$ as catalysts.

**Experimental/methodology.** Atomically precise mono- ($Au_{25}(SR)_{18}$), bi- ($PtAu_{24}(SR)_{18}$; $Cu_xAu_{25-x}(SR)_{18}$) and trimetallic ($Cu_xPtAu_{24-x}(SR)_{18}$) nanoclusters were synthesized, isolated and characterized by UV-Vis and MALDI-MS, based on previous experience [1-5].The trully monodispersed clusters were supported on $CeO_2$. The cluster catalysts were pretreated by a combined oxidation/reduction process prior to the water gas shift reaction in a continous flow reactor set-up coupled with online with GC and MS analysis. The correlation between the catalytic activity and the structural dynamics under reaction conditions was studied by *operando* DRIFTS and XAFS (Au $L_3$-edge and Cu K-edge) experiments. Further CO-FTIR experiments were perfomed to complement the surface characterization.

**Results and discussion.** The kinetic studies with the nanocluster catalysts ($PtAu_{24}$, $Cu_xAu_{25-x}$ and $Cu_xPtAu_{24-x}$) showed an enhancement of the catalytic activity by shifting the reaction onset to lower temperatures compared to pure Au nanocluster catalysts. Whereas the XAFS analysis at the Au $L_3$-edge showed the stability of the cluster structure without sintering of the particles during reaction conditions; Cu K-edge together with the IR-CO results revealed the migration of Pt and Cu metal atoms within the cluster. The Pt atom, originally located in the inner core of the cluster, migrated to the surface creating a single atom site, which is stabilized by the Au core cluster structure. In the case of Cu atoms, monodisperse atoms/small clusters form on the Au cluster surface during pretreatment but develop into Pt-Cu and Cu-Au nanoalloy sites in the case of trimetallic nanoclusters during the reaction. Therefore, bimetallic nanoclusters evolved into stable single site in the case of Pt and small cluster with Cu, that increase their catalytic activity in the WGS and show long stability under reaction conditions. However, in the case of the trimetallic clusters, a continuous evolution of the metal species is obseved, which also affects their catalytic performance. Understanding the dynamics of cluster catalysts at the atomic level is important information for the design of optimcal active cluster sites.

**Keywords:** Nanoclusters, Assembling, Catalysis

**Introduction.** At the core of our research is a unique method for breaking bulk metals down to single metal atoms (SMA) and then reassembling them to nanoclusters (MNC) size with precise size and chemical composition.[1,2] In this way we can provide a solution for a sustainable use of scarce metals of technological importance (e.g. Pt, Au, Pd), by maximising utilisation of every atom, and to unlock new properties that emerge in metals only at the atomic scale, leading to substituting critical metals with abundant ones, and providing a platform for next generation of materials for catalysis.

**Results and discussion.** In this work, we will show how we disassemble bulk materials into single atoms and then to keep them as single atoms or reassemble them to nanocluster size in liquid media and powder surfaces and their catalytic applications. Using ionic liquid media as 'support', we have created Pd nanoclusters that combine the features of both heterogeneous and homogeneous catalysts. We determine the atomic structures and electronic environments of a series of metal nanoclusters in ionic liquids at different stages of formation, leading to a discovery of Pd nanoclusters with a core of ca. 1.8 nm surrounded by a diffuse dynamic shell of atoms in $[C_4C_1Im][NTf_2]$. Comparison of the catalytic activity of Pd nanoclusters in alkene cyclopropanation reveals that the atomically dynamic surface is critically important, increasing the activity by a factor of ca. 2 when compared to compact nanoclusters of similar size. Additionally, kinetic studies of cyclopropanation of alkenes mediated by the dynamic Pd nanoclusters revealed an observed catalyst order of 1, underpinning the pseudo-homogeneous character of the dynamic Pd nanoclusters. Using a solid powder, we have atomically dispersed and stabilized Pt atoms on *g*-$C_3N_4$ using a scalable, ligand-free, whithout allow them to assembly to MNCs. The deposition of Pt on *g*-$C_3N_4$ improved hydrogen production *ca.* 370 times (5 h reaction) when compared to bare *g*-$C_3N_4$, thus demonstrating a high activity compared to other reported systems. We ascribe its high photocatalytic activity to the highly dispersed naked Pt species on *g*-$C_3N_4$, and due to electron-hole pair recombination decrease, thus enhancing the hydrogen evolution.

**Keywords:** Iron-oxide clusters, Copper-oxide clusters, Alumina support, Synergistic effect, Low temperature, Total catalytic oxidation, Toluene

**Introduction.** Catalytic oxidation is one of the most important processes for removing of low concentration volatile organic compounds (VOCs) from industrial waste gases. [1] Transition metal nanoparticles immobilized on a suitable support are low-cost alternative to currently used noble metal-containing catalysts. [2,3] A synergistic effect was observed in some cases over bimetallic transition metal supported catalysts that enhanced their total oxidation activity at lower temperature in comparison to monometallic ones. [2,3] To study the mentioned phenomenon, CuFe-functionalized γ-alumina was designed. Namely, alumina is one of the most commonly used industrial catalyst supports because it is easily scalable and cost-effective.

**Experimental/methodology.** Cu-Fe functionalized alumina supports synthesized from ammonium dawsonite ($NH_4AlCO_3(OH)_2$) precursor with different Fe loadings (from Fe/Al=0.005 to Fe/Al=0.05) and constant Cu loading (8 wt.%) were prepared using a two-step synthesis approach. Structure-property-activity relationship of bimetal CuFe-γ-alumina catalyst for the gas-phase total oxidation of toluene as a model VOC at lower temperature (200–380 °C) was studied. A fundamental understanding of the catalyst and the reaction mechanism is elucidated by advanced microscopic (AR TEM) and spectroscopic characterizations (NMR, XAS) as well as by temperature-programmed surface techniques ($H_2$-TPR, TPD-$O_2$ TPD/R-toluene, pulsed toluene oxidation reaction).

**Results and discussion.** By rational design of bimetal CuFe-γ-alumina catalyst, synthesized from dawsonite alumina precursor, the activity in total oxidation of toluene as a model VOC at lower temperature (200–380 °C) is achieved. It was found out that the nature of the metal-support bonding and the optimal abundance between Cu-O-Al and Fe-O-Al species in the catalysts leads to synergistic catalytic activity promoted by small amounts of iron (Fe/Al=0.005). The change in the metal oxide-cluster alumina interface is related to the nature of the surfaces to which the Cu atoms attach. In the most active catalyst, the $CuO_6$ octahedra are attached to 4 Al atoms, while in the less active catalyst they are attached to only 3 Al atoms. The oxidation of toluene occurs via the Langmuir-Hinshelwood mechanism. The presented material introduces a new family of low-cost and scalable oxidation catalysts with superior efficiency at lower temperatures. Understanding the structure-property-activity relationship of the designed bimetallic oxide catalysts on alumina support is extremely important not only for the described targeted application for air pollution prevention, but also for other applications in heterogeneous catalysis, green chemistry, advanced manufacturing, and furthermore in electrocatalysis and photocatalysis.

# Highly-porous conjugated polyelectrolytes for water absorption and visible light photocatalysis

Sebastijan Kovačič,* Sarah Jurjevec, Tomaž Kotnik, Gregor Žerjav, Albin Pintar

National Institute of Chemistry, Hajdrihova 19, 1001 Ljubljana, Slovenia E-mail: sebastijan.kovacic@ki.si

**Introduction**. Powdered semiconducting oxides (e.g. $TiO_2$ or ZnO) are certainly the most widely used solid photocatalysts in heterogeneous photocatalysis, as these materials are cheap and efficient in converting water pollutants to $H_2O$ and $CO_2$. However, fast recombination of charge carriers, the form factor (i.e., powders) and the inability to absorb in the visible light range severely limit their practical use. Porous conjugated polyelectrolyte polymers (CPeP) exhibiting attractive properties such as high porosity, extensive π-conjugation with visible light activity, and polyelectrolyte character have recently emerged as an interesting alterantive and have attracted much attention for various applications such as heterogeneous photocatalysis, $CO_2$ capture or absorption.[1],[2]

**Experimental/methodology.** In this study, various poly(aryleneethynylene; PAE)-based CPeP were synthesised by Sonogashira-Hagihara polycondensation of 1,3,5-triethynylbenzene and various iodinated benzene derivatives as building blocks, using high internal phase emulsions as templates for porosity.[3] In addition to Sonogashira-Hagihara reaction, emulsion templated poly(arylene-cyano-vinylene) and poly(imine) networks have been synthesized using Knoevenagel [4] or Schiff base [5] condensation reactions. The conjugated foams were characterized in detail by solid-state NMR and FTIR spectroscopy, elemental analysis, diffuse reflectance spectroscopy (DRS), photoluminescence (PL), and cyclic voltammetry (CV). Finally, their photocatalytic performance was evaluated using a fluorescent probe molecule technique.

**Results and discussion.** The resulting highly porous CPeP exhibited significant semiconducting properties in the visible light region due to their π-extended poly(aryleneethynylene) backbone with donor-acceptor character and optical band gaps in the range of 1.70-2.35 eV. Coumarin and $ABTS^{-+}$ were used as probe molecules to image the oxidation and reduction activity within the π-conjugated system of the PAE-based polyHIPE network. The ability of PAE-based polyHIPE to photo-degrade water pollutants was demonstrated by the degradation of the endocrine disrupting component bisphenol A (BPA) dissolved in water under visible light.

# Deciphering the Mechanism of Crystallization of MIL-53 and UiO-66 Metal-Organic Frameworks

Olesya Semivrazhskaya,[1] Daniil Salionov,[2] Adam Clark,[2] Nicola Casati,[2] Maarten Nachtegaal,[2] Marco Ranocchiari,[2] Saša Bjelić,[2] René Verel,[1] Jeroen van Bokhoven[1,2], Vitaly Sushkevich[2,*]

**Introduction.** Metal-organic frameworks (MOFs) have been studied in depth by chemists and material scientists because of their tunable adsorption and (electro) catalytic properties as well as diversity of discovered topologies. However, after more than twenty years of research, understanding of mechanisms of their nucleation and growth is still lacking, hence hindering further progress in reproducible synthesis and modulating the size and shape of the crystals, targeted for scale-up. The present work introduces a detailed molecular-level mechanism of the formation of Al-containing MIL-53 and Zr-containing UiO-66 MOFs, unraveled by combining *in situ* time-resolved mass spectrometry, XAS, MAS NMR spectroscopy, and PXRD. We show for the first time how the MOF topology alters the crystallization mechanism by manipulating chemical reactions responsible for both nucleation and growth.[1,2]

**Results and discussion.** We show that the formation of MIL-53 starts with deprotonation of terephthalic acid, which is required to coordinate aluminum cations, forming various adducts comprising aluminum, terephthalate, hydroxyl, and nitrate fragments. The released protons induce the decrease of pH and hydrolysis of N,N-dimethylformamide to dimethylamine and formate species. The latter interact with aluminum and incorporate into aluminum-terephthalate adducts. The nucleation process starts after achieving the maximal concentration of deprotonated terephthalate in the mixture. The formate anions incorporate into nuclei with a rate similar to the terephthalate one. The complete consumption of terephthalic acid from the solution terminates nucleation and launches the crystallization phase of MIL-53. During this stage, the agglomeration of nuclei occurs, accompanied by the release of monomeric species to the solution, demonstrating that, in contrast to the general belief, a solid-solid crystallization mechanism is in action. Notably, formate species preserve in MIL-53. At the end of crystallization, the soluble $[(CH_3)_2NH_2]_x(NO_3)_x$ salts are found as the main by-products.[1]

The synthesis of UiO-66 is initiated by the autocatalytic formation of soluble zirconium chloroterephthalates via exchange reaction, with the gradual increase of the number of terephthalate linkers in the zirconium coordination environment. The pre-formation of $[Zr_6(OH)_4O_4]$ nodes was not confirmed. A by-product of the exchange reaction is HCl, which accumulates in the solution, leading to a decrease in pH and the formation of a spectroscopically distinct DMF···HCl adduct. This adduct undergoes hydrolysis, leading to free formate species and dimethylammonium chloride. In turn, after reaching ~20% of terephthalate exchange with zirconium chloride, the hydrolysis leading to the formation of the first nuclei starts. This process implies the rapid solution-mediated formation of the $[Zr_6(OH)_4O_4]$ nodes, with no stable sub-stoichiometric zirconium-oxo clusters being detected. The terephthalate linker becomes a part of the nuclei, while formate species formed by hydrolysis of DMF remain intact in the solution, in contrast to Al-containing MIL-53. The nuclei are structurally identical to the secondary building units of UiO-66; however, they lack long-range order, which they gain during growth. Crystal growth represents the rate-limiting step in UiO-66 crystallization, with nucleation proceeding almost 10 times faster, leading to many small crystals with a narrow size distribution of about 200 nm. The synthesis of the MOF ends with the stabilization of pH, complete consumption of Zr precursors from the solution and absorption of residual water and HCl by the pore system of UiO-66.[2]

# Tuning the Au nanocluster catalyst activity in the selective alkyne semihydrogenation reaction: ligand and support effect

Noelia Barrabés[1,*], Rareș Banu[1], Jesus Mengual,[2] Eduardo Palomares[2], Fernando Rey[2]
[1]*TU Wien, Institute of Materials Chemistry, Vienna, Austria*
[2] *ITQ - Universitat Politècnica de València -(UPV-CSIC), Valencia, Spain*
[*]*noelia.rabanal@tuwien.ac.at*

**Introduction.** The semihydrogenation of alkynes is of particular interest due to its importance in the production of fine chemicals and polymers. An efficient catalyst that can selectively convert alkynes to alkenes without overhydrogenation to alkanes is needed to remove trace amounts of alkynes before the alkene polymerization process or to convert alkynes to fine chemicals. Recently, gold catalysts is appearing as an alternative related to its lower reductive ability in comparison to Pd, reporting exceptional selectivity and high activity [1]. In order to understand the correlation of the activity and selectivity with structural properties of the catalysts, atomically precise and controlled nanocatalyst is required. Heterogeneous catalytic research of atomically precise gold nanoclusters is an emerging field opening new opportunities for accurate studies of size-dependent properties, atomic structure effects and reaction mechanisms in catalysis. In our previous works, operando XAS and IR measurements have revealed the strong influence of the cluster structure, ligand configuration and support material on their stability and reactivity[2-4]. Therefore, the synergistic effects between the cluster size/structure, the nature of the ligand and the surface area as well as the acid/base properties of the support on the catalytic activity and stability of the supported clusters were investigated in the alkyne semihydrogenation reaction in order to optimize their catalytic performance.

**Experimental/methodology.** We investigated two different ligand-protected gold nanoclusters (thiolate-protected ($SC_2H_4Ph$) $Au_{25}$ and phosphine-protected ($PPh_3$) $Au_{11}$) in the selective hydrogenation of phenylacetylene to styrene.[5] Alumina with acidic properties, MgO with basic properties, and Mg/Al hydrotalcite (HT), a layered material with an intermediate basicity, were used as support materials. The correlation between the catalytic activity and the structural dynamics and the support properties effect under reaction conditions was studied by DRIFTS, XPS and XAFS studies.

**Results and discussion.** Strong differences in activity and selectivity were found depending on the cluster-ligand configuration and also on the nature of the support. To determine the influence of the ligand, the catalysts were tested without pretreatment and with pretreament prior to the reaction, where the catalytic activity decreased in the phosphine-protected clusters, while high activity and selectivity was obtained with the thiolate-protected clusters (Fig.1). Preliminary analysis of the spectroscopic studies disclosed the different interaction at the interface between the cluster and the oxide surface depending on the acid-base properties, in agreement with the catalytic behaviour, directing the catalytic performance.

# MAX phase as an efficient heterogeneous catalyst for nitrostyrene chemoselective hydrogenation

Iuliana M. Chirica,[1, 2] Mihaela M. Trandafir,[1] Florentina Neatu,[1] Stefan Neatu,[1] Andrei Kuncser,[1] Varun Natu,[3] Michel W. Barsoum,[3] Mihaela Florea[1],[2*]

**Introduction.** When a molecule contains multiple functional groups, it can be difficult to catalyze the hydrogenation of a single functional group due to the fact that the thermodynamic driving factors are similar. Scientists have developed solid catalysts that selectively interact with one functional group without affecting the others through hydrogenation to solve this issue.[1] MAX phases are well-known for their unusual metal and ceramic properties and numerous investigations on other properties have been undertaken so far. In spite of possessing the necessary qualities for such processes, their potential application as catalysts or as support for catalytic active species had been largely neglected until recently. [2]

**Experimental/methodology.** Here, we demonstrate how MAX phase can be used to catalyze the chemoselective hydrogenation of a nitro group from functionalized nitroarene, such as 4-nitrostyrene (4-NS) (Figure 1) and 3-nitrostyrene (3-NS). Hydrogenation of these molecules yields functionalized aniline derivatives, which are essential intermediates for a wide variety of chemicals with significant industrial applications [3]. Except for our study, no MAX phase-catalyzed or MAX-supported hydrogenation processes have been reported yet.

**Results and discussion.** This research indicates that MAX phase materials made of $Ti_3SiC_2$, $Ti_2AlC$, or $Ti_3AlC_2$ may chemoselectively hydrogenate 4-NS to 4-AS (4-aminostyrene) with a complete selectivity (100%), but at a relatively modest conversion rate (less than 4 %). In order to maintain its preferential selectivity and improve the conversion, MAX phase was used as support for various Pd loadings. Based on the data obtained, it is clear that the appropriate Pd content/dispersion onto selective support is crucial, and that exceeding this amount diminishes the MAX phase's selective effect, potentiating only the non-selective effect of Pd [4]. Another essential point in chemoselective hydrogenation reactions is the adsorption and activation of $H_2$, which takes place differently function of the Pd dispersion. A sample with an extremely low Pd loading (130 ppm Pd, for example) converted 100% of 4-NS with a selectivity of 93% of 4-NS, while increasing the Pd loading resulted in a decrease in selectivity. Furthermore, we improved the turnover frequency by a factor of 100 in comparison to earlier studies in the literature by adjusting the Pd loading (Figure 1). This is achievable by the presence of a large number of metals, most likely as single atoms, which heterolytically activate the $H_2$ in $H^+/H^-$ pairs, favoring the hydrogenation of polar groups (such as nitro) over non-polar ones [1]. Modified MAX phases were found to be highly efficient and chemoselective, and their development has far-reaching implications for developing low-cost, abundant, environmentally safe metal catalysts.

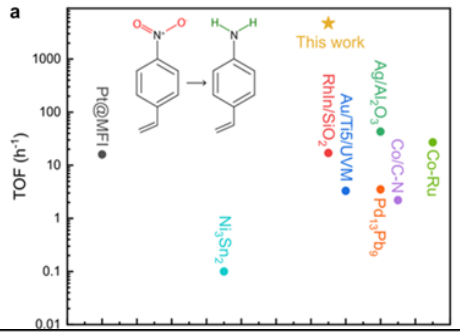

**Figure 1**: a) TOF results compared with some of the highest reported in the literature for catalysts with 100% conversion and > 80% selectivities of 4-NS to 4-AS.

# Ethanol dehydration over hybrid aluminosilicate catalysts prepared by non-hydrolytic sol-gel: One-pot synthesis vs. Surface grafting

Lucie Leonova[1], Zdenek Moravec[1], Petr Sazama[2], Jana Pastvova[2], Damien P. Debecker[3], Ales Styskalik[1*]

**Keywords:** Ethanol dehydration; Aluminosilicate; Non-hydrolytic sol-gel; Hydrophobicity.

**Introduction.** Hybrid materials based on metallosilicates (including aluminosilicates) exhibit better catalytic performance in various reactions when their surface is more hydrophobic.[1] Generally, the introduction of organic groups can be approached either by onepot synthesis or postsynthetic modification. Herein, a thorough and complex study was performed to evaluate the influence of acidity and hydrophobicity on catalytic performance of aluminosilicate materials in ethanol dehydration.

**Experimental/methodology.** In this study, the aluminosilicate catalysts were prepared by non-hydrolytic sol-gel (NHSG) either by acetamide elimination or alkylhalide elimination.[2] The non-aqueous condensations provided well-dispersed aluminum atoms (Si/Al = 16) in the porous silica structure. The introduction of organic groups into the structure was approached by two various synthetic strategies – either post-synthetical modification[3] or one-pot synthesis.[4] Structure, porosity, acidity, and hydrophobicity of NHSG-prepared catalysts, and the stability of organic groups were closely followed by MAS NMR studies, $N_2$ physisorption, IR-pyridine analyses, water adsorption, and TG/DSC, respectively. Finally, aluminosilicates were tested as heterogeneous catalysts in ethanol dehydration to ethylene.

**Results and discussion.** In the two-step synthesis the fully inorganic matrix was post-synthetically modified by grafting trimethylsilyl groups.[3] The number of reacted ≡Si−OH moieties and thus the trimethylsilyl groups loading was controlled via a temperature vacuum pre-treatment of aluminosilicate samples. While porosity and structure of aluminosilicates after trimethylsilyl groups grafting were very similar to the parent material, the water sorption measurements showed that trimethylsilylated aluminosilicates adsorb 2.5−3 times less water ($p/p_0$ = 0.3) in comparison to the parent aluminosilicate catalyst. The truly hydrophobic surface of these catalysts did influence the course of ethanol dehydration: The turn-over frequency scaled up with the number of trimethylsilyl groups grafted on the catalyst surface.[3]

In the one-pot synthesis, the methylsilyl groups were introduced and the water sorption measurements revealed that the hydrophilicity of both methylated samples and non-methylated samples were virtually identical.[4] The total number of acid sites did not change upon methylsilyl groups introduction. However, some Brönsted acid sites converted into Lewis acid sites upon methylation. In this case, acidity modulation played a pivotal role in ethanol dehydration. Ethanol conversion increased with the number of acid sites while higher Lewis acid sites content provided an increased selectivity to ethylene.[4]

In conclusion, this study discloses the differences between the one-pot and two-step organic groups introduction into the NHSG-prepared aluminosilicate catalysts. Moreover, it compares the impact of organic groups incorporated by diverse strategies on structure, acidity, and hydrophobicity of aluminosilicate catalysts and put it into the context of ethanol dehydration.

**Introduction.**

The selective, gas-phase hydroformylation (HF) of light ($C_{2-4}$) olefins remains an enduring objective for heterogeneous catalysis. The process has been demonstrated with excellent selectivities on molecular Co and Rh catalysts in solution and in supported ionic liquids (SILP).[1] The development of an alternative process in the gas phase, with all-solid catalysts, is attached to various technical incentives and appealing as both an olefin functionalization route as well as a reactive separation alternative to energy intensive cryogenic distillations. Despite intense research efforts, solid catalysts have hitherto shown lower activity and particularly poorer selectivity compared to their molecular counterparts. Herein we report that isolated Rh atoms stabilized on oxygen-defective $SnO_2$ uniquely unite excellent TOF with essentially full selectivity in the gas-phase hydroformylation of ethylene.[2]

**Experimental.**

Rh single-atom catalysts (SACs) have been synthesized by oxidative metal dispersion and atom trapping on various $MO_2$ oxides at a surface-specific metal content of 1.0±0.1 $Rh_{at}$ $nm^{-2}$. The catalysts have been characterized via XRD, HAADF-STEM and *in situ*/*operando* XAS, CO-FTIR and Raman spectroscopies. Gas-phase ethylene hydroformylation tests were performed in a SS-310 fixed-bed reactor at 20 bar and T= 383-503 K using a feed of $CO:H_2:C_2H_4$ 1:1:1 (v).

**Results and discussion.**

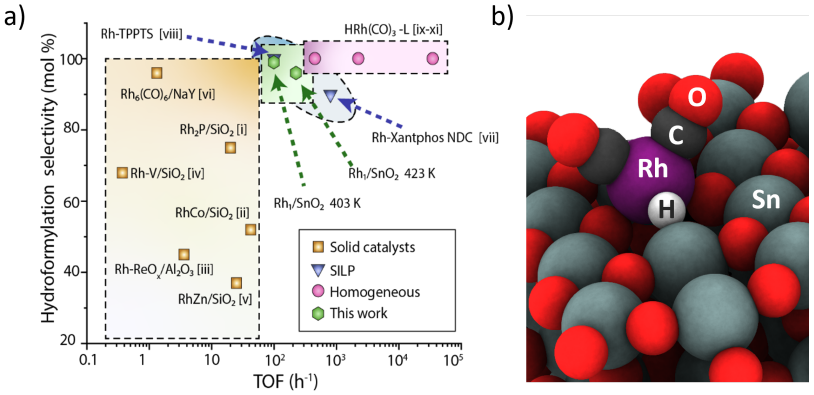

**Figure 1: a) Comparison of the performance of a $Rh_1/SnO_2$ SAC with state-of-art solid and molecular catalysts in solution or on SILP for the gas-phase HF of ethylene. b) Resting Rh hydride dicarbonyl active species predicted by DFT on the surface O-depleted $Rh_1/SnO_2$(110).**

Gas-phase ethylene HF tests revealed modest activities (TOF<4$h^{-1}$) and HF selectivities (<70% (mol)) for $Rh_1$ species on $ZrO_2$ and $CeO_2$, as well as for $Rh_n$ aggregates on $SiO_2$, in good accordance with previously reported performances for solid Rh catalysts. In stark contrast, $Rh_1/SnO_2$ attained TOF values up to 225 $h^{-1}$ alongside hydroformylation selectivities >95 %. This performance is comparable to those thus far exclusive of molecular catalysts operating in liquid media, either in solution or within the ionic liquid overlay on SILP (Figure 1a). *Operando* XAS and *in situ* FTIR and Raman spectroscopies, coupled to periodic DFT calculations, signify the importance of modulating the density of surface bridging-type $O_{vac}$ –the formation of which is energetically facile on $SnO_2$ under HF conditions – to unlock an unusually high coordination pliability at the mononuclear Rh centers (Figure 1b), responsible for the exceptional ethylene HF performance.

**Keywords:** Liquid metal catalysis, alkene oligomerization, single-atom catalysis

**Introduction.** Supported catalytically active liquid metal solutions (SCALMS) has proved to be a scientific breakthrough in catalytic dehydrogenation of alkanes, which is a key process in chemical energy storage technologies and for applying alkanes as feedstock for chemical transformations [1]. This new class of heterogeneous catalysts consists of catalytically active liquid alloy droplets on a porous support. Ga-rich alloys of Pd, Pt, Rh (Ga > 90 at%) have recently been demonstrated to serve as highly efficient and stable catalysts for dehydrogenation of alkanes and cycloalkanes [1-3]. Previous studies on SCALMS catalysts conclude that the extraordinary and unique catalytic activity arises from the high dynamicity of the surface of the liquid alloys with dynamic appearance and disappearance of single catalytic active metal atoms with a very short residence time at the surface [1,4,5]. In this contribution, we will present our research in the field of selective C-C-linkage reactions as well as the first account of non-precious metal SCALMS – namely the Ga-Ni SCALMS system for alkene oligomerization [6]. As a model reaction, ethylene oligomerization was chosen by the fact that most catalysts for this reaction are molecular in nature and that the oligomerization of lighter alkenes is of great industrial interest.

**Experimental section.** The silica supported Ga-Ni SCALMS catalysts were prepared by a physical impregnation method using ultrasonication [7]. The catalysts were characterised by inductively coupled plasma atomic emission spectroscopy (ICP-AES) and scanning electron microscopy with energy-dispersive X-ray spectroscopy (SEM-EDX). Catalytic results have been obtained in a continuous operated fixed-bed reactor setups and analysed by on-line gas chromatography (GC) with a flame ionization detector (FID).

**Results and discussion.** The SCALMS system of 1.5 at% Ni in Ga on silica ($Ga_{67}Ni/SiO_2$) was found to provide highly stable and efficient catalysis for the oligomerization of ethylene with a high selectivity towards linear C4 compounds, good Ni-based productivity, and long-term stability. The activity of the Ga-Ni SCALMS was found to be highly dependent on the Ga/Ni atomic ratio of the alloy and performance was generally enhanced with increasing Ga/Ni ratio. This behaviour can be linked to the liquid nature of the alloy, where single Ni atoms in the liquid Ga matrix provide reactive single-atom surface sites. The Ga-rich SCALMS systems furthermore outperformed both solid Ga-Ni intermetallic compounds and Ni nanoparticles. Thus, the concept of SCALMS provides a very technical approach for single-atom catalysis and the development of active non-precious metal based SCALMS systems uncovers entirely new frontiers within supported single-atom catalysis.

# Novel synthesis of sub-nanometric high entropy alloy clusters on $CeO_2$ nanorods

N. Hashimoto[1], K. Mori[1*], N. Kamiuchi[2], H. Yoshida[2], H. Yamashita[1*]

[1]*Graduate School of Engineering, Osaka University, Osaka, Japan*

**Introduction.** High entropy alloys (HEAs) are novel metallic materials, consisting five or more elements with near-atomic ratio and form simple single phase like *fcc* or *bcc*. HEAs show unique properties such as extraordinary thermal stability, specific strength and corrosion resistance, such that HEAs are fascinating materials. We previously reported the synthesis of CoNiCuRuPd HEA NPs with a mean diameter of 2 nm, in which there are large gaps between the reduction potentials of the constituent elements, using the pronounced hydrogen spillover effect of $TiO_2$[1]. In this study, the synthesis of $CeO_2$ nanorods ($CeO_2$-NRs) on which sub-nanometer CoNiCuZnPd HEA clusters consisting of 13 atoms were formed with the aid of a pronounced hydrogen spillover effect on readily reducible $CeO_2$ (110) facets. These clusters also showed a unique structural reversibility in response to repeated exposure to oxidative/reductive conditions, based on the sacrificial oxidation of the non-noble metals.

**Experimental/methodology.** CoNiCuZnPd/$CeO_2$-NR catalysts were prepared via a simple impregnation method. In this process, $CeO_2$-NRs were dispersed in distilled water, after which a metal precursor solution ($Co^{2+}$, $Ni^{2+}$, $Cu^{2+}$, $Zn^{2+}$, $Pd^{2+}$) was added to the suspension. The mixture was subsequently stirred and then evaporated by heating at 60 °C under vacuum. Finally, the specimen was reduced under a flow of hydrogen gas at 600 °C to yield CoNiCuZnPd/$CeO_2$-NRs.

**Results and discussion.** The EDX maps of CpNiCuZnPd/$CeO_2$-NRs acquired over a specific region clearly shows all elements and indicates the formation of highly dispersed quinary CoNiCuZnPd HEA nanoclusters having diameters of less than 1 nm. FT-EXAFS spectra at Pd K-edge demonstrated that the exsistance of not only Pd-Pd bonds but also Pd-M (M=Co, Ni,Cu,Zn) bonds, indicating the formation of quinary HEA particles. In addition, the total coordination number (CN) values ($CN_{Pd-Pd}$, + $CN_{Pd-M}$)were determined 5.6. The diameter of the quinary CoNiCuZnPd alloy cluster having a CN of 5.6 can be estimated to be 0.79 nm, consisting of 13 atoms, according to the relationship between the CN and the diameter of a Pd cluster.

The catalytic activity were evaluated by the nitric oxide (NO) reduction by hydrogen. The quinary CoNiCuZnPd/$CeO_2$-NRs exhibited higher activity in comparison with monometallic Pd/$CeO_2$-NR catalyst(Fig. 1(a)). Futhermore, the stability of HEA catalysts were assessed by using *in situ* XAFS under NO-$H_2$ conditions. In the case of quinary CoNiCuZnPd/$CeO_2$-NRs, the randomly distributed Pd atoms formed core nuclei encapsulated by non-noble metal oxide shells (that is, Pd@$MO_x$; M = Co, Ni, Cu and Zn) via the sacrificial oxidation of the base metals under NO. These structures could be reversibly changed back to well-mixed HEA nanoclusters under a $H_2$ atmosphere(Fig. 1(b)).

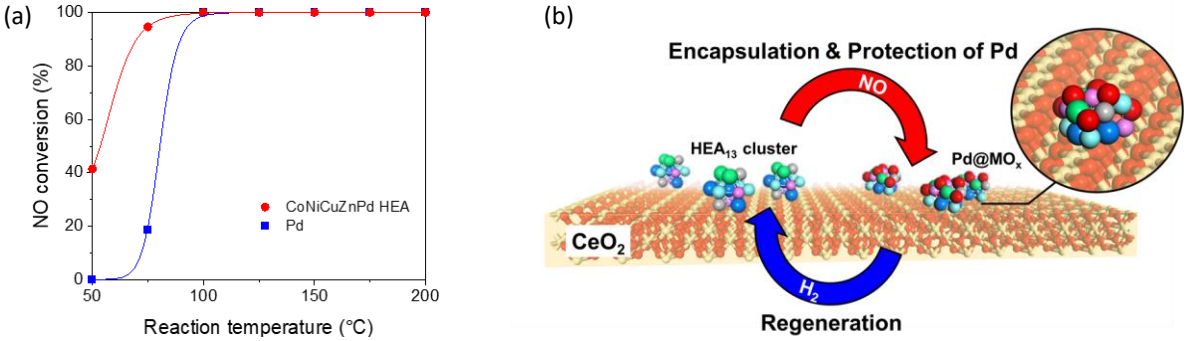

**Figure 1 (a) NO reduction activity of CoNiCuZnPd/$CeO_2$-NRs and Pd/$CeO_2$-NRs. (b) Proposed structural changes of CoNiCuZnPd/$CeO_2$-NRs under NO-$H_2$ conditions.**

**Introduction.**

Ammonia is attracting wide interest as a next-generation energy carrier in the hydrogen society. In the current ammonia production process (Haber-Bosch process), high temperature is required to overcome the high reaction energy barrier of dissociating stable nitrogen triple bond (N≡N), and high pressure is needed to compensate for the low thermodynamic conversion ratio. The development of a highly active ammonia synthesis catalyst will increase the energy efficiency of ammonia synthesis by lowering the operating temperature and pressure of Haber-Bosch process.[1] The exsolution method has been gaining attention as a method for preparing nanoparticle catalysts with controlled size and distribution and enhanced interaction between the nanoparticle and the support. In this research, exsolved Ru-$BaCe_{0.9}Y_{0.1}O_{3-\delta}$ (BCY) catalyst shows strong metal-support interaction than other samples, which could enhance catalytic activities by accepting electrons from the alkaline earth support and changing the electronic structure of Ru metal. In addition, metal agglomeration was prevented during the catalytic reaction, due to the strong anchoring of Ru nanoparticles on the BCY support. Ammonia synthesis rate of exsolved Ru-BCY catalyst was increased when compared with the Ru-BCY synthesized by the impregnation method, the commonly employed catalyst synthesis method, and the commercial Ru/C catalyst.[2]

**Experimental/methodology.**

The Ru-doped-BCY support was synthesized using the glycine nitrate process (GNP). The exsolution process was conducted by reducing the resultant powder at a high temperature (1000 °C) under a reducing atmosphere (5% $H_2$, in Ar-balanced) for 5 h (ex-Ru/BCY). XRD, SEM, TEM, EXAFS, and XPS characterizations revealed that the exsolved Ru nanoparticles have strong metal-support interaction between Ru-BCY. The ammonia synthesis reaction was conducted in a quartz fixed-bed reactor with $H_2$ and $N_2$ gas with high purities

**Results and discussion.**

An exsolution process is implemented to improve catalytic activity by modulating the geometry and electronic structure of Ru. Ru nanoparticles exsolved on a $BaCe_{0.9}Y_{0.1}O_{3-\delta}$ support showed uniform size distribution, 5.03 ± 0.91 nm, and exhibited one of the highest activities, 387.31 $mmol_{NH3}\ g_{Ru}^{-1}\ h^{-1}$ (0.1 MPa and 450 °C). The role of exsolution and $BaCe_{0.9}Y_{0.1}O_{3-\delta}$ support are studied by comparing the catalyst with control samples and in-depth characterizations. The size of the nanoparticle was maintained during the reaction, as the Ru nanoparticles prepared by exsolution were well-anchored to the BCY support with in-plane epitaxy. The electronic structure of Ru is modified by in situ Ba promoter accumulation around the base of the Ru nanoparticles. Therefore, exsolved Ru nanoparticles on BCY (ex-Ru/BCY) showed improved activity for the ammonia synthesis reaction compared to catalysts prepared using the conventional preparation method.

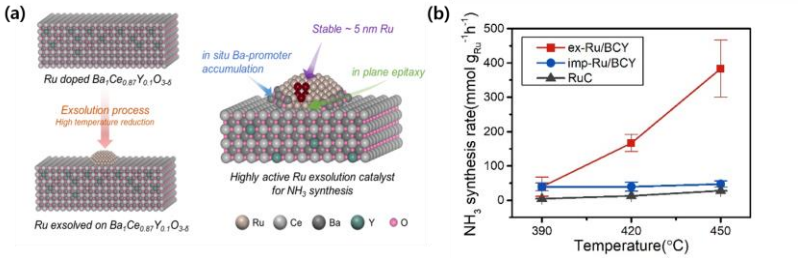

**Figure 1 (a) schematic of synthesized exsolved Ru catalyst (b) NH3 synthesis rate of each sample.**

**Keywords:** carbon dioxide hydrogenation, exsolution, methanol synthesis, Ni-Ga catalysts

**Introduction.** For a sustainable and carbon-neutral future, the atmospheric concentration of $CO_2$ and energy usage should be limited. Moreover, $CO_2$ is a cheap carbon source that provides a promising and environmentally friendly pathway to synthesize essential hydrocarbons and chemicals and the catalytic hydrogenation of $CO_2$ to methanol could be a straightforward solution. Redox exsolution enables us to produce stable and highly active catalysts. In exsolution, homogenously dispersed metallic nanoparticles, emerge at the surface of perovskite support by thermal or electrical reduction. These active sites on the surface of perovskite result in high thermal stability and resistance to poisoning by carbon deposition as well as high catalytic activity. Among transition metals, which are industrially applicable, Ni-Ga-based catalysts have gained increased attention due to their active sites for $CO_2$ reduction (Fig 1 a).

**Experimental/methodology.** Ni-Ga exsolution was induced from a $LaCaTiO_3$ support prepared by a modified solid-state synthesis. In order to exsolve particles, the samples were reduced at a temperature in a controlled atmosphere furnace, under a continuous flow of (wet and dry) $H_2$ at a temperature range of 600-900 °C. The crystalline phase components of all freshly prepared and reduced samples were investigated using powder X-Ray diffraction (XRD): CuKα-radiation, 2θ = 20-90. Rietveld refinement was carried out by the GSAS software. The structure and homogeneity, particle size, population, and local structure/elemental distribution of the exsolved nanoparticles of the materials were analyzed using scanning electron microscopy (SEM) and transition electron microscopy (TEM). The catalytic activity/selectivity was evaluated at atmospheric pressure between 150-300°C.

**Results and discussion.** Single phase $La_{0.5}Ca_{0.4}Ni_{0.1}Ga_{0.1}Ti_{0.8}O_3$ and $La_{0.48}Ca_{0.41}Ni_{0.1}Ga_{0.06}Ti_{0.84}O_3$ were synthesized. The diffraction patterns of the as-prepared Ni-Ga bimetallic catalysts (Fig 1b), showed characteristic peaks, almost identical to a $LaCaTiO_3$ perovskite implying the successful substitution of both dopants in the perovskite lattice.. The exsolution temperature affected the catalytic performance as different surface ratios between the two dopants were observed. Characterization of catalysts pre and post reaction via SEM-EDX, TEM, etc will also be presented.

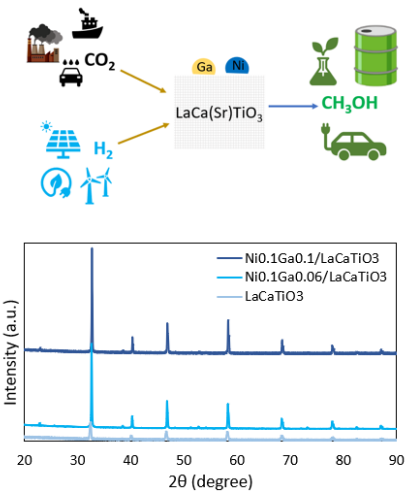

Fig 1: Schematic representation of the concept of the exsolved catalyst for $CO_2$ hydrogenation to methanol (a), XRD pattern of $LaCaTiO_3$, $Ni_{0.1}Ga_{0.06}/LaCaTiO_3$, $Ni_{0.1}Ga_{0.1}/LaCaTiO_3$ (b).

# Intermittent Ammonia Synthesis over a Cs-promoted Ru/SGCNT catalyst

Shih-Yuan Chen[1]*, Masayasu Nishi[1]*, H. Tateno[1], T. Mochizuki[1], H. Takagi[1] T. Nanba[1]

[1]*National Institute of Advanced Industrial Science and Technology (AIST), 16-1 Onogawa, Tsukuba, Ibaraki 305-8569, Japan.*

**Introduction.** $NH_3$ is industrial synthesized by the Fe-catalyzed Haber-Bosch (HB) process under severe conditions (> 400 °C, 10 MPa), which heavily relies on fossil energy, equal to ≈ 2% of the global energy supply and ≈ 1–2% of global $CO_2$ emissions. Ideally, the Ru-catalyzed HB process for $NH_3$ synthesis can be performed under milder conditions. However, the Ru-based catalysts, particularly Ru/carbon, generally suffer from $H_2$ inhibition and deactivation caused by methanation of the carbon framework and sintering of Ru. Super-growth carbon nanotubes (SGCNT) with high stability were developed by Zeon Corporation (ZEON) and AIST using a water-assisted chemical vapor deposition method. Herein, an SGCNT-supported Cs-promoted Ru catalyst with a Ru loading of 10 wt% and a Cs/Ru molar ratio of 2.5 (denoted as Cs-Ru/SGCNT) was prepared for 0.1–8 MPaG $NH_3$ synthesis under intermittent operation conditions, which simulated electrolysis driven Haber–Bosch (eHB) $NH_3$ synthesis using photovoltaic electricity. The performance and durability of Cs-Ru/SGCNT catalyst were correlated to the active components of Cs-promoted Ru particles examined by *in situ* studies, and compared with previously reported catalysts [1,2].

**Experimental/methodology.** The active components of Cs and Ru were impregnated on SGCNT (product code: ZEONANO®SG101, Zeon, Japan), resulting in a Cs-Ru/SGCNT catalyst [1]. $NH_3$ synthesis was studied in a fixed-bed reaction system equipped with a GC-2014 insutrment (Shimadzu, Japan). The performance and durability of the prepared Cs-Ru/SGCNT catalyst were correlated to the active components (i.e., Cs-promoted Ru nanoparticles), which were studied by *in situ* X-ray absorption spectroscopy (XAS) and temperature-programmed reduction (TPR) under the reaction conditions. The results were compared with the analogs using mesoporous carbon (MPC) and activated carbon (AC) [2].

**Results and discussion.** Cs-Ru/SGCNT is superior to two analogs of Cs-Ru/MPC and Cs-Ru/AC in catalyzing 0.1-0.9 MPaG $NH_3$ synthesis, particularly those operated at pressurized conditions (Fig. 1(a)). The *in situ* XAS and TPR studies show that the active components of Cs-Ru/SGCNT are consisted of Ru nanoparticles (2.7 nm) surrounded by well-dispersed Cs species (graph centered in Fig. 1(b)). Figs. 1(b,c) show the long-term $NH_3$ synthesis of Cs-Ru/SGCNT catalyst under intermittent operation conditions, which simulate eHB $NH_3$ synthesis process. The results show that Cs-Ru/SGCNT can quickly start up to yield approxiatemly 2.5-3.5% of $NH_3$ at 250-400 °C (running in the daytime) and stop at 50 °C (shutdown in the night). The performance and durability of Cs-Ru/SGCNT remain nearly unchanged after 7 cycles (~140 h). In summary, the Cs-Ru/SGCNT catalyst with Cs-promoted Ru nanoparticles as the active components are active and durable in $NH_3$ synthesis under intermittent operation conditions. It would be a potential candidate for eHB $NH_3$ synthesis with which the electrolytic hydrogen production is varied by the supply of renewable electricity.

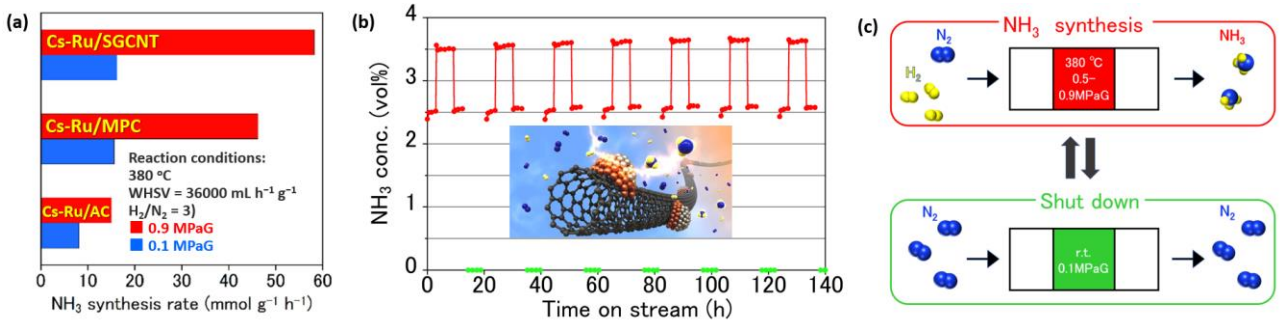

**Fig. 1.** Intermittent $NH_3$ synthesis over a Cs-Ru/SGCNT catalyst in comparison with previously reported catalysts.

# Revealing Hydrogen Spillover Pathways in Reducible Metal Oxide Catalysts

K. Shun, K. Mori*, H. Yamashita

*Graduate School of Engineering, Osaka University, Osaka 565-0871, Japan*
**mori@mat.eng.osaka-u.ac.jp*

**Keywords:** Hydrogen spillover, Reducible metal oxide

**Introduction.** Hydrogen spillover is a dynamic phenomenon which is initiated by the dissociation of hydrogen molecules followed by the migration onto the reducible metal oxide supports.[1] Spilled hydrogen atom shows specific behavior compared with gaseous hydrogen, thus it dramatically promotes the reduction of metal ions and the catalytic performance. However, understanding of its dynamic behavior, such as at what temperature it can take place, and what pathway it follows, is still lacking because the observation method is not well established. Our group has reported Ru and Ni, an immiscible metal combination, specifically form RuNi solid solution alloy by an assist of hydrogen spillover on the surface of $TiO_2$[2]. In this work, we evaluated hydrogen spillover pathways in typical reducible metal oxide such as $TiO_2$, $CeO_2$ and $WO_3$ by combining Ru-Ni alloy nanoparticle formation, *in-situ* techniques, kinetic analysis, and density functional theory calculation.

**Experimental/methodology.** $RuCl_3{\cdot}3H_2O$ and $NiCl_2{\cdot}6H_2O$ were supported on $TiO_2$ by conventional impregnation method, after which the sample were reduced under $H_2$ dosage at a heating rate of 5 $^oC$/min up to 300 $^oC$ to obtain RuNi/$TiO_2$. Catalysts with $CeO_2$ and $WO_3$ as their supports were also prepared by the same method. In order to evaluate the alloy effect of Ru and Ni in the catalytic reaction, the prepared catalyst was applied to the hydrogen production reaction from ammonia borane (AB ; $NH_3BH_3$).

**Results and discussion.** RuNi/$TiO_2$ and RuNi/$CeO_2$ showed enhanced activity over those of corresponding monometallic Ru catalysts in the hydrogen production reaction from AB indicating the formation of RuNi solid solution alloy nanoparticles. On the other hand, RuNi/$WO_3$ didn't show any activity improvement compared with that of Ru/$WO_3$ indicating the segregation of Ru and Ni. These results suggest that hydrogen spillover occurred on the surface of $TiO_2$ and $CeO_2$, while hydrogen spillover is absent on the surface of $WO_3$. Systematic characterization such as *in-situ* XAFS, *in-situ* DRIFT and MS measurements under the H/D exchange reaction were performed in order to evaluate the hydrogen spillover pathways for each support. These results demonstrated that hydrogen spillover on $TiO_2$ and $CeO_2$ preferentially proceeded on their surface rather than within their bulk phases. Conversely, hydrogen spillover favorably occurred within the bulk prior to the surface over $WO_3$. (Figure 1).[3]

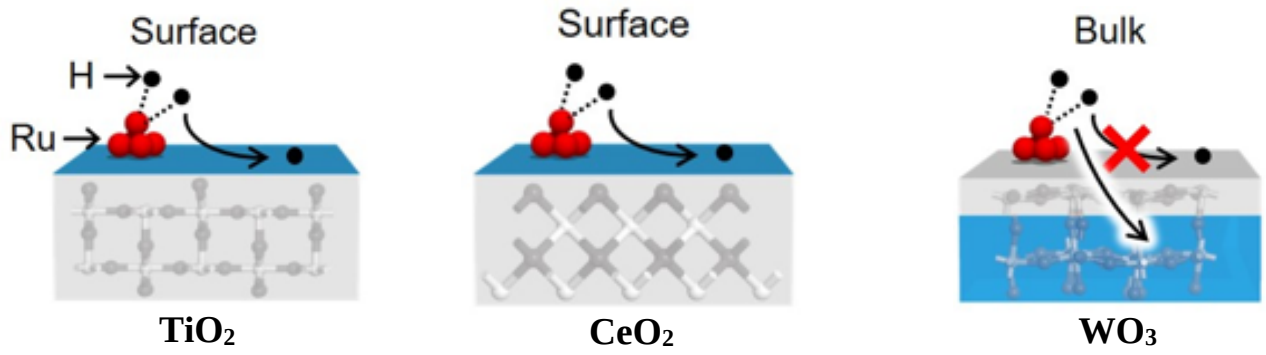

**Figure 1. Proposed spillover pathways for $TiO_2$, $CeO_2$, and $WO_3$.**

# Metathesis of ethylene with 2-butenes over $MoO_x$-based catalysts: effect of support on catalyst activity and mechanistic insights into carbene formation

T. Otroshchenko*, Q. Zhang, E.V. Kondratenko

*Leibniz-Institut für Katalyse e.V., Albert-Einstein-Str. 29a, 18059 Rostock, Germany*

**Keywords:** metathesis, propene, carbenes, molybdenum oxide

**Introduction.**

Metathesis of ethylene with 2-butene to propene over catalysts with supported oxides of Mo, Re or W is attractive from both industrial and fundamental viewpoints. From a mechanistic viewpoint, the metathesis reaction occurs with participation of catalytically active metal-carbenes,[1] which must be formed *in situ* upon reaction of feed olefins with supported metal-oxide species. The main purpose of the present study was to investigate the influence of the kind of support on catalyst activity in the metathesis of ethylene with 2-butene as well as to elucidate mechanistic insights of carbene formation through the reaction of highly dispersed $MoO_x$ species with ethylene or 2-butenes. Such knowledge would provide a basis for rational catalyst design and optimization of treatment/reaction conditions.

**Experimental/methodology.**

A series of Mo-containing catalysts were prepared by incipient wetness impregnation of pre-calcined oxidic suppports ($SiO_2$, $Al_2O_3$, $ZrO_2$, $Al_2O_3$-$SiO_2$, $ZrO_2$-$PO_4$ or $TiO_2$-$SiO_2$) with an aqueous solution of $(NH_4)_6Mo_7O_{24}{\cdot}4H_2O$. The solids were dried in air at 110°C overnight and calcined at 500°C for 8 h. The catalysts were characterized by $H_2$-TPR, $NH_3$-TPD, $C_2H_4$-TPD, $C_4H_8$-TPD, UV-vis and DRIFT spectroscopy. Catalytic tests were performed at 50°C in a fixed-bed reactor with a feed consisting of 45.5 vol% $C_2H_4$ and 45.5 vol% trans-2-$C_4H_8$ in $N_2$.

**Results and discussion.**

The kind of support strongly influences an apparent Mo-related turnover frequency ($TOF_{Mo}$) of propene formation (Figure 1). The catalysts based on individual metal oxides showed lower $TOF_{Mo}$ than their counterparts on the basis of promoted/mixed oxides.[2] The $TOF_{Mo}$ values of Mo/$ZrO_2$-$PO_4$ and Mo/$TiO_2$-$SiO_2$ are more than 350 and 100 times higher than those of Mo/$ZrO_2$ and Mo/$TiO_2$, respectively. The higher activity of catalysts based on promoted or mixed-oxide supports is more likely related to the presence of lattice defects created in the support materials after their promotion. Such defects may facilitate the transformation of $MoO_x$ to Mo-carbenes under reaction conditions or improve the intrinsic activity of the latter.

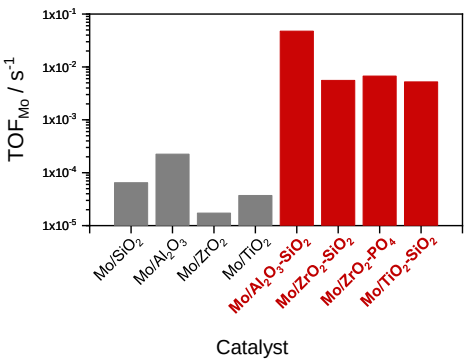

**Figure 1** The Mo-related propene formation rate ($TOF_{Mo}$) at 50°C over different catalysts.

It has also been demonstrated that $TOF_{Mo}$ can be increased by creation of a certain type of hydroxyls in the vicinity of $MoO_x$ through the modification of support surface with non-metallic promoters (S, Cl or P).[3] Such hydroxyls participate in 2-butene adsorption facilitating transformation of $MoO_x$ into active Mo-carbenes. The results of $C_2H_4$-TPD, $C_4H_8$-TPD as well as *in situ* DRIFTS experiments led us to the conclusion that 2-butene but not ethylene is able to convert $MoO_x$ species into Mo-carbenes at 50°C. The latter open the possibility for ethylene engagement into the metathesis reaction.

The findings elucidated in the current work open new possibilities for purposeful preparation of supports and catalysts on their basis for low-temperature propene formation from ethylene and 2-butenes and provide insights into the role of individual olefins for *in situ* formation of Mo-carbenes from $MoO_x$.

**Keywords:** atomic layer deposition, gallium oxide, surface sites, BDH.

**Introduction.** Materials based on $Ga_2O_3$ have been widely used as heterogeneous catalysts for alkane dehydrogenation reactions.[1] In this context, supported or unsupported $Ga_2O_3$, in which surface $Ga^{3+}$ sites reside in different coordination environments, have been studied with the aim to correlate specific surface properties (such as the Lewis acidity strength) with their catalytic performance.[2] Towards this end, understanding the role of different $Ga^{3+}$ sites as well as controlling the coordination geometry and acidity (Lewis and Brønsted) of surface and interfacial sites are necessary for the rational optimization of Ga-based dehydrogenation catalysts. Here, we utilized atomic layer deposition (ALD) to prepare $GaO_x/SiO_2$ materials with precisely controlled surface sites. The coordination environment of Ga and the surface acidity of the prepared materials were studied by a variety of methods including Ga K-edge XAS, $^{71}$Ga MAS NMR and $^{15}$N DNP SENS using pyridine as a probe molecule and the results were correlated to the catalytic performance in isobutane dehydrogenation (BDH).

**Experimental/methodology.** TMG1-, TMG5- and TMG10-$SiO_{2\text{-}500}$ materials were prepared by 1, 5 or 10 ALD cycles of trimethylgallium (TMG, 300 °C deposition temperature) onto silica that had been partially dehydroxylated at 500 °C ($SiO_{2-500}$); ozone was used as an oxidant.[4] The as-prepared materials were subsequently calcined in synthetic air at 500 °C for 4 h (5 °C min$^{-1}$) to give Ga1-$SiO_{2-500}$, Ga5-$SiO_{2-500}$, Ga10-$SiO_{2-500}$ materials (4.9, 18.2 and 31.9 wt% Ga, respectively, according to elemental analysis).

**Results and discussion.** Figure 1a presents $^{15}$N DNP SENS spectra of Ga1-, Ga5-, Ga10-$SiO_{2-500}$ after the desorption of $^{15}$N-pyridine (Py) at 150 °C. Resonances due to mild LAS (250-256 ppm), strong LAS (233-237 ppm) and strong BAS (201 and 216-221 ppm) are observed. The relative intensity of these peaks varies with the thickness of the $GaO_x$ shell such that abundant strong BAS and strong LAS are found mostly in Ga1-$SiO_{2-500}$. With the growth of the $GaO_x$ layer, the relative fraction of BAS with respect to that of LAS decreases, reaching its lowest ratio in Ga10−$SiO_{2-500}$. Also, the fraction of medium LAS increases with an increasing thickness of the $GaO_x$ layer. Next, the surface acidity of the prepared $GaO_x/SiO_2$ materials was correlated with their catalytic performance in BDH (Figure 1b). Ga1-$SiO_{2-500}$, the catalyst that contains more abundant strong LAS is more active (per Ga) and stable in BDH than Ga5- and Ga10-$SiO_{2\text{-}500}$ (Figure 1b). $^{71}$Ga MAS NMR and surface studies allow to associate strong and mild LAS with tetracoordinate and pentacoordinate Ga sites, respectively. Overall, our results indicate that strong LAS drive activity in BDH while mild LAS lead to catalyst deactivation through coking.

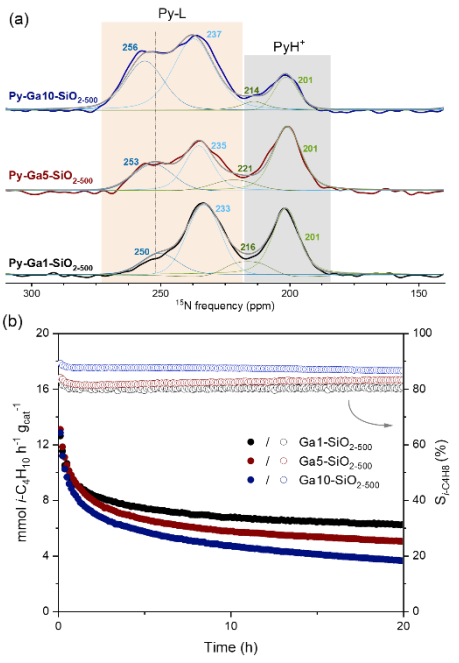

*Figure 1. (a) $^{15}$N-DNP SENS spectra of Py-Ga1-, Ga5-, Ga10-$SiO_{2\text{-}500}$. (b) Activity and selectivity to isobutene over 20 h time-on-stream (500 °C, WHSV = 8.5 h$^{-1}$).*

# Copper-Decorated Iron Carbide Nanoparticles Heated by Magnetic Induction as Adaptive Multifunctional Catalysts for the Selective Hydrodeoxygenation (HDO) of Aldehydes

S.-H. Lin[1,2], W. Leitner[1,2], A. Bordet[1*]

[1]*Max Planck Institute for Chemical Energy Conversion, Mülheim an der Ruhr, Germany*
[2]*Institute of Technical and Macromolecular Chemistry RWTH Aachen University, Aachen, Germany*
[*]*alexis.bordet@cec.mpg.de*

**Introduction.** The selective HDO of aldehydes to methylene units in the side chain of multifunctional aromatic substrates is an important transformation with applications ranging from the production of fine chemicals to the upgrading of biomass feedstock to value-added chemicals.[1] To provide alternatives to stoichiometric methods that involve toxic reagents and wastes, recent efforts focused on the development of catalytic systems possessing such reactivity. However, the development of catalytic systems fulfilling the requirements of high yields, selectivity, and environmental compatibility remains a challenge.

**Experimental/methodology.** Magnetic induction offers the possibility to heat directly magnetic catalysts in an extremely localized, rapid, and energy efficient way, saving the need to heat the whole reactor environment. In turn, this may result in milder overall process temperatures and lower energy consumption.[2] In the present work, Cu-decorated iron carbide nanoparticles (Cu@ICNPs) were prepared, characterized, and used as catalysts for the selective HDO of aldehydes using magnetic induction heating. (Fig. 1) The impacts of catalyst structure and composition, as well as of the heating mode (classical vs. magnetic induction) were carefully investigated.[3]

**Results and discussion.** When heated by magnetic induction, Cu@ICNPs were found highly active and selective for the HDO of aromatic aldehydes to aromatic alkanes under mild conditions (3 bar $H_2$, 105 °C). As a result, a broad variety of aldehydes could be readily hydrodeoxygenated under these conditions, while no HDO activity was observed even at 200°C. These results indicate that with magnetic induction heating, the reaction proceeds at the surface of the Cu@ICNPs at a temperature much higher that what can be measured at the surface of the reactor, confirming a very localized heating of the catalyst. Interestingly, the catalyst's adaptivity to intermittent power supply was demonstrated by stopping and re-starting the AC magnetic field regularly. (Fig. 1d) This approach is simple and flexible, and can pave the way toward the development of other magnetically-responsive adaptive catalytic systems capable of promoting challenging transformations under mild conditions through magnetic induction heating.

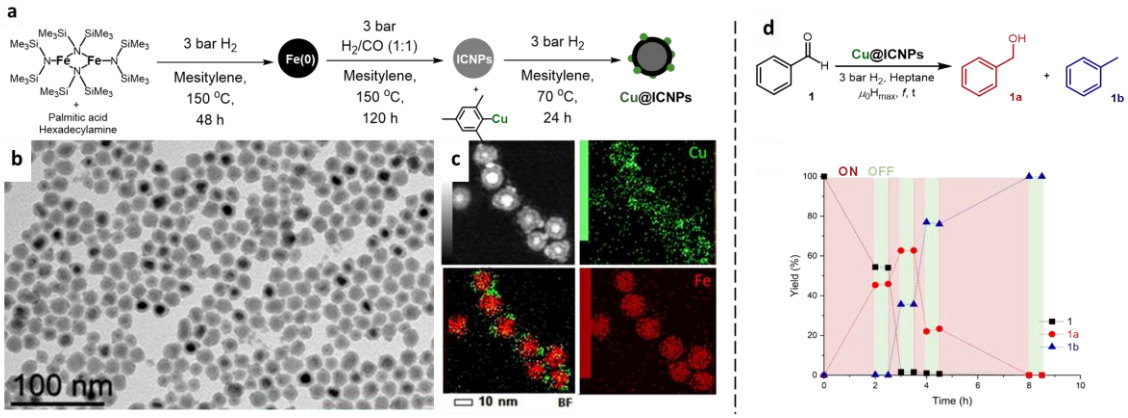

Figure 1. a-c) Synthesis and characterization of Cu@ICNPs. d) Time profile of the HDO of **1** under magnetic induction. Reaction conditions: **1** (35.5 mg, 0.33 mmol, 15 eq.), Cu@ICNPs (10.0 mg, 0.023 mmol Cu), heptane (0.5 mL), $H_2$ (3 bar), 72 mT, 350 kHz.

# Scalable laboratory synthesis of Cu-based methanol catalysts

S. Pitter[1*], L. Warmuth[1], D. Guse[2], K. Herrera Delgado[1], M. Herfet[1], M. Kind[2], T. Zevaco[1]

[1] *Institute of Catalysis Research and Technology, KIT, Karlsruhe, Germany,* [2] *Institute for Thermal Process Engineering, KIT, Karlsruhe, Germany,* [*] *stephan.pitter@kit.edu*

**Keywords:** Cu-based catalysts, methanol synthesis, precipitation, catalyst synthesis scaleup

**Introduction.** Methanol is considered one of the key intermediates on the way to a transformation towards sustainable carbon cycles, due to its physicochemical properties. Methanol also continues to offer the option of a chemical energy store that can be transported over longer distances. Based on conventional technologies, production facilities in many places are already under construction that rely on renewable sources for starting materials ($H_2$, $CO_2$) and energy. In addition, various technological options are being examined which, in contrast to conventional, centralized and large-scale production, are aimed at smaller, decentralized production sites.

In the future, more robust technologies will also require further development of the underlying process technology, in which the use of tailored catalysts plays a central role.[1] Important developments of Cu-based catalysts have contributed both to the fundamental understanding of the functioning, hence significantly improving the materials in direction of their industrial application. However, the transferability of findings from academic research into process engineering development remains a challenge, which is increasingly addressed by the use of high-throughput-experimentation (HTE) and, more recently, by the application of Artificial Intelligence (AI) supported material development.[2]

**Experimental/methodology.** Our approach is to engineer the generation of Cu/Zn-based catalytically active materials to provide robust data for quality control and subsequent scale-up during their lab-scale development. Basis of our approach is the semi-continuous co-precipitation, where initial precipitation takes place in a micromixer under highly turbulent conditions within a very short period of time to achieve largely identical conditions for the subsequent aging of the initially precipitated particles.[3] This procedure offers advantages with respect to the homogeneity of the malachite-based crystal phases formed after aging and can be adjusted via the operating parameters towards optimized macroscopic properties (e.g. morphology, surface).[4]

**Results and discussion.** In this contribution, we report on a detailed study of the preparation of $Cu/ZnO/ZrO_2$ catalysts that are particularly suitable for the production of methanol from $CO_2$-rich syngas. We are investigating the complex dependencies of the formation and restructuring of the crystal phases at different metal ratios, pH ranges and temperatures for precipitation and aging. This knowledge can be used to further enhance the catalytic properties after calcination and reduction. An example of such dependence is the difference in productivity (activities) of a series of $Cu/ZnO/ZrO_2$ catalysts in catalytic tesst, which differ only in the fact that precipitation and aging during catalyst precursor synthesis takes place at different temperatures, with an optimum of the catalytic activity at 55 °C. Using a variety of methods to characterize these materials, it is shown which structure-activity relationships play a prominent role in order to further promote catalyst development. Time-dependent formation of the crystal phases during aging will be discussed, which is relevant for further development of catalyst production. In addition, we will demonstrate that catalyst material in the range of several hundred grams can be produced in a short time already on laboratory scale by means of semi-continuous co-precipitation.

**Keywords:** Hydrogen peroxide, In-situ ammoximation, Palladium-gold alloys.

**Introduction.** Cyclohexanone ammoximation to the corresponding oxime, a precursor to Nylon-6, is one of the best examples of an industrial process that utilises preformed $H_2O_2$.[1] Decoupling oxime synthesis from industrial $H_2O_2$ production would lead to significant environmental and financial savings.[2] However, until recently no alternative approach has been reported that is simple or robust enough to replace current technology. Within this submission, we report that despite the challenging reaction conditions, the in-situ synthesis of $H_2O_2$ from the elements is not only compatible with oxime production but rivals the current industrial process, achieving yields of the oxime in excess of 95%, with these findings reported in recently in a series of leading scientific journals [2-4].

**Experimental/methodology.** Catalyst synthesis follows a conventional wet impregnation of precious metal salts onto a TS-1 carrier. Evaluation of catalyst activity towards in-situ ketone ammoximation is conducted using a high-pressure batch regime under industrially reaction conditions, utilising dilute streams of $H_2$ and $O_2$.

**Results and discussion.** AuPd nanoalloys in conjunction with TS-1 are shown to be highly active towards the ammoximation of cyclohexanone to the corresponding oxime via in-situ $H_2O_2$ production, achieving cyclohexanone oxime yields which rival the current industrial process. Through extensive study, the key role of Au in promoting reactivity and stability is identified (Figure A) and our approach is shown to be applicable to a range of ketones (Figure B). The optimal catalyst formulation was observed to be stable up to 200 h on-stream, under industrially relevant reaction conditions. Detailed techno-economic assessment reveals that through the in-situ approach financial savings of approximately 13% can be achieved over the current industrial process.

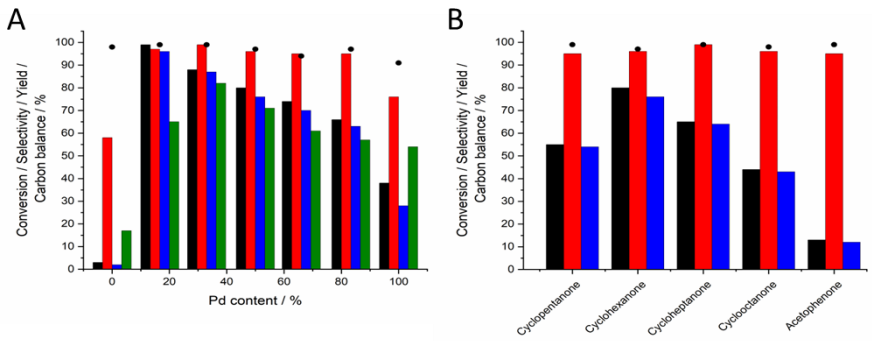

**Figure A.** The effect of Au:Pd ratio on catalytic activity towards cyclohexanone ammoximation. **Figure B.** Versatility of the in-situ approach to other substrates. **Ammoximation reaction conditions:** Ketone (2 mmol), $NH_4HCO_3$ (4 mmol), 5% $H_2/N_2$ (420 psi), 25% $O_2/N_2$ (160 psi), catalyst (0.075 g), TS-1 (0.075 g), t-BuOH (5.9 g), $H_2O$ (7.5 g), reaction time 3 h, reaction temperature 80 $^{O}$C, stirring speed 800 rpm. ***Key*:** Conversion (*black bar*), oxime selectivity (*red bar*), oxime yield (*blue bar*), $H_2$ selectivity (*green bar*), carbon balance (*black circles*).

**Keywords:** ammonia oxidation, single-atom catalysis, cerium oxide, manganese, nitrous oxide

**Introduction.** In the modern endeavour for sustainability and process intensification in the chemical industry, selective oxidations of hydrocarbons constitute a key challenge. In this regard, nitrous oxide, $N_2O$, a mono-oxygen donor, offers an effective solution, unlocking the path towards more efficient and direct manufacture of an array of bulk chemicals, such as propylene oxide and phenol.[1] However, its high cost, stemming from the conventional production route via ammonium nitrate decomposition, precludes industrial implementation. Accordingly, direct ammonia, $NH_3$, oxidation to $N_2O$, a more facile and economical process, offers an attractive alternative but requires the development of a suitable catalyst.

**Methodology.** The performance of manganese-based catalysts in continous-flow $NH_3$ oxidation to $N_2O$ is evaluated. The structure of the best system is elucidated by advanced microscopy, electron paramagnetic resonance (EPR) and X-ray photoelectron spectroscopy (XPS) analysis. Advanced mechanistic studies by temporal analysis of products and density functional theory simulations are conducted.

**Results and discussion.** We report low-valent manganese atoms stabilized on ceria, $CeO_2$, as the first stable catalyst for $NH_3$ oxidation to $N_2O$, exhibiting two-fold higher productivity than the state-of-the-art Au nanoparticles on $CeO_2$.[2] The single-atom low-valent nature of the catalyst is revealed by means of advanced microscopy, EPR and XPS analyses (**Fig. 1a-c**). The reaction proceeds via a Mars-van Krevelen mechanism, with participation of lattice O species of $CeO_2$. The ability of undercoordinated manganese species to activate gas-phase $O_2$ and facilitate the formation of a N-N bond are revealed to be instrumental to the outstanding catalytic performance. No deactivation is observed over 70 h on stream (**Fig. 1d**). $CeO_2$-supported isolated transition metals emerge as a novel class of materials for $N_2O$ production, encouraging future studies to evaluate their potential in selective catalytic oxidations at large.

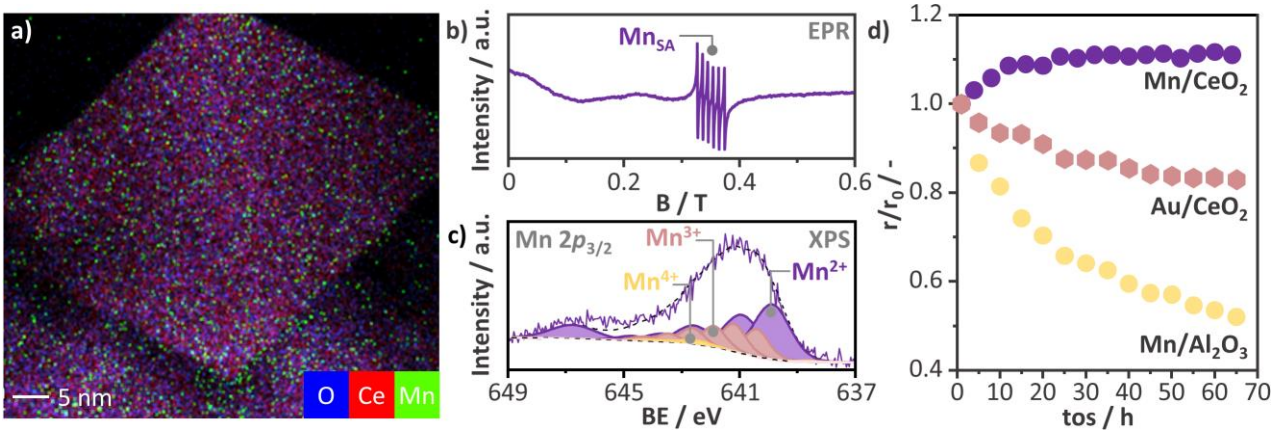

**Figure 1. (a) Elemental map, (b) EPR and (c) XPS spectra of $Mn/CeO_2$. (d) Stability test of selected catalysts.**

# Bimetallic catalyst synthesis using galvanic displacement, electroless deposition methods and application for renewable chemical production

Weijian Diao[1*]
[1]*Villanova University, Villanova PA, United States*
[*]*Weijian.diao@villanova.edu*

**Introduction.** From petroleum refining to pharmaceuticals to automobile emission control, supported metallic catalysts are widely used in industrial processes and daily life. Bimetallic catalysts have been widely used in industrial processes which offer better performance of activity, selectivity and lifetime comparing to monometallic due to ensemble/geometric effects, electronic effects, and/or bifunctional effects. However, bimetallic catalysts are typically prepared on an industrial scale using either successive impregnation or co-impregnation methods which frequently provide inadequate control over placement of each metal with varying compositions and distributions of each metal [1].

**Experimental/methodology.** Using rational bimetallic synthesis methods including galvanic displacement (GD) and electroless deposition (ED) [2,3], different series of bimetallic catalysts including Pt-Ru, Pd-Au, Pd-Ag, Ag-Ir have been prepared with controllable composition and structure. Bimetallic catalysts synthesized by GD and ED methods have shown supreme performance for many different applications including selective hydrogenation reactions, selective oxidation reactions as well as direct methanol fuel cell. Detailed reaction mechanism study shows that precisely controlled bimetallic catalysts prepared by electroless deposition method significantly improve catalyst performance with ensemble/geometric effects, electronic effects, and/or bifunctional effects. In this study, metal precursors for Pd, Pt, Ir, Ag, Au and Cu were used for galvanic displacement (GD) and electroless deposition (ED) of secondary metal on primary metal. GD and ED liquid bath concentrations were measured using atomic adsorption spectroscopy (Perkin Elmer AAnalyst 900). Catalytic surface properties were obtained by XPS and $H_2$ chemisorption measurements using a Micromeritics ASAP 2920. XRD obtained from a Rigaku MiniFlex II and STEM images taken from a JEOL JEM-2100F were used for particle size measurements.

**Results and discussion.** Several series of bimetallic catalysts including Pt-Ru, Pd-Au, Pd-Ag, Ag-Ir have been prepared with controllable composition and structure with galvanic displacement (GD) and electroless deposition (ED) method. Surface coverage of secondary on primary metal varies from 5% to 97% based on chemisorption analysis. XPS, TPR, STEM and chemisorption indicated controlled bimetallic catalyst surface with strong metal-metal interactions. Bimetallic catalysts were tested for different applications including selective hydrogenation/oxidation, direct methanol fuel cell. With highly dispersed secondary metal and preciously controlled primary metal ensemble, significantly improve catalyst performance of activity, selectivity and stability were observed with ensemble/geometric effects, electronic effects, and/or bifunctional effects.

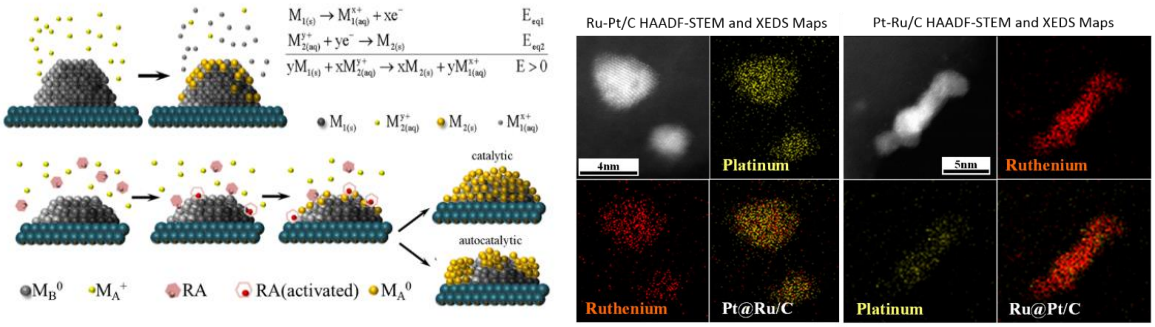

**Figure 1. (A). Galvanic displacement (GD) and Electroless deposition (ED) methods; (B) HAADF-STEM of Ru-Pt and Pt-Ru bimetallic catalysts prepared by ED method [3].**

**Introduction.** As it can be shown basing on many representative examples, cenosphers extracted from fly ashes (generated worldwide in mass scale by energy sector) can be efficiently used in catalysis as supports or, after appropriate functionalization, also as composite catalytic materials. Their exploitation remains in agreement with main principles of circular economy, where a waste material from one industrial process can be successfully used (directly or after necessary valorization) as valuable material in another process. Cenospheres exhibit several interesting features making them particularly useful as catalytic supports. First of all, they are thermally stable as they were formed at temperatures exceeding 1200°C from non-flammable mineral components naturally occurring in coal. Cenospheres are rich in silicon, aluminum, iron, and alkali elements. On the other hand, cenospheres show relatively low specific surface areas. To overcome this disadvantage additional structural modifications are sometimes required. Our goal was to check whether commercial cenospheres can be used as suitable support materials for copper- and zinc-based catalysts for hydrogenation of $CO_2$.

**Experimental/methodology.** Commercial cenospheres of 150 and 300 μm in diameter (labelled hereafter as Cen-150 and Cen-300) have been impregnated with appropriate amounts of aqueous solutions of copper and/or zinc nitrates and then calcined at 400°C for 4 hours to obtain final catalytic systems. Both cenospheres and the supported oxide catalysts have been structurally (XRF, XRD, RS), texturally (SEM, porosimetry) and functionally (RS, DRIFT, UV-Vis/DR) characterized in detail.

**Results and discussion.** As it can be inferred from both XRD and RS results, interactions between cenosphere surfaces and the deposited phases are rather weak, favoring the formation of CuO and ZnO three-dimensional nanorystallites even at such low concentrations of the deposited phases as 0.5 mol. % of Cu or 0.3 mol. % of Cu and 0.2 mol. % of Zn. It was thus confirmed that cenospheres belong to the supports limiting natural tendency of the deposited oxide phases containing copper and zinc to expand. Simultaneously, as revealed by DRIFT, due to relatively many different stabilization sites ocurring on their surfaces, heterogeneity of surface hydroxyls stabilized on cenosphere-supported catalysts was distinctly strong. Moreover, our studies confirmed that cenosphere-supported oxide phases are stable and can be considered as useful catalytic materials for many reactions of environmental and technological importance, like e.g. hydrogenation of carbon dioxide.

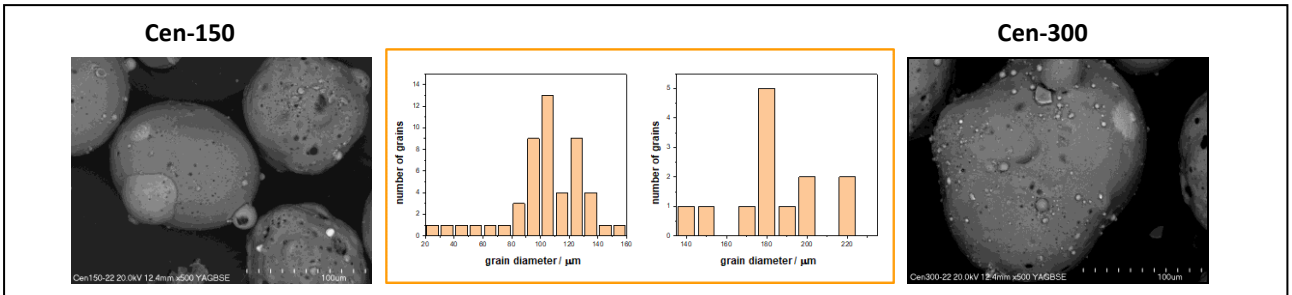

**Fig. Morphological features of the studied cenospheres revealed by SEM/EDS analyses.**

**Keywords:** metal oxide clusters, base catalyst, $CO_2$ fixation, super base

**Introduction.** Metal oxide clusters, called as polyoxometalates, have been widely used as acid and redox catalysts. Since Mizuno *et al*. reported the base catalysis of monooxotungstate $[WO_4]^{2-}$ [1] and polyoxotungstate $[HGeW_{10}O_{36}]^7$ [2], the base catalysis of metal oxide clusters has attracted much attention [3]. However, their basicity has not been yet studied systematically. Recently we found that polyanionic $[Nb_{10}O_{28}]^{6-}$ clusters acted as Brønsted and Lewis base catalysts [4,5]. In addition, the $[Nb_{10}O_{28}]^{6-}$ cluster was active for $CO_2$ fixation reactions to amine compounds. The large negative charges of surface oxygen atoms of $M^V$ oxide clusters are expected to contribute to the base catalysis from density functional theory (DFT). In this study, we investigated the base catalysis of the metal oxide clusters using Knoevenagel, aldol condensation reactions, and $CO_2$ fixation reactions. We found that $[M_6O_{19}]^{8-}$ (M = Nb, Ta) clusters were active for acetone condensation reaction (p$K_a$ = 26.5), which means that the $[M_6O_{19}]^{8-}$ are superbase. DFT calculation revealed that the Brønsted base sites are the bridged O sites on the cluster surface.

**Experimental/methodology.** tetrabutylammonium (TBA) salts of $[M_6O_{19}]^{8-}$ (TBA-$M_6$, M = Nb, Ta) were synthesized by a microwave-assisted hydrothermal method in tetrabutylammonium hydroxide aqueous solution according to the literature[4,5]. The fabricated clusters were characterized by ESI-MS, FT-IR, elemental analysis, and XAFS analysis, and the adsorption energy was calculated by DFT calculation. Base catalytic properties were evaluated by KC reactions, where nitrile compounds of different p$K_a$ were reacted with benzaldehyde (BA) in DMSO at R.T. and 70°C under $N_2$ atmosphere. $CO_2$ fixation to styrene oxde (**SO**) was carried out in a batch-type reactor under atmospheric gas pressure. The reaction solutions were analyzed by GC-FID and GC-MS using an internal standard.

**Results and discussion.** The TBA-$M_6$ were characterized by elemental analysis, ESI-MS, UV-Vis, FT-IR, TG-DTA, and XAFS analyses. From the ESI-MS spectra, the signals assingend to $(TBA)_m(H)_n[M_6O_{19}]^{(8-m-n)-}$ were detected. In addition, the absorption bands characterized by the Lindqvist-type $[M_6O_{19}]^{8-}$ structure were observed in FT-IR spectra. These results indicate the synthesis of $[M_6O_{19}]^{8-}$. Next, the base strength of metal oxide clusters was tested by Knoevenagel condensation reactions. The TBA-$M_6$ clusters showed catalytic activities for the reaction of benzyl alcohol with 4-methoxybenzyl cyanide (p$K_a$ = 23.8). In addition, the TBA-$M_6$ clusters were also active for acetone condensation reaction (p$K_a$ = 26.5). The catalytic activities of TBA-$Ta_6$ were higher than those of TBA-$Nb_6$ for these reactions. DFT calculation revealed that the average negative charges of surface oxygen atoms of $[Ta_6O_{19}]^{8-}$ were higher than those of $[Nb_6O_{19}]^{8-}$[6]. The strong basisity of $[Ta_6O_{19}]^{8-}$ is due to the negativities of surface oxygen atoms. The proton adsorption sites were evaluated by DFT calculations using proton adsorption energy. The bridged O sites on the surface of the cluster is expected to be proton adsorption sites whereas the terminal O sites are most negatively charged and are expected to act as base sites[6]. In addition, Lewis base properties of TBA-$M_6$ were evaluated by $CO_2$ fixation reactions. $CO_2$ fixation reactions to noto only **SO** but also amino compounds proceeded over both catalysts although TBA-$Ta_6$ had higher conversion than TBA-$Nb_6$.

# Synthesis, characterization and purification of tailor-made polyoxometalate (POM) catalysts for catalytic applications via the lacunary anion $[PMo_9O_{34}]^{9-}$

Jan-Christian Raabe[1*], Maximilian J. Poller[1] and Jakob Albert[1]

**Keywords:** Synthesis, Characterization, Nanofiltration, Membranes, Polyoxometalates, Purification

**Introduction.** Polyoxometalate (POM) catalyst synthesis for RedOx catalytic applications proves to be extremely challenging, as the most suitable substitution metal and a suitable synthesis strategy must be found. From a synthetic point of view, difficulties often arise in finding the optimal synthesis conditions, e.g. pH value, right precursor compound, purification of the resulting raw product etc.[1] The latter is currently the biggest challenge in synthesis, since defined pH values are required during POM synthesis and the precursor compounds usually contain alkali metals. This leads to undesired salt formation. Since both the POM and the alkali salt are equally soluble in aqueous medium, an efficient purification is usually severely limited. In organic synthesis, column chromatographic purifications have proven to be the method of choice for product separation; however an equivalent method for the separation of purely inorganic compounds does not yet exist. Therefore, we present a POM synthesis strategy starting from a triple lacunary Keggin species, with which a maximum of three out of twelve metal positions can be occupied by foreign transition metals. Directly coupled to the synthesis approach, we present an efficient nanofiltration process on a nanoporous membrane as diafiltration process, with which the salts can be completely removed from the POM raw product.[2]

**Experimental/methodology.** The synthesis strategy is based on an *in situ* lacunary approach. Here, the species $[PMo_9O_{34}]^{9-}$ (LHPA-3) is synthesized starting from molybdate and phosphate precursors in acidic aqueous solution.[3] In the next step the vacancies of the lacunary anion are filled by adding foreign, RedOx active transition metal precursors [M] (Figure 1).[4]

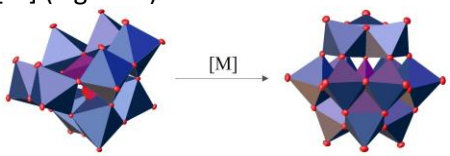

*Figure 1: Filling of the vacancies with foreign transition metals results in a substituted Keggin-type structure.*

The purification of the reaction solution (feed fraction) to remove unwanted salts is done by an nanofiltration process over four cycles in which the alkali salts are enriched in the permeate fraction and the POM in the resulting retentate fraction.[2]

**Results and discussion.** Using this approach we were able to incorporate different catalytically active transition metals into LHPA-3. All compounds were characterized spectroscopically and electrochemically. Furthermore, we could show that the incorporated transition metal has an influence on the whole electronic structure of the POM which causes a shift of the different RedOx processes, measured by electrochemical techniques. Our new developed nanofiltration process for desalination of POMs proves to be efficient since all POM elements seem to be rejected and the salts are removed completely.

**Keywords:** Heterogeneous Catalysis / Functionnal Mesoporous materials / sol-gel chemistry

**Introduction.** Polymer-functionalized mesoporous silica materials combine the textural properties of mesoporous materials and the chemical properties of polymers. These two features make them excellent candidates for diverse applications such as catalysis. The synthesis of such hybrid materials is limited by the functionalization step; a high density of polymers and a homogeneous distribution of this polymer within the pores remain difficult to reconcile [1]. We present here the synthesis and first results on catalytic properties of polymer-functionalized mesoporous silica materials prepared by an innovative and versatile process based on polyion complex (PIC) micelles, the Mesopic process, which overcomes the issues of density and homogeneity of functionalization [2, 3].

**Experimental/methodology.** The Mesopic process consists in the formation of polyionic complexes (PIC) formed by electrostatic interaction between two hydrophilic polymers, namely (i) double-hydrophilic block copolymer : either a poly(poly(ethylene oxide)-methyl ether acrylate)-b-poly(styrene sulfonate) (PAPEO-b-PSS, bearing strong acid groups) or a poly(poly(ethylene oxide)-methyl ether acrylate)-b-poly(acrylic acid) (PAPOE-b-PAA, bearing weak acid groups) and (ii) an oppositely charged polyamine. During the sol-gel process, the PAPEO chains are anchored in the silica. The polyamines are then removed from the PIC assembly by pH stimulation, thus revealing the porosity and the weak/strong acidic functions. Materials are characterized by TEM, SAXS, TGA, ICP/MS, $N_2$ adsorption, and acid-base titration to determine the number of acid functions.

Catalytic materials bearing strong acid sites have been evaluated in the esterification of fatty acids by methanol. The experiments have been carried out in batch reactor using carboxylic acids going from hexanoic to palmitic acid in methanol at 60°C during the desired time. Catalytic materials bearing weak acid sites have been evaluated in the Mannich reaction using as substrates cyclohexanone, aniline and benzaldehyde in acetonitrile, in a btach reactor at 40°C during the desired time. Reaction products analysis was carried out using GC-MS and GC-FID.

**Results and discussion.** We first showed in both cases that despite the PAPOE chains not being covalentely bonded to the silica, the materials remain stable in catalytic conditions and the reaction media, i. e. methanol and acetonitrile.

We further showed that, in the case of esterification reaction, we could obtain conversion up to 20-30% comparable to what can be obtained using Amberlyst 15 catalysts, or for other sulfonic acid functionalized silicas.

The first experiments on weak acid catalysts in the Mannich reactions also exhibited good results, comparables to those precedently obtained by the group, using alginic acid heterogeneous catalysts [4].

These results evidence the great potential of such materials, synthesized by the Mesopic process, avoiding the costly calcination step, and they will be discussed in details during the conference.

# Shielding effect of mesoporous catalysts for plasma-enhanced catalytic synthesis of ammonia under ambient conditions

Y. Wang[1], X. Tu[1*]

[1]*Department of Electrical Engineering and Electronics, University of Liverpool, Liverpool, L69 3GJ, UK*

**Keywords:** Non-thermal plasma; Plasma catalysis; Ammonia synthesis; Mesoporous catalysts; MCM-41.

**Introduction**

Plasma catalysis is a promising technology for decentralized small-scale ammonia ($NH_3$) synthesis under mild conditions using renewable energy and shows great potential as an alternative to the conventional Haber-Bosch process[1]. To date, this emerging process still suffers from a low $NH_3$ yield due to limited knowledge in designing highly efficient catalysts and the in situ plasma-induced reverse reaction (i.e., $NH_3$ decomposition). Here we show that a bespoke design of supported Ni catalysts using mesoporous MCM-41 could enable efficient plasma-catalytic $NH_3$ production at 35 °C and 1 bar with >5% $NH_3$ yield at 60 kJ/L. Specifically, the Ni active sites were deliberately deposited on the external surface of MCM-41 to enhance plasma-catalyst interactions and hence improve $NH_3$ production. The desorbed $NH_3$ could then diffuse into the ordered mesopores of MCM-41 to be shielded from decomposition due to the absence of plasma in the mesopores, that is, shielding protection, thus driving the reaction forward effectively. This strategy sheds light on the importance of a rational design of catalysts specifically for improving plasma-catalytic processes[2].

**Experimental/methodology**

Plasma-catalytic $NH_3$ synthesis was conducted in a coaxial dielectric barrier discharge (DBD) plasma reactor with circulating water as the ground electrode, which can maintain a reaction temperature of 35 $^{o}$C during the reaction. The DBD reactor was connected to an AC high-voltage power supply with a peak voltage of up to 25 kV. The discharge power was controlled between 16 and 40 W, and the frequency was fixed at 9.2 kHz.

**Results and discussion**

Compared to the plasma alone, packing the DBD reactor with $SiO_2$ or MCM-41 supports enhanced the ammonia synthesis rate ($R_{NH3}$), i.e., 575 µmol/g/h (plasma alone) vs. 1131 µmol/g/h (with $SiO_2$) and 1452 µmol/g/h (with MCM-41). The comparatively high $R_{NH3}$ value of the plasma-MCM-41 system could be ascribed to the highly porous structure of MCM-41 compared to $SiO_2$. As expected, loading Ni onto either $SiO_2$ or MCM-41 enhanced the $R_{NH3}$ significantly, proving the active role of metallic Ni in ammonia synthesis. Again, the Ni/MCM-41 catalysts were more active than Ni/$SiO_2$ with the following activity order: Ni/MCM-out > Ni/MCM-both > Ni/MCM-in > Ni/$SiO_2$. In particular, Ni/MCM-out exhibited a high $NH_3$ yield of about 3.7%, which was ~8 times higher than that of the plasma alone. Furthermore, the plasma-catalytic system using Ni/MCM-out displays very promising performance (at a low flow rate of 40 mL/min) with a high $NH_3$ yield (5.3%) and concentration (27115 ppm) at an energy yield of 1.2 g$NH_3$/kWh. The energy yield of the Ni/MCM-out system could be improved to 3.9 g$NH_3$/kWh by increasing the flow rate to 1.2 L/min, but this operation compromises the ammonia concentration. To illustrate this enhancement of $NH_3$ yield using mesoporous catalyst, we have developed a unique integrated plasma/FTIR cell for *in situ* probing of plasma-induced surface reactions over different Ni/MCM-41 catalysts, together with comprehensive catalyst characterization and plasma diagnostics, to clearly demonstrate and elucidate this new strategy for enhanced plasma-catalytic ammonia synthesis under ambient conditions with solid and convincible evidence.

[*]*christoph.rameshan@unileoben.ac.at*

**Keywords:** tailored surfaces, exsolution, nanoparticles, perovskite oxides, reverse water-gas shift reaction

**Introduction.** In the field of $CO_2$-utilization, perovskite-type oxides are promising catalysts for the $CO_2$-activation e.g., via the **r**everse **W**ater-**G**as **S**hift reaction (rWGS) [1, 2]. The $ABO_3$ structure of these materials allows for tailored properties such as enhanced catalytic activity and selectivity, as certain metal compositions trigger *in-situ* nanoparticle exsolution of the B-site elements (e.g., Co, Fe, …) under reducing conditions [3]. Hereby, the transition metals migrate from the lattice to the surface, forming uniformly distributed, stable, and catalytically active metallic nanoparticles, anchored in the perovskite support.

**Experimental/methodology.** Several Pechini sol-gel protocols for perovskite-type oxides are known [4], but their influence on the resulting material is not always comprehensible. By varying the synthesis conditions through changing the pH and/or adding different additives/complexing agents, the impact on the catalyst **N**d$_{0.6}$**C**a$_{0.4}$**F**e$_{0.9}$**Co**$_{0.1}$O$_3$ (NCF-Co) was investigated. The materials were analysed and compared via **X**-**R**ay **D**iffraction (XRD) and **S**canning **E**lectron **M**icroscopy (SEM), in addition to **T**emperature **P**rogrammed **R**eduction measurements (TPR). Surface areas were determined using the **B**runauer–**E**mmett–**T**eller method (BET) [5]. The exsolution process was monitored in regards to on-set temperatures and the size of the particles after rWGS reaction.

**Results and discussion.** Most synthesis variations resulted in phase-pure catalyst materials, displaying different surface morphologies (Fig. 1) and areas. Not all methods could enhance the catalytic activity, preliminary results suggest that a combination of elevated pH and additives, such as ethylene glycol, might be most promising in regards to enhanced catalytic activity.

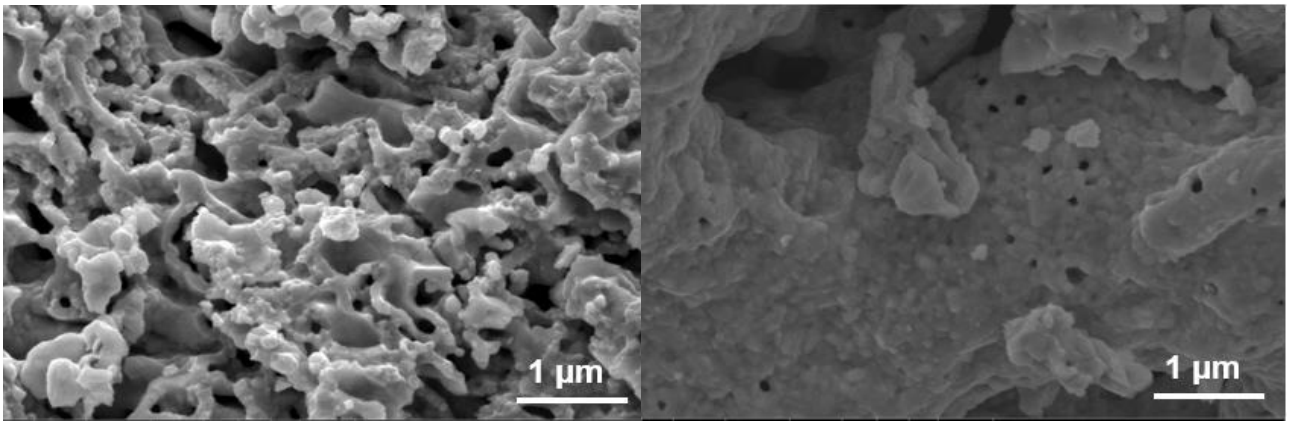

**Fig. 1: SEM images of Nd$_{0.6}$Ca$_{0.4}$Fe$_{0.9}$Co$_{0.1}$O$_3$, using modified Pechini sol-gel methods: pH 1 and addition of ethylene glycol and citric acid (4:1 ratio, left), adjusted to pH 3 with ammonia (right).**

# Lewis acid zeolites by regioselective manipulation of germanosilicates

M. Shamzhy*, J. Zhang, S. Abdi, J. Čejka

*Charles University, Prague, Czech Republic*
**mariya.shamzhy@natur.cuni.cz*

**Introduction.** Zeolites are porous crystalline solid acid catalysts that are widely used in the petrochemical industry and have a high potential for new applications. A particularly interesting class of zeolites includes germanosilicates. Although the use of germanosilicates in catalysis is strongly limited by their weak acidity and low hydrothermal stability, the enhanced lability of Ge-O vs. Si-O bonds and the regioselective location of Ge atoms in certain framework positions make them ideal starting materials for rational top-down synthesis of catalysts with tunable functionalities and structures [1]. To tailor Lewis acid catalysts with variable metal sites, we have developed post-synthesis isomorphous substitution of Ge with different tetravalent elements coupled with Ge recovery and recycling [2]. In addition, we have produced a unique set of Lewis acid zeolites with monotonically changing micropore sizes when combining a controllable size reducing of Ge-enriched structural units and the incorporation of framework tetravalent elements [3].

**Experimental/methodology.** IWW, IWR, UOV, and UTL zeolites of different chemical compositions were hydrothermally synthesized and further subjected to different postsynthesis modifications (e.g., isomorphous substitution with tetravalent elements or Assembly-Disasembly – Organisation – Reassembly [1]). The resultant catalysts were thoroughly characterized using X-ray diffraction, physisorption, electron microscopy, chemical analysis, and IR, NMR, and UV-VIS spectroscopies. The Ti-containing catalysts were tested in the epoxidation of alkenes, while Sn- and Zr-substituted ones were assessed in the Meerwein-Ponndorf-Verley (MPV) reduction of aldehydes.

**Results and discussion.** By optimizing the degermanation conditions, up to 94 % of Ge was recovered from zeolites of different structures and further recycled in their hydrothermal synthesis. Subsequent metalation of degermanated materials resulted in a set of Ti-, Sn-, and Zr-substituted IWW and UTL catalysts outperforming hydrothermally synthesized zeolites of the same structure in the epoxidation of 1-octene and MPV reduction of furfural. This result is explained by a higher concentration of framework metal sites achieved when using the top-down vs. bottom-up synthesis approach.

The combination of Ti or Sn incorporation and rearrangement of Ge-enriched structural units in the IWW, IWR, UTL and UOV frameworks resulted in a series of Lewis acid zeolites with controllable structures and micropore sizes. Diffraction and microscopy analyses verified the structural characteristics of the daugther materials, while IR spectroscopy using adsorbed probe molecules (pyridine, $d_3$-acetonitrile) evidenced the existence of different framework four-valent metal coordination environments (‘closed’ and ‘open’ sites). Control over the structural and acidic characteristics of designed zeolites allowed us to address their property-function relationships. In 1-hexene and cyclohexene epoxidation, the conversion of reactants and selectivity towards the targeted epoxides gradually decreased with micropore size of Ti-containing zeolites. In contrast, in MPV-reduction of citronellal, higher selectivity to the targeted product was achieved over daughter Sn-substituted zeolites with a smaller reaction space around acid centers compared to the parent stannogermanosilicates. In summary, the proposed synthesis approach that utilizes both structural and chemical modification of germanosilicates provides the tool for better control over the characteristics of zeolite catalysts.

**Keywords:** Ammoximation, cyclopentanone, cyclopentanone oxime, TS-1

**Introduction.** Nylon 6 is currently an oil-derived polymer whose production encompasses the reaction of cyclohexanone with hydroxylamine to render cyclohexanone oxime, its further Beckmann rearrangement to caprolactam and the subsequent polymerization to Nylon 6. A very sustainable route to produce Nylon has recently been industrially implemented that involves the in-situ synthesis of hydroxylamine by the catalytic oxidation of ammonia with $H_2O_2$ in the presence of Titanium Silicalite zeolite (TS-1) that reacts with cyclohexanone yielding the oxime.[1] Interestingly, Nylon 5 could be produced from cyclopentanone (CPONE) following the same sustainable reaction route developed for Nylon 6, the $H_2O_2/NH_3$ ammoximation of CPONE, Beckmann rearrangement to the lactam (δ-valerolactam) and polymerization to Nylon 5.

**Experimental/methodology.** A series of parent TS-1 catalysts with different Ti loading was prepared using a modified dried sol-gel conversion protocol. This methodolgy results in a low usage of TPAOH while still yielding TS-1 crystallites with dimensions of a few hundred nm. Larger crystallite size prevents the access of the solution to the inner part of the crystallite. Additionally, aiming at improving the activity, a TS-1 prepared with an initial ratio of Ti/S= 0.12 during the preparation was further modified by post-treatment of this parent TS-1 with TPABr and ethylamine (EA).

**Results and discussion.** The ammoximation of cyclopentanone to cyclopentenone oxime has been studied using a series of zeolites and mesostructured silica with different heteroatoms and structures. Because the best catalytic activity was that of TS-1, a series of catalyst varying amounts of Ti was synthesised and characterised by chemical analysis, XRD), $N_2$ adsorption, deuterated acetonitrile chemisorption, UV-VIS spectroscopy and XPS. It was found that the intrinsic rate per Ti site (TOF number) in TS-1 catalysts strongly depends on the Ti loading, showing a volcano type curve (Fig. 1). Additionally it was observed that the simultaneous postreatment of TS-1 with TPAOH and EA results in a substantial increase of the TOF that was explained by the creation of new Ti species (such as $Ti(OSi)_3OH$ and $Ti(OSi)_2(OH)_2(H_2O)_2$).

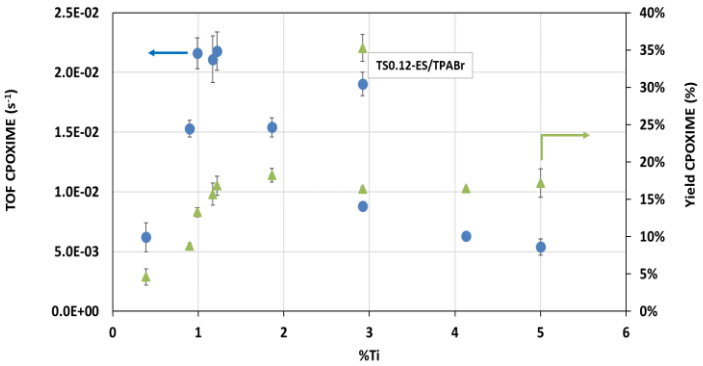

**Figure 1.** Study rate of reaction of as-prepared samples. Reaction conditions: 0.5 h of reaction time (except for T/Si= 0.003 that is 2 h), 70 °C, 1 wt % catalyst, 5 wt % of cyclopentanone, 85 % t-BuOH/$H_2O$, $H_2O_2$/CPO and $NH_3$/CPO mol ratio of 1.2.

**Keywords:** Silicoaluminophosphate, CIT-16P, SAPO-17, 3D-3D Transformation, Methanol-to-olefins

**Introduction.** The methanol-to-olefins (MTO) process uses small-pore silicoaluminophosphate (SAPO) molecular sieves with lower acid strength than isomorphous zeolite counterparts to convert methanol. The selectivity of light olefins (ethylene, propylene, and butylenes) is primarily determined by the cage topology [1] and acid site density [2] of the used small-pore molecular sieves. This study presents a new SAPO material, CIT-16P, that transforms to SAPO-17 and produces more propylene than ethylene in MTO reaction, supporting our theory of acid site density in erionite-type molecular sieves. [2] Results of CIT-16P-derived SAPO-17 are also compared to those of the recently-reported isomorph ECNU-38P. [3]

**Experimental/methodology.** Bisquinuclidinium-butane (DiQ-$C_4$) was used as the organic structure-directing agent (OSDA) for CIT-16P. The best gel composition and hydrothermal condition for CIT-16P was 0.04 $SiO_2$ : 0.47 $Al_2O_3$ : 0.45 $P_2O_5$ : 0.29 DiQ-$C_4$-$(OH)_2$ : 40 $H_2O$ at 190 °C, 72 hours. The transformation of the framework into SAPO-17 was achieved by removing OSDA from as-made CIT-16P. The MTO reaction tests were performed at 400 °C with a weight-hourly space velocity of 1.3 $h^{-1}$ of methanol in a fixed-bed reactor.

**Results and discussion.** The ideal crystallization conditions for CIT-16P were found in the vicinity of those for SAPO-17 (ERI) and SAPO-56 (AFX). The transformation of CIT-16P into SAPO-17 was indicated by the change of the powder X-ray diffraction (PXRD) patterns before and after the removal of occluded OSDA. The Rietveld refinement of the PXRD pattern of as-made CIT-16P revealed that it is entirely composed of distorted cancrinite composite building units stabilized by the presence of occluded OSDA and the extra oxygen site (Figure 1, left) confirmed based on the solid-state $^{27}Al$ NMR spectrum. In the MTO reaction at 400 °C, SAPO-17 derived from CIT-16P produced more propylene than ethylene (E/P ~ 0.66, Figure 1, middle), which contradicts our cage-defining ring theory [1] for MTO selectivity distribution. The low Si content (Si/T ~ 0.02) of the parent CIT-16P may be responsible for this low E/P ratio, which results in sluggish formation of aromatic intermediates (Figure 1, right). [2] Also, CIT-16P showed a longer catalytic lifetime and higher conversion than ECNU-38P-derived SAPO-17 [3] due to its lower external acid sites.

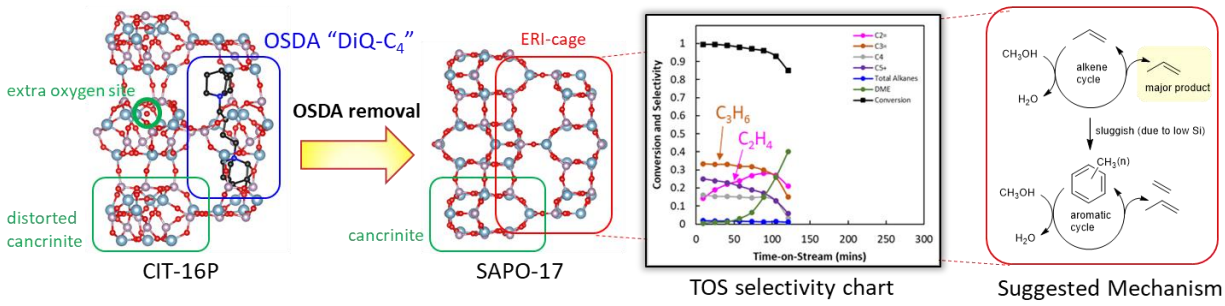

**Figure 1.** (left) Transformation of CIT-16P into SAPO-17, (middle) MTO time-on-stream olefin selectivity chart, and (right) suggested MTO mechanism within a low-Si ERI cage

# Hidden limitations: lactate synthesis over Sn-BEA zeolites with record Sn contents synthesized by a novel bottom-up strategy

Gleb Ivanushkin[1], Michiel Dusselier[1*]

**Keywords:** Lewis acid catalysis, Sn-BEA, biomass conversion, methyl lactate, zeolite synthesis

**Introduction.** A key challenge for the chemical industry is the efficient and selective conversion of substrates derived from biomass. For the last two decades, Sn-BEA zeolites have emerged as first-class Lewis acid catalysts for a variety of biomass-related reactions: isomerization and epimerization of sugars [1], Baeyer-Villiger oxidation [2], and Meerwein-Ponndorf-Verley reduction [3]. Furthermore, the chemical route of producing lactic acid and alkyl lactates from carbohydrates using heterogeneous Lewis catalysts has great potential since low-cost purification and reduced (salt) is implied in the technology [4]. Nowadays, attaining high metal loadings in Sn-BEA catalysts is only possible through the post-synthetic approach, which is limited by the inherited properties of the parent zeolite. Here, by using a novel hydrothermal synthesis procedure, we were able to synthesize a series of Sn-BEA zeolites, among which one with the highest ever reported Si/Sn (final material) ratio of 14. This ratio has never been obtained in hydrothermal synthesis. On top, we have run catalytic conversions of 1,3-dihydroxyacetone (DHA) to methyl lactate (ML) and compared these results with the widely described Sn-BEA-F made via the fluoride approach (and with less Sn).

**Experimental/methodology.** The synthesis of the new Sn-BEA is the subject of a patent application and will be detailed in the talk, but it involves a new reactor type and a hydroxide media environment. Catalytic tests at low temperature (80°C) of DHA in methanol to ML were performed in 10 mL thick-walled glass reactors placed in a preheated block. Generally, 112.6 mg of DHA, 80 mg of catalyst, 60 mg of naphthalene, and 5.0 mL of methanol were added in the glass reactor, put in the block, and vigorously stirred for the required time, followed by rapid chilling in an ice bath for sampling. For high-temperature reactions (>100°C), a closed stainless steel reactor with a sampling valve was used. After the reaction, products were quantified through GC-FID analysis using a calibration curve.

**Results and discussion.** A Sn-BEA zeolite series with a wide Si/Sn ratio variation of 14-200 was synthesized. For benchmarking, a sample of Sn-BEA-F (classic fluoride approach) was made with Si/Sn 160. For all materials, phase purity was verified with PXRD, while crystallinity, surface area, and micropore volume were calculated from $N_2$-physisorption. Crystal size, heteroatom distribution, and chemical composition of synthesized zeolites were determined by TEM EDX and confirmed by ICP-AES. Moreover, the amount of Lewis acid sites was determined by FT-IR of absorbed $CD_3CN$ as a probe molecule. The evaluation of catalytic data suggests that the Sn-BEA zeolite with Si/Sn 14 demonstrates 3-fold improved productivity after one hour of reaction versus the comparison sample. Based on the Arrhenius plot in a wide temperature range, very similar apparent activation energies were established (64 kJ/mol for both materials), which corresponds to the literature [5]. We have evidence that both samples undergo mass transport limitations: we surmise Sn-BEA-F has classic diffusion limitations occurring due to long-distance diffusion in the large crystals (10 µm), while the extreme concentration of Lewis sites cannot be efficiently supplied by enough diffusing reactants in the small-crystal Sn-BEA Si/Sn 14 (200 nm).

**Keywords:** organo-alkalis taylored LDH, condensation and aldol addition reactions

**Introduction.** Solid bases received a pretty high importance in the catalytic field due to their well-known advantages of non-corrosive and easier product separation for a a variety of domains [1] including environmental protection or fine chemistry. Among these, hydrotalcites-type materials (LDH) continue to elicit a great interest for catalysis owing to their specific properties. Further, the replacement of the alkaline cation with organic alkalis may offer a more viable alternative also avoiding the contamination of the product [2]. Based on this state of the art, the aim of this study was to re-visit LDH structures prepared in the presence of TMAOH (Tetramethylammonium Hydroxide) or TBAOH (Tetrabutylammonium Hydroxide) and to evaluate these materials in the synthesis of 3-ethoxypropionitrile by aldol addition and 2,6-dicyclohexylidene-cyclohexanone by Claisen-Schmidt condensation.

**Experimental/methodology.** The synthesis of LDH was carried out in a Mortar Grinder at a rate of 100 rot·min$^{-1}$ for 1 h at a pH of 10 at RT taking quaternary salts as hydrolysis agents. For comparison, nitrates were as well co-precipitated from corresponding solutions, both with inorganic/organic bases. All the resulted solids were washed until a neutral pH, dried at 120 °C for 24 h and further calcined at 460 °C for 18 h. The samples were structurally characterized by XRD, DRIFT, BET, DTA-TG, and TEM. Their basicity was evaluated from the irreversible adsorption of acrylic acid ($pK_a$ = 4.2) and phenol ($pK_a$ = 9.9). The catalytic reactions were carried out in batch conditions following a continuous evaluation of the yield.

**Results and discussion.** Claisen-Schmidt condensation and the synthesis of 3-ethoxypropionitrile require catalysts with different basicities [3]. For the Claisen-Schmidt condensation the addition of Zn or Y to the Mg-Al-LDH in loadings below 15 % led to an increase of the basicity (higher for Zn) that corresponded to an increase of the conversion with almost 14% compared to the parent LDH. Noteworthy, the selectivity in the 2,6-dicyclohexylidene-cyclohexanone product was total. No benzoic acid as by product due to the oxidation of benzaldehyde has been detected.

The basicity was as well influenced by the organic base utilized in the construction of the LDH. TBAOH which has an increased basicity compared to TMAOH generated a more basic catalyst and, in acordance, the conversion of cyclohexanone to the dicondensate compound on this LDH was 10% higher.

On the other side, the comparison of Li-Al and Mg-Al-Y LDH indicated an enhanced basicity of the LDH with Y (four times higher) compared to the catalysts with Li. Correlated to this, the activity of the Mg-Al-Y LDH in the synthesis of 3-ethoxypropionitrile was three times higher.

Recycling the catalysts five times occurred with no change in the catalytic behavior thus demonstrating a very good stability, also confimed by the investigated characterization techniques.

**Keywords:** organic semiconductors, Knoevenagel condensation, Schiff-base condensation, Staudinger reaction, photocatalysis.

**Introduction.**

Organic semiconductors, particularly conjugated polymers (CPs), have shown exceptional optoelectronic properties and are being explored for commercial applications, such as organic light-emitting diodes (OLEDs) and organic field-effect transistors (OFETs). Conjugated porous polymers (CPPs), on the other hand, are materials that combine the optoelectronic properties of their non-porous congeners, i.e., CPs, with high porosity and lightweightness.[1] As such, they have shown promise as catalysts for photocatalytic transformations. However, metal-catalyzed reactions are usually used for their synthesis, e.g., Suzuki, Sonogashira, or Yamamoto, which poses a certain risk for (waste) water remediation since metallic catalyst residues can enter the water and contaminate it.[2] Therefore, there is great interest in metal-free polycondensation reactions for the synthesis of organic semiconductors for heterogeneous catalysis.

**Experimental/methodology.**

In this study, different transition-metal-free reactions such as Knoevenagel, Schiff-base, or Staudinger reactions were used to prepare highly porous π-conjugated foams by soft-templating, which were characterized in detail using solid-state NMR and FTIR spectroscopy, elemental analysis, diffuse reflectance spectroscopy (DRS), photoluminescence (PL), and cyclic voltammetry (CV). These highly porous foams were then evaluated for their photocatalytic performance in the sulfoxidation of methyl phenyl sulfide and degradation of model organic pollutants in water.

**Results and discussion.**

For the first time, organocatalyzed reactions (i.e., Knoevenagel, Schiff-base, or Staudinger reactions) and soft templates (i.e., emulsions or foams) were combined to obtain highly porous π-conjugated foams.[3,4] The special optoelectronic properties of these foamy photocatalysts enable them to efficiently catalyze a model sulfoxidation reaction or the degradation of aniline dissolved in water under visible light.

**Keywords:** metal organic frameworks, visible light absorption, hydrogen, water splitting, titanium SBU

**Introduction.** The world's growing need for renewable energy sources make it imperative to find sustainable and green fuels, e.g. hydrogen ($H_2$). However, photocatalytic water splitting for $H_2$ production is still a challenging reaction for ordinary metal-oxide-based catalysts.[1] Metal-organic frameworks (MOFs) are porous and crystalline materials that have been widely investigated by the scientific community in recent years and show excellent properties as photocatalysts. In this regard, Ti-based MOFs are particularly interesting because their photo-responsive behavior promotes $H_2$ evolution reaction (HER), one of the half reactions for water splitting.[2] A newly described and photoactive Ti-MOF with 2D secondary building units (SBUs) and a biphenyl organic linker has caught our attention due to its unique structure and promising composition for enhanced light absorption.[3]

**Experimental/methodology.** In this contribution, we investigate the photocatalytic properties of *COK-47* towards HER under diverse light sources and compare it to benchmark Ti-based MOFs. We have replicated the original syntheses reported by Smolders[3], yielding two materials: COK-$47_{Small}$ and COK-$47_{Large}$. We have also come up with a new and simplified synthesis procedure using titanium(IV) tetraisopropoxide (TTIP) and biphenyl-4,4'-dicarboxylic acid (BPDC) as precursors in a DMF/MeOH mixture. The mixture is heated using microwave (MW) irradiation for 1h and after filtration, milling and drying, COK-$47_{\mathbf{New}}$ is obtained. All materials were thouroughly investigated in terms of their structure and morphology (XRD, TEM), connectivity and state (FTIR, Raman, XPS), surface area and missing ligand defects ($N_2$-physisorption and TGA) and optoelectronic properties (PL, TRES, DFT). Finally, their photocatalytic performance towards hydrogen evolution reaction was tested.

**Results and discussion.** We did a first-time detailed investigation on the optoelectronic and photocatalytic properties towards HER of COK-47. This new MOF is highly active in both UV and visible (with 29.5 and 8.6 $\mu mol\ h^{-1}$), setting it amongst the most active MOFs for – especially visible light driven – HER.

We were also able to identify the impact of defects and surface area on the activity and unraveled important insights on the reaction mechanisms of different sacrificial agents. Our data strongly suggests a ligand to metal charge transfer mechanism (LMCT), which, in combination with the 2D SBUs, allows for an efficient charge separation and extraction process.

**Keywords:** photocatalysis, organic synthesis, carbon nitride

**Introduction.** The *ad hoc* post-synthetic structural modification of graphitic carbon nitride (g-CN) offers a pathway for triggering a large range of organic reactions with a considerable increase of photocatalytic efficiency. As demonstrated both exeprimentally and theoretically, such improved efficiencies are the result of a better suited interaction between the CN surface and the reacting substrates.

**Experimental/methodology.** Various types of modification were carried out on the pristine g-CN for the specific photocatalytic organic C-X coupling (X = C, N, O, S). Amorphization and reduction (am-CN and red-CN) were performed by subjecting the g-CN to thermal treatiment under argon and hydrogen/argon flow respectively. Carbon vacancies were introduced by means of microwave irradiation (mw-CN).

**Results and discussion.** The pristine g-CN prepared by the melamine precursor was used as a starting platform and as the benchmark catalyst for the various photocatalytic organic reactions. The first target reaction was the C-C coupling between perflruoroalkyl compounds and halogenated electron rich substrates, where highest activities were observed with the am-CN photocatalyst, which showed a 5-fold higher activity as compared to g-CN.[1,2] By means of detailed structural charaterization and advanced $^{15}F$ NMR studies, the higher activity was partly related to the improved halogen-bonding between the structure of am-CN and the halogenated reagent. Moreover, given the radical mechanism of the reaction, DFT calculations [3] and EPR experiments [4] revealed the importance of defective domains and radical distributrion. The Ni-based dual photoredox catalysis was next explored for the C-X coupling of a variety of substrates, and it emerges that the mw-CN was by far the best photocatalyst. In this case, the more complex catalytic mechanism and the most critical structural parameters that defined the activity trends were discovered through a comprehensive investigation of the structure activity realtionship with various advanced methods of charaterization employing XPS, EPR, nanoIR, solid state NMR, HRTEM. It was found that the formation of C vacancies in the g-CN was instrumental to harness the CN-Ni binding and elecrtron transfer, thanks to the formation of either triazole moieties or imine/amine sites able to bind Ni to form a squre planar complex. DFT computational methods highighted the differences in energies of the possible complexes as well as the charge transfer dynamics. The catalysis exhibited a large scope with good to excellent activities, and a production rate for the model reaction that exceeded that of other benchmark photocatalysts.

**Keywords:** Plasmonic $Cu_2SSe$, Biomass valorization, $CO_2$ promoted reactions, Photon-driven process.

**Introduction.** Plasmon-induced catalysis (PIC) is a rapidly growing research interest with many potentially known strategic applications. Over the last two decades, the PIC has been recognized as a promising approach to many conventional thermo-photo-electro catalytic conversions [1]. However, various strategies have been developed to optimize their high catalytic activity in fine chemical synthesis and the associated plasmonic properties can enhance the selectivity and broad light-matter interactions. Indeed, colloidal semiconductor nanocrystals (NCs) of Cu chalcogenides have a unique size and shape-dependent catalytic performance that emerges due to nano-confined quantum dots. Whereas, the associated defects, band-structure engineering, and alloying influences the structural and optoelectronic properties [2]. Owing to the remarkable advances in copper chalcogenides with different sizes, shapes and tuneable compositions have promoted several PIC applications. The ubiquitous thermo-photo-electro catalytic reaction includes selective oxidation, selective reduction, cross-coupling, and addition reactions [3]. Moreover, Cu chalcogenide NCs have gained tremendous attention due to their high abundance, environmental compatibility, potentially stable crystal structures, and broad range of compositions. Thus, PIC with Cu chalcogenide NCs offers a realistic approach for large-scale synthesis and sustainable applications ($CO_2$ reduction, and biomass valorization), that can alleviate greenhouse gases [4].

**Results and discussion.** In the present study, we are exploring the cuprous sulfide-selenide ($Cu_2SSe$) alloy NCs for PIC applications. Nevertheless, the chemical synthesis route is used to prepare the $Cu_2S$, $Cu_2Se$, and $Cu_2SSe$ NCs, where the cation exchange mechanism induces the formation of the $Cu_2SSe$ phase. **Fig. (a)** shows the comparative XRD pattern of $Cu_2S$, $Cu_2Se$ and $Cu_2SSe$, reveals the structural purity and the phases obtained for $Cu_2Se$ and $Cu_2S$ are significant matches with their JCPDS data ($Cu_2Se$:65-2982 and $Cu_{1.96}S/Cu_{1.92}S$:29-0578). Indeed, the change in XRD phases of the prepared $Cu_2SSe$ NCs discloses the formation of binary chalcogenide, and these XRD peaks are close matches with JCPDS card number $Cu_2SSe$:24-0376. **Fig. (b)** and **(c)** show the SEM and AFM images of $Cu_2SSe$, relate the nanocrystalline nature and exhibit the localized surface plasmon resonance (LSPR) properties. Detailed measurements of LSPR are being persuaded and PIC applications are in progress. Finally, the control experiments are also being performed and will tailor the product selectivity by designing advanced heterostructures with low-dimensional materials.

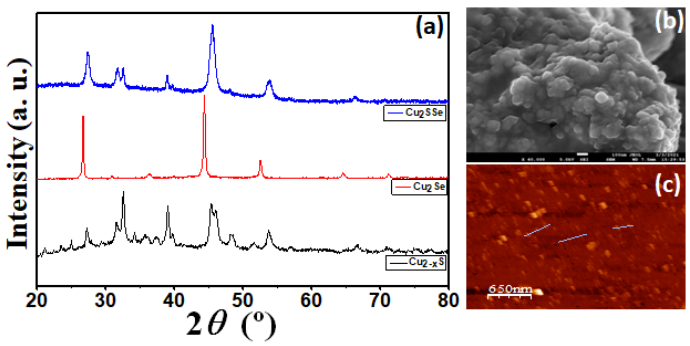

**Fig.** XRD of $Cu_2S$, $Cu_2Se$, and $Cu_2SSe$ (a); SEM of $Cu_2SSe$ (b); AFM of $Cu_2SSe$ (c).

**Keywords:** Mxenes, photocatalysis, hydrogen

**Introduction.** MXenes are recently discovered 2D materials that present interesting properties for a wide range of applications. MXenes are constituted by alternate layers of a metal (M) and a carbon or nitride layer (X), the latter always internal and sandwiched between two metal sheets.[1] Normally, these materials are obtained by delamination of the corresponding MAX phase by removal of $Al^{3+}$ with HF.[2] Due to the corrosive and hazard risks associated to the use of concentrated aqueous HF solutions, there is a need to develop alternative green delamination procedures. On the other hand, for application in photocatalysis, it is necessary to control the band gap of these materials and to align the energy of the conduction and valence band to the optimal potentials to promote a particular chemical reaction. Considering the two commented problems of MXene synthesis, it occurred to us that innovative preparation procedures could be used to avoid HF, while transforming a conductive MXene into a semiconductor material for its use in photocatalysis. Herein it is reported that laser ablation of the MAX phases is a general procedure to prepare MXene quantum dots (MxQDs) that are able to evolve hydrogen photocatalytically upon irradiation with Visible light.

**Experimental/methodology.** *Material preparation*: Preparation of MxQDs was carried out suspending the MAX phase (3 mg) in water (4 mL). The suspension was sonicated and irradiated with the second harmonic of a Q-switched Nd:YAG laser. Formation of MxQDs was followed by measuring periodically the optical absorption and photoluminescence ($\lambda_{ex}$ 350 nm) of the cuvette.

*Photocatalytic experiments*: The photocatalytic reactions were carried out using a suspension of the corresponding MxQDs that was re-dispersed in 16 mL of Milli-Q water adding 4 mL of triethanolamine (TEOA) as sacrificial electron donor. The suspension was stirred at room temperature and irradiated with a 300 W Xenon lamp equipped with a cut off filter ($\lambda > 450$ nm) to ensure irradiation with visible light. The evolving gases were analyzed connecting directly the photoreactor to an Agilent 490 Micro GC system.

**Results and discussion.**Herein, we have reported that 532 nm laser ablation in liquid in the absence of any aggressive reagent produces MXene QDs. The process of MxQDs formation can be conveniently followed by the increase in the optical absorption in the UV and photoluminescence intensity as well as by dynamic laser scattering of the suspension. HR-TEM imaging confirms the crystallinity of the materials and their MXene structure with average lateral particle size of 5 nm, while according to their thickness measured by AFM most of them are constituted by single layer or few layers of MXene QDs. Importantly, the procedure leads to oxygen-terminated MXenes, IR spectroscopy suggesting the presence in some cases of terminal O-H ($Ti_3C_2$ and $Ti_2C$ QDs) and O ($V_2C$ QDs) groups. The trend in the bandgap energy as a function of the particle size and surface termination of these MxQDs has been estimated by DFT calculations. This strategy should lead to effective band engineering. The bandgap opening in QDs has allowed us to determine the photocatalytic $H_2$ generation activity in the absence of photosensitizing dyes, giving values in the range of $mmol_{H2}xg^{-1}$ that are in the range of the best photocatalysts, even without further optimization.

**Keywords:** Atomic Layer Deposition, 2D materials, photocatalysis, electrocatalysis, HER.

**Introduction.** 2D semiconductor transition metal dichalcogenides have attracted considerable attention due to their layered structure, suitable band gap, electrochemically active unsaturated edges and relatively good stability against photocorrosion. These properties result promising for different applications including, Li-ion batteries, photocatalysis and hydrogen evolution reaction (HER). Apart from the widely studied 2D $MoS_2$, 2D selenide and telluride equivalents - $MoSe_2$ and $MoTe_2$ - have recently gained considerable interest, due to their higher electrical conductivity, wider inter-layer distance and narrower bandgap (as compared to $MoS_2$), high surface area and close to zero Gibbs free energy edges for hydrogen adsorption. Unlike sulfide dichalcogenides, the lack of Se and Te precursors have prevented the synthesis of selenide and telluride dichalcogenides by ALD. In order to surpass such impediment, we present a set of novel in-house synthesized Se and Te compounds, which were successfully combined with commercial Mo precursor to synthesize $MoSe_2$ and $MoTe_2$ by ALD [1-5].

**Experimental/methodology.** The 2D molybdenum dichalcogenides where synthesized by ALD, using commercial precursor for Mo and S, and in-house precursors for Se and Te. The prepared samples where characterized using SEM, TEM, XPS, Raman and XRD. In order to analyze the catalytic performance, photocatalysis (by the degradation of methylene blue and hexane) and electroctalysis (HER in acidic and basic media) tests were performed.

**Results and discussion.** The as-deposited ALD $MoS_2$, $MoSe_2$ and $MoTe_2$ on substrates of different nature were extensively characterized by different techniques, which confirmed the chemical composition and revealed the growth of 2D flaky nano-crystalline $MoS_2$, $MoSe_2$ and $MoTe_2$. In parallel, $MoS_2$, $MoSe_2$ and $MoTe_2$@$TiO_2$ nanotube layers (TNTs) heterostructures were fabricated in a simple and fast fashion to explore and exploit the $MoS_2$, $MoSe_2$ and $MoTe_2$ photo- and electrocatalytic properties. TNTs act as excellent photoactive supporting material providing a high surface area, unique directionality for charge separation, and highly effective charge collection. The presentation will introduce and describe the synthesis of the 2D Mo dichalcogenides, the corresponding physical and electrochemical characterization and encouraging results obtained in HER [4,5], photocatalysis [4-6] and Li-ion batteries [7].

**Keywords:** 2D $MoS_2$, platinum, nanoparticles, cluster, SACs, HER, electrocatalysis, STM

**Introduction:**

Transition metal chalcogenides are broadly investigated catalysts, limited by the relative inertness of their pristine basal plane $MoS_2$ single layers modified by substitutional oxygen can harvest the synergistic benefits of stably anchored single-atom sites and activated $MoS_2$ basal planes. [1]

$MoS_2$ single-layer substrates with embedded non-metal heteroatoms also offer the benefit of site densities that are much higher than those reported previously in the literature for metal SACs on various substrates. Substitution of heteroatoms with different electronegativity as compared to the substituted chalcogenide atoms induces a local redistribution of the charge density. This can create a complex charge density landscape where ions can find their preferred sites for efficient adsorption and charge transfer [2].

**Experimental/methodology.**

The resulting active sites are of interest not only for their catalytic activity but also as anchoring sites for other metal atoms. Taking advantage of this property, we planned to form platinum nanoparticles, clusters and single Pt sites on the surface of 2D $MoS_2$, and then compared their catalytic properties in electrocatalytic hydrogen evolution reaction.

**Results and discussion**

The results of the research yielded interesting and forward-looking results from several The ultra-efficient Pt-$MoS_2$ catalysts are able to reach the activity of commercial Pt-C catalysts at three orders of magnitude lower Pt loadings of ~10 nanograms/$cm^2$, utilizing Pt a hundred times more efficiently than Pt single atom catalysts.

**Keywords:** ultradispersion, molybdenum sulfide, HDS catalysts, operando XAS, hydrogen evolution

**Introduction.** Layered transition metal (TM) sulfides like $MoS_2$ ($WS_2$, $ReS_2$) are widely studied in reactions involving $H_2$. The edges of $MoS_2$ slabs are currently viewed as the active sites. However, along with slabs, small clusters and single atoms (SAs) are present, with unknown structure and activity. Our research is focused on the structure and activity of these subnanometric sulfidic TM entities. Such species might be adsorbed on the support or be embeded into a framework (e.g. of a MOF or of N-doped carbon)[1]. In this work we applied different syntheses to obtain ultradispersed Mo sulfide species, studied their activity in thiophene hydrodesilfurization (HDS) and hydrogen evolution reaction (HER), then followed their evolution during the reactions by XAS *operando*.

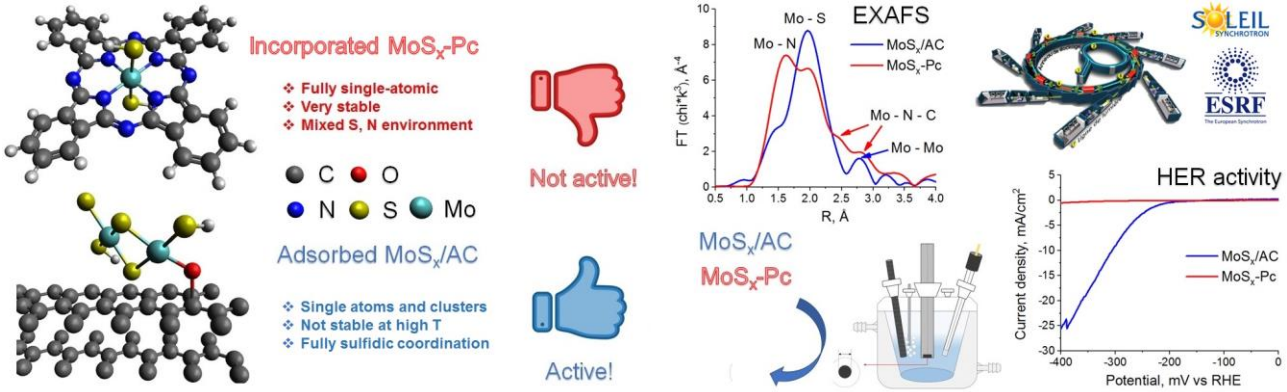

**Figure 1 Structures of incorporated and adsorbed $MoS_x$, the corresponding EXAFS spectra and HER activity**

**Experimental/methodology.** The catalysts (1 wt.% Mo) were obtained via dry impregnation/adsorption or via one-pot routes. Various supports (activated carbon (AC), $TiO_2$, $SiO_2$, $Al_2O_3$) and various one-pot techniques were used. The systems were sulfided in $H_2S/H_2$ flow and characterized by TEM, UV-vis DRS, Raman, XRD, STEM-ADF and tested in the HDS of thiophene and in the electrochemical HER. The evolution of Mo species during sulfidation and during the HDS and HER reactions was investigated by *operando* QXAS at the ROCK beamline of SOLEIL synchrotron (for HDS) and *operando* HERFD XANES at the FAME-UHD beamline of ESRF synchrotron (for HER).

**Results and discussion.** The adsorbed few-atom clusters are exemplified by the $MoS_x$/AC catalyst and incorporated single atoms - by a phthalocyanine polymer $MoS_x$-Pc (Fig. 1). While $MoS_x$/AC demonstrated high specific activity per Mo atom in HDS and high current densities in HER, $MoS_x$-Pc was not active (Fig. 1). Physico-chemical techniques (Raman, STEM..) attest that few-atom clusters and SAs are present in $MoS_x$/AC,[2] whereas $MoS_x$-Pc contains only SAs. Operando QXAS has shown that Mo species on AC during sulfidation are transformed into sulfidic oligomers with 2-3 Mo atoms. In the $MoS_x$-Pc, Mo remains single-atomic, surrounded by 4 N and 2 S atoms (Fig. 1). Both species are stable during the HDS reaction. When exposed to HER conditions in the acidic media the adsorbed $MoS_x$ are oxidized and in $MoS_x$-Pc sulfur is replaced by oxygen. Our results suggest that both HER and HDS reactions require the presence of several (at least 2) Mo atoms in the active site, whereas fully single-atomic $MoS_nN_m$ species are inactive.

# Towards catalyst design and databases for molecular OER catalysis

Michael J. Craig,[1] Cian Clarke,[1] Timo Sommer,[1] Felix Kleuker,[1] Max García-Melchor,[1*]

[1]*School of Chemistry, CRANN and AMBER Research Centres, Trinity College Dublin, College Green, Dublin 2, Ireland*

[*]*E-mail: garciamm@tcd.ie*

**Keywords:** water oxidation, hydrogen production, catalyst design, machine learning, databases.

**Introduction.** Despite fossil fuels having brought forth the dawn of civilisation as we know it, they have also left an enduring effect on the Earth's climate. To address this, it is imperative that we devise renewable technologies to decarbonise our economy. For example, one could envision using sunlight to drive (photo)electrochemical water splitting devices to produce $H_2$, a highly energy-dense fuel when compressed and stored. A major roadblock in realizing this, however, is the lack of affordable and high-performing catalysts for the oxygen evolution reaction (OER).[1]

**Experimental/methodology.** All the quantum chemical calculations described in this presentation have been performed using density functional theory methods as implemented in the software Gaussian09, while machine learning models have been developed using scikit-learn.

**Results and discussion.** The first part of this talk will describe our recent findings which demonstrate that molecular catalysts obey the same OER scaling relations observed for heterogeneous systems, and thereby are constrained to the "overpotential wall" imposed by such relations.[2-4] This part will also discuss how some of the most active complexes reported in the literature can circumvent the overpotential wall, and how this knowledge can be translated into a set of catalyst design principles to advance the discovery of "ideal" molecular OER catalysts.

The second part of the presentation will be dedicated to the high-throughput screening of molecular OER catalysts using well-known ligand scaffolds and transition metals, demonstrating the universality and method independent nature of scaling relations.[5] This study has also led to the discovery of new complexes based on earth-abundant elements with predicted activities comparable to Ru-based catalysts, as well as the development of machine learning algorithms to assess OER activity at almost no computational cost and with errors comparable to state-of-the-art DFT methods.[6]

In the final part of this talk, we will outline our ongoing research efforts in the generation of a curated molecular OER database and compliant with the principles of findability, accessibility, interoperability, and reusability (FAIR).

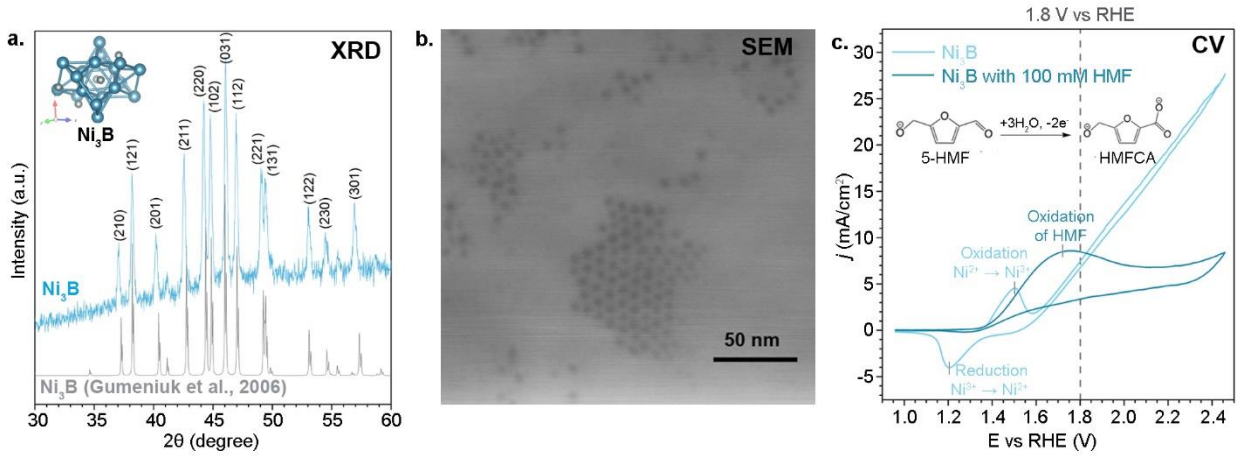
# Engineering the Solid State Synthesis and Processing of Nickel Boride Nanocrystals for Electrocatalytic Application

Jennifer Hong,[1,2] Dr. Loredana Protesescu,[1*] Prof. Dr. Paolo Pescarmona[2*]



[1]*Material Chemistry, Zernike Institute of Advanced Material (ZIAM), University of Groningen*

[2]*Sustainable Chemical Products and Catalysis, Engineering and Technology institute Groningen (ENTEG), University of Groningen*

**Introduction** Metal borides ($Ni_xB_y$, $Co_xB_y$), a relatively unexplored class of materials, have in recent years started to garner interests as they have shown potential to be efficacious electrocatalysts for water electrolysis under challenging conditions such as high pH or high temperatures.[1] Despite the increased surface area and surface optimization that are commonly displayed by other nanosized materials, the nanostructured $M_xB_y$ remains underdeveloped despite the prospective enhanced performance. The limited development of nano $M_xB_y$ is mainly due to the difficult synthetic process. Recent works have shown that synthetic methods at lower temperatures (<400 ºC) yield amorphous polydisperse nanocrystals (NCs), while phase purity remains an issue at higher temperatures.

**Experimental/Methodology** Here, a simple, scalable solid-state reaction of metal precursors ($NiCl_2$ or $Ni^0$, $CoCl_2$) and sodium borohydride ($NaBH_4$) is demonstrated to obtain a phase-pure nanocrystalline $Ni_xB_y$, $Co_xB_y$ and $(NiCo)_3B$. These nanostructured $Ni_xB_y$ were studied as electrocatalysts for the electrooxidation of the bio-based 5-(hydroxymethyl)furfural (HMF) to produce various useful products. The electrocatalytic tests were performed under the oxidative condition at pH 13 (0.1 M KOH) and constant potential of 1.8 V vs RHE with catalyst loading of 0.05 mg/cm$^2$.

**Results and Discussions** Through the solid-state reaction of either metallic $Ni^0$ or $NiCl_2$ with $NaBH_4$ at a relatively low temperature (400 °C) under atmospheric pressure, crystalline nanosized $Ni_2B$ and $Ni_3B$ could be obtained with high yield in pure phase and with narrow size distribution (15-30 nm) while reaction of $CoCl_2$ and $NaBH_4$ produce exclusively $Co_2B$ NCs. Through extensive mechanistic studies, we show that Ni nanoclusters (*approx.* 1 nm) are intermediate in the boriding process, while the halide precursors lower the decomposition temperature of the $NaBH_4$ (used as a reducing agent and B source). Using reaction mediators, we probe the differential nucleation and growth of Ni (clusters) or $Ni_xB_y$ NCs while using L (amine, phosphine) and X-type (carboxylate) mediators.

The $M_xB_y$ nanopowders obtained was made into solution-processable inks via surface treatment with nafion/DMSO then loaded onto carbon paper support. Compared to the prior study done on the electrooxidation of 5-HMF with $Ni_xB_y$, we conducted our process at lower pH in order to prevent the formation of humin.[2] Furthermore, we were able to decrease the catalyst loading 20x lower than previously reported while retaining similar activity to samples with higher $Ni_xB$ catalyst loading. Our study reveals the efficiency of $Ni_xB$ NCs in HMF conversion (51%) and the extremely high selectivity towards HMFCA (75%).

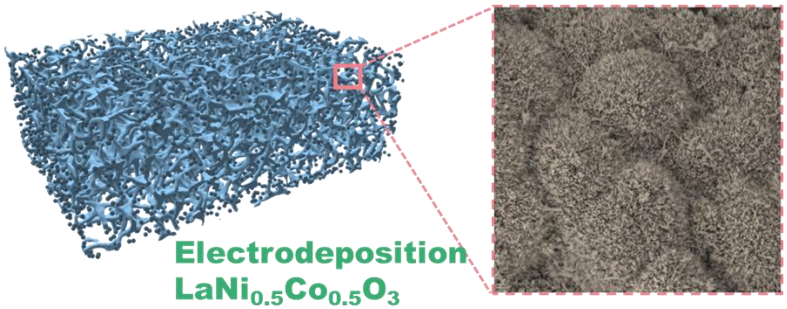
# Electrodeposition synthesis of hierarchically structured $LaNi_{0.5}Co_{0.5}O_3$ nanosheets as the cathode of intermediate-temperature Li-$O_2$ battery

Qianyuan Qiu, Jiaqi Wang, Penghui Yao, Yongdan Li*



*Department of Chemical and Metallurgical Engineering, School of Chemical Engineering, Aalto University, Espoo, Finland*

**Keywords:** Electrodeposition, $LaNi_{0.5}Co_{0.5}O_3$, Li-$O_2$ battery

**Introduction.** Lithium-oxygen (Li-$O_2$) batteries with high theoretical energy densities have great potential for a new generation of energy storage technology[1-3]. Their main limitations, however, are the slow kinetics of ORR and OER, the low mass-energy density, and inferior cycling stability compared with other energy storage devices[4]. Our previous work has shown that $LaNi_{0.5}Co_{0.5}O_3$ (LNCO) is a promising candidate for a high-performance cathode catalyst in an intermediate-temperature Li-$O_2$ battery due to its excellent conductivity and intrinsic catalytic activity. Many techniques, such as sol-gel, template, co-precipitation, and spray pyrolysis, have been developed to synthesize LNCO. However, these methods mostly require high pressure, high temperature, and a long experimental period. Therefore, one of the current challenges is to controllably fabricate large-scale, superior-quality perovskite layers for enhanced efficiency Li-$O_2$ batteries via low-cost manufacturing processes. Electrodeposition processes have been employed to synthesize nanostructures because of their mild reaction conditions, controllable parameters, and cost-effectiveness. Nevertheless, research on the preparation of LNCO by electrodeposition is not mentioned.

**Experimental/methodology.** The treated Ni foam working electrode is immersed into a 30 mL solution containing 0.01 M $La(NO_3)_2$, 0.005 M $Ni(NO_3)_2$, and 0.005 M $Co(NO_3)_2$. An Ag/AgCl is used as the reference electrode, and a Pt plate is used as the counter electrode. After 15 cyclic voltammetry measurement between -0.3 V and −1 V (vs. Ag/AgCl) at a scan rate of 5 mV $s^{-1}$ at 70 °C, porous nanosheets $LaNi_{0.5}Co_{0.5}O_3$ is uniformly generated. The obtained product is washed with deionized water for several times and dried at 40 °C in vacuum.

**Results and discussion.** Here, we present a method for preparing hierarchically structured $LaNi_{0.5}Co_{0.5}O_3$ nanosheets by electrodeposition to develop an intermediate-temperature Li-$O_2$ battery. In this work, we focus on adjusting electrodeposition parameters, such as temperature, electrolyte concentration, electrodeposition method, time, and solvent, in designing and fabricating LNCO nanosheets. The LNCO nanosheets make the Li-$O_2$ battery with a high mass-energy density and a long cycle life. The exceptional characteristics of LNCO nanosheets in Li-$O_2$ batteries at intermediate temperatures make them a potential material for application in metal-air batteries.

# Supramolecular organocatalysis with novel BTA helical structure

Dr. Antonio Valverde-González, Prof. Laurent Bouteiller and Dr. Matthieu Raynal
Sorbonne Université, CNRS, Institut Parisien de Chimie Moléculaire, Equipe Chimie des Polymères, 4 Place Jussieu, 75005 Paris, France.

**Keywords:** enantioselectivity, supramolecular organocatalysis, helix, BTA

**Introduction.**
Novel catalytic approaches, which possess recognition sites and a modular backbone, may constitute a suitable approach to achieve site selectivity. Supramolecular helical polymers composed of benzene-1,3,5-tricarboxamide (BTA) units, as a scaffold for asymmetric catalysis[1] have proven to be efficient when the BTA ligand is functionalized with an aryl phosphine ($PAr_2$) moiety that can promote metal-catalyzed reactions such as the rhodium-catalyzed hydrogenation of dimethyl itaconate,[2] the copper-catalyzed hydrosilylation of acetophenone derivatives,[3,4] and the copper-catalyzed hydroamination (HA) of styrene.[5] This is mainly because the fact that BTA monomers assemble in solution through a combination of aromatic and hydrogen bonding yielding well-defined supramolecular helices.[6] The configuration of the product and the selectivity of the reaction are correlated to the handedness and optical purity of the helices, which can be finely controlled by means of stereogenic groups located in the side chain of the BTA ligand[19] or in a phosphine-free monomer (the latter is also called a "sergeant"). However, organocatalytic active species have not been yet incorporated into these helical systems. Specifically, we are interested in hydrogen-bond-donor groups (HBD) such as thioureas with the aim of serve as a direct the interactions with carbonyl containing substrates.

**Experimental/methodology.**
Benzene-1,3,5-tricarboxamide (BTA) have been prepared with a $C_2$-symmetry**.** Thus, two long chiral alkyl changed were introduce through and amide formation, whereas in the third position the catalytically active HBD species (with the thiourea moiety) were introduced also through an amide function. Corresponding assemblies were prepared in non-polar solvents (such as toluene) and the corresponding characterizations techniques were applied to confirm both the helicity and formation of the assembly (such as: UV-Vis, CD, FT-IR, NMR and SANS/SAXS). Enantiomeric excess of the catalytic tests was analyzed by HPLC

**Results and discussion.**
Mixtures of BTA monomers were evaluated in model asymmetric reactions. Analytical data, in combination with control experiments, validate the expected design, i.e. that both thiourea and catalytic moieties act cooperatively for the activation of the substrate.

**Keywords:** carbene ligands, organic synthesis, CAAC, BICAAC

**Introduction.** Ligand development is a useful tool to fine-tune transition-metal complex-based catalyst systems. Hypovalent carbon compounds, carbenes have also emerged as a possible ligand class. As novel molecular skeletons have been discovered, carbenes turned into a widely investigated topic. Modifications on their structures is qiute common in the case of NHC ligands, but still not widely spread at better sigma donor and pi acceptor types, cyclic and bicyclic (alkyl)(amino)carbenes (CAAC and BICAAC). The presentation points out the substitution possibilities of these classes and discusses its impact on their catalytic performance.

**Results and discussion.** The convenient CAAC and BICAAC ligand syntheses were modified to enable the tuning of the steric and electronic properties of the desired ligands. The substitution on the *N*-moiety enabled steric modifications that had serious impact on the catalytic metathesis of olefins with BICAAC-Ru-alkylidene complexes.[1] On the other hand, the tuning of the alkyl substituent in the vinicity of the carbene atom had impact on the Pd-BICAAC-PEPPSI complex-catalyzed Heck-reaction.[2] Moreover, the polarity of the carbene ligands could also be tuned by applying polar trimethylammonium groups at the *N*-substituent. This modification allowed the preparation of such Ru-alkylidene–CAAC complexes those could convert olefins in polar, protic media like alcolhols, which considered as green solvents.[3] The presentation also gives an overview about the further possible modifications on these ligand systems – illustrated with yet unpublished results.

# Design of organometallic complexes as precursors for catalysts with tuneable properties

L. Frederiksen[1*], P. J. Dyson[1]

[1]*École Polytechnique Fédérale de Lausanne, Lausanne, Switzerland*
[*]*lindsey.frederiksen@epfl.ch*

**Keywords:** ruthenium, nickel, core-shell, nanoparticles, hydrogenolysis, lignin

**Introduction.** Coreshell nanoparticles (CSNPs) show excellent stability and selectivity for catalysis due to the presence of a protective shell encapsulating the active nanoparticle surface.[1] The increased stability and selectivity have proven beneficial for biomass conversion to value-added chemicals[2] – an important topic for a more sustainable future. However, there are major challenges with reproducibility and control over nanoparticle properties, particularly in the field of heterogeneous catalysis.[3] Herein we propose a strategy for the reproducible synthesis of nanoparticles with variable properties to help bridge the gap between catalyst preparation and catalyst properties. CSNPs were synthesized from organometallic precusors and applied to C–O bond hydrogenolysis in lignin model compounds under mild conditions (100 °C and 20 bar $H_2$). By correlating the nature of the organometallic precursors and CSNP preparation method parameters with the structure of the resulting CSNPs, we are developing a methodology for preparing CSNPs with tuneable physical properties. Studying the relationship between CSNP physical and chemical properties allows us to identify key features that indicate greater stability and higher activity in C-O bond hydrogenolysis.

**Experimental/methodology.** A variety of ruthenium and nickel complexes featuring *N*-heterocyclic carbene (NHC) ligands (Ru-NHC and Ni-NHC) were prepared and used to generate NPs. The NPs were characterized by HR-TEM, XPS, and ICP-OES, and applied to the mild hydrogenolysis (100 °C and 20 bar $H_2$) of lignin model compounds (diphenyl ether, benzylphenyl ether, and phenethyl phenyl ether) to determine their activity, selectivity, and stability.

**Results and discussion.** NHC ligands featuring alkyl side chains (Fig. 1) were chosen to emulate the carbon chains of many surfactants previously used to generate stabilized NPs.[4] The length of the carbon chain was varied to study the effect on shell thickness and porosity, and, as a result, the activity, selectivity, and stability of the NPs. After a sequential chemical reduction and pyrolysis of the organometallic precusors, the physical properties, such as shell thickness, can be related to the precursor nature and variables in the NP synthesis method. After application to the hydrogenolysis of lignin model compounds under mild conditions, structure-activity relationships identify the most important physical properties for predicting catalytic activity, stability, and selectivity.

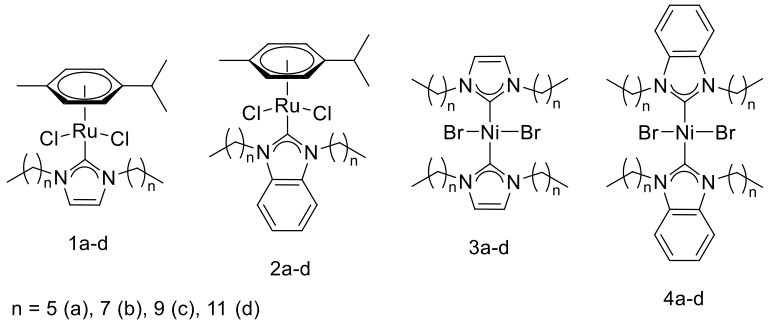

**Figure 1. Ru-NHC and Ni-NHC organometallic precursors for the generation of CSNPs.**

# Tunable materials with catalytic properties dedicated for chemical and biochemical processes

A. Chrobok[1*]

[1]*Silesian University of Technology, Gliwice, Poland*
[*]*anna.chrobok@polsl.pl*

In this contribution, research on the development of new, specialized catalysts required for designing of clean, environmentally friendly technologies dedicated for the production of high-added value organic compounds for chemical industry will be presented. Heterogenization of the catalyst is one of the most widely favoured green approaches to environmentally friendly process. This goal is achieved by designing of catalysts based on innovative nanomaterials and ionic liquids. The resulting hybrid materials, based on multiwalled carbon nanotubes (MWCNTs) with unique mechanical, magnetic, thermal and electronic properties, as well as non-volatile ionic liquids as "green" media, combine the unique properties of both materials. Ionic liquid can be immobilized on the surface of solid currier *via* chemical bound or *via* physical interactions. Novel ionic liquids with acidic properties, both Brønsted and Lewis acids, will be presented. [1] In addition, ionic liquids based on renewable raw materials, mainly D-glucose, will be presented, which are a convenient environment for enzymatic reactions (Fig.1).[2] The developed catalytic materials are characterized by high activity, selectivity and stability in selected chemical processes: esterification, alkylation, oxidation, cycloaddition, including biomass valorisation and others. Special emphasis will be placed on the improving of biocatalysts activity, selectivity as well as stability in the organic environments. [3-4]

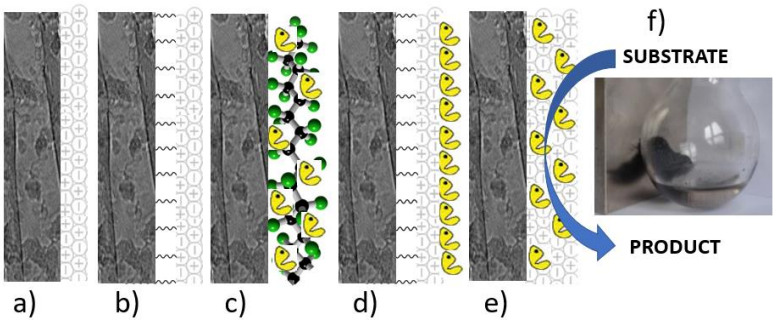

**Fig. 1.** Tuning of MWCNTs-based catalysts: (a) non-covalent bounding of acidic ionic liquid; (b) covalent bounding of acidic ionic liquid; (c) non-covalent bounding of enzyme to MWCNTs modified with teflon; (d) covalent bounding of ionic liquid to MWCNTs with non-covalent bounding of enzyme; (e) non-covalent bounding of enzyme to MWCNTs modified with ionic liquids; (f) magnetic separation of biocatalyst.

Easy separation of the catalyst from the post-reaction mixture, the possibility of reuse of isolated catalyst to the new reaction cycles and economic availability make the developed technologies attractive for industrial applications. An important issue will also be the presentation of exemplary processes in continuous flow conditions, where separation of the catalyst from the reaction mixture is not necessary, which positively affects the reduction of the number of unit operations, the economy of the process and thus protects the environment.
In summary, ionic liquid-based strategies will be presented as a generic approach to tailoring catalysts for industrially-relevant reactions, to generate both environmentally and economically sustainable processes.

**Keywords:** Catalysis, Industry, Quantum Chemistry, Mechanism Analysis, Screenings

**Introduction**
In recent years, computer simulations and especially quantum chemical DFT simulations have become an increasingly important tool to support and accelerate chemical research. Selected examples from academic and industrial research collaborations will be presented to show how useful the combination of experimental and simulations is today.
With the help of simulations, we were able to correct previously proposed popular mechanisms in the chemical literature, and we succeeded in bringing new materials and reactions from the idea via simulations and selected experiments to the application level. On selected examples we are presenting this successful approach.

**Experimental/methodology**
Mechanism Analysis, Virtual Screening, Selected Experiments, Scaleup

**Results and discussion**
Organocatalysis: Proline-Catalyzed Cascade Reactions with Carbohydrates

Through an in-depth analysis, we succeeded in developing a suitable mechanism that describes the experimental data of the yields for the proline catalyzed reaction of different carbohydrates with methyl ketones. Here we were able to show that, contrary to the established Houk-List mechanism, the carbohydrate with proline must also be present in order to match the experimental results of our academic partner. Here we were able to show that, contrary to the established Houk-List mechanism, the carbohydrate must also react with proline in order to match the experimental results. [1]

Industrial Catalysis: Ru-Catalyzed Asymmetric Hydrogenation of β-Ketoesters

In this case, we were able to find the most plausible mechanism for this catalytic reaction by investigating many possible individual reaction steps. Here, the focus was on describing the surprising reversal of enantioselectivity at different HCl concentrations. Again, our mechanism deviates from the mechanism known from literature (proposed by Noyori), but describes the experimental results very well. [2]

Methanol Catalysis: Low-Temperature Hydrogenation of Carbon Monoxide

In a very short time, we were able to develop a completely new process for methanol production, from paper to simulations to experimental proof. This process requires significantly less pressure and temperature (120-150 °C, 30-50 bar) than established industrial approaches. This approach is currently being further developed in the project E4MeWi, MeFuSION and scaled-up by the Startup C1 Green Chemicals AG. [3]

**Keywords:** homogenous catalysis, machine learning, hydrogenation

**Introduction.** Modern computational methods, especially with regard to machine learning, are of increasing interest in molecular catalysis. However, application for homogeneous transition-metal catalysts has remained sparse, mainly due to the lack of large high-quality datasets.[1] Recently, we introduced novel derivatives of the triphos ligand (1,1,1-tris(diphenylphosphinomethyl)ethane) and reported their unprecedented activity in Ru-catalyzed hydrogenation reactions.[2] We now set about further optimizing the structure of the triphos ligand and breaking the symmetry of the ligand by modifying a single phosphine arm (Figure 1). This allows fine control over the *trans*-effect and thus, enables specific catalyst tailoring to given substrates. However, since these new triphos$^{AB2}$ ligands result in an increased chemical space of different substitution patterns, classical experimental catalyst synthesis and subsequent catalyst screening becomes unfeasible.

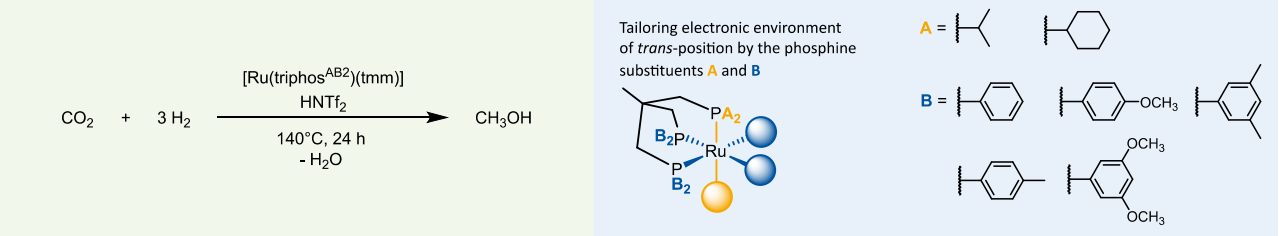

**Figure 1:** Different [Ru(triphos$^{AB2}$)(tmm)] catalyst structutes investigated experimentally and computationally for the hydrogenation of $CO_2$.

**Experimental/methodology.** To understand the mechanistic implications of significantly changing the electronic and steric nature of one coordination site, we use computational methods to describe and investigate the mechanism of [Ru(triphos$^{AB2}$)(tmm)] catalysts in the hydrogenation of carbon dioxide ($CO_2$). Additionally, the resulting energy spans can subsequently be correlated with the experimental results, which are generated in parallel for selected [Ru(triphos$^{AB2}$)(tmm)] complexes (Figure 1). Further, correlation between molecular descriptors and thermodynamic and kinetic properties are investigated, paving the way for application of machine learning models.

**Results and discussion.** The application of modern computational methods for mechanistic investigation on the [Ru(triphos$^{AB2}$)(tmm)] catalyzed $CO_2$ hydrogenation allows us to narrow the chemical space that needs to be probed experimentally. In particular, the incorporation of deactivation pathways into our mechanistic model allows for the first time a qualitative agreement of the computational results with experimental work for the [Ru(triphos$^{AB2}$)(tmm)] catalyzed $CO_2$ hydrogenation. Furthermore, a careful selection of molecular descriptors allows for a drastic reduction in the computational effort for a qualitative estimation of catalyst performance.

# Carbon Nanofiber Supported Mixed Mo and W Carbides for Deoxygenation of Lipid-based Feedstocks

M. Führer, T. van Haasterecht, J.H. Bitter*

*Wageningen University, Biobased Chemistry and Technology, Wageningen, The Netherlands*
*Harry.Bitter@wur.nl*

**Keywords:** mixed metal carbides, carbon nanofibers, characterization, biomass conversion

## Introduction

Mono metallic tungsten and molybdenum carbides have been shown to be viable replacements for noble metal catalysts in deoxygenation of biobased feedstocks.[1,2] Though both metals show activity for the deoxygenation of stearic acid, a model compound for biobased lipids, Mo-carbides showed the highest activity. Interestingly, the selectivity is different for carbon supported Mo-carbides to W-carbides catalysts, the former ones are more selective towards oxygenates at low conversion levels, while the W-carbides are more selective towards alkenes at low and high conversions levels.[2] To investigate to which extend we can combine the advantages of both single carbides, we report here on preparation, characterization and performance of carbon nanofiber supported mixed Mo/W-carbides. We will show that the mixed carbides with a higher Mo/W ratio (3:1) reached higher yields of aldehydes and alcohols, while the carbides with a lower Mo/W (1:3) ratio yielded high concentrations of alkenes.

## Experimental/methodology

Carbon nanofibers were in house prepared by decomposition at 550 °C of $CO/H_2$ using a $Ni/SiO_2$ catalyst. The catalysts were prepared by incipient wetness impregnation with solution of ammonium heptamolybdate and/or ammonium metatungstate to yield catalysts with 0.9 mmol metal $g^{-1}_{catalyst}$ and Mo:W ratios of 3:1, 1:1 and 1:3. The carburization was performed using the carbothermal reduction method. The prepared samples were thoroughly characterized by TEM/EDX, nitrogen physisorption, chemisorption of $H_2$ and CO, XRD and temperature programmed desorption of ammonia.
The catalysts were tested (without exposing to air) in a batch autoclave for stearic acid deoxygenation in 30 bar $H_2$ at 350 °C. The turnover frequency (TOF) values were based on CO and $H_2$ chemisoprtion after 1 hour of reaction.

## Results and Discussion

Figure 1 shows a typical TEM/EDX image of the used mixed carbide catalyst and the assesment of TOF as function of Mo loading. The Mo/W ratio was found (not shown in the figure) to influence the product yield towards either oxygenates or alkenes following a hydrodeoxygenation pathway. The more Mo-rich samples have a higher yield towards oxygenates, while the more W-rich samples have higher yields towards the alkene intermediate. The linear relation of the $H_2$ site based activity together with the evolution of the product distribution as function of the Mo content of the catalyst, suggests that the $H_2$ site density is a better descriptor for site base activity than the CO site density.

# What are the active sites on $Ni/CeO_2$ for $CO_2$ methanation?

S. Tada[1], R. Kikuchi[1*]

[1]*Hokkaido University, Sapporo, Japan*
[*]*rkikuchi8@eng.hokudai.ac.jp*

**Keywords:** Carbon dioxide, Nickel, Ceria

**Introduction.** The rapid increase in $CO_2$ emissions since the Industrial Revolution has made addressing climate change imperative. $CO_2$ methanation through metal catalysts is crucial for carbon neutrality. Despite high activity reported for $Ni/CeO_2$ in previous studies [1-3], understanding of the active site structure is limited. This study aims to deepen knowledge on $Ni/CeO_2$ active sites for $CO_2$ methanation and provide better catalyst design guidelines, with a focus on investigating the impact of oxygen vacancies on reaction activity.

**Experimental/methodology.** We made $Ni/CeO_2$ catalysts using a wet impregnation method, where $CeO_2$ (JRC-CEO-2 from Catalysis Society of Japan) was impregnated with an aqueous solution of Ni nitrate. The resulting powder was dried at 100°C and calcined at 600°C for 3 hours. Characterization was performed using $N_2$ adsorption, XRD, $H_2$-TPR, XPS, and HAADF-STEM. Performance was evaluated in a 4 mm I.D. fixed-bed quartz reactor under atmospheric pressure. 300 mg of catalyst was reduced at 600°C with 5% $H_2$/Ar before testing. The reactant ($CO_2/H_2/N_2$ = 1/3/1) was fed into the reactor at a GHSV of 10,000 $h^{-1}$, and the outlet gas composition was monitored using an online micro gas chromatograph (Varian CP-4900).

**Results and discussion.** We tested $CO_2$ methanation on $Ni/CeO_2$ catalysts (Figure 1a). $CO_2$ conversion increased from 3% to 58% as temperature rose from 250°C to 400°C with 1wt% $Ni/CeO_2$ catalyst. Above 400°C, $CO_2$ conversion stayed around 60%. With other catalysts, $CO_2$ conversion significantly increased as temperature rose from 250°C to 400°C, then reached equilibrium. We also tested CO methanation (not shown). Only 1wt% $Ni/CeO_2$ had low CO methanation activity.

Based on our performance tests and characterizations, we proposed a $CO_2$ methanation mechanism for $Ni/CeO_2$ (Figure 1b). Low Ni loading creates Ni-Ce mixed oxides with Ni-$V_{OX}$-Ce sites that are active in forming CO through reverse water gas shift. High Ni loading (5 and 10 wt%) results in many metallic Ni nanoparticles supported on Ni-Ce mixed oxides, which are capable of methanating CO.

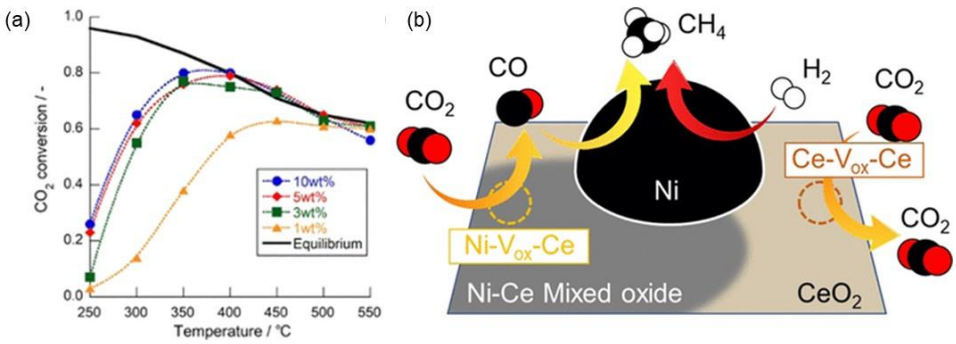

Figure 1 Effect of Ni loading on $CO_2$ methanation over $Ni/CeO_2$: (a) $CO_2$ conversion and (b) $CH_4$ selectivity. (c) Reaction Mechanism of $CO_2$ Methanation over $Ni/CeO_2$. Adapted with permission from [4]. Copyright 2021 American Chemical Society.

# Modification of $Rh/TiO_2$ Single Atom Catalysts with Amine-Fuctionalized Organic Monolayers to Promote $CO_2$ Hydrogenation

A.H. Jenkins[1], J.W. Medlin[1*]
[1]*Dept. of Chemical & Biological Engineering, University of Colorado, Boulder, CO, USA*
[*]*medlin@colorado.edu*

**Keywords:** Single atom catalysts, $CO_2$ reduction, catalyst stability.

**Introduction.** Significant attention has recently been focused on atomically dispersed supported metals, also referred to as single atom catalysts (SACs), though maintaining stability at elevated temperatures is a challenge. Recently, phosphonic acid (PA) monolayers have been applied to supported metal catalysts[1] and SACs in order to improve catalyst stability and alter adsorbate binding. Modification of $Rh_1/Al_2O_3$ and $Rh_1/TiO_2$ SACs with methylphosphonic acid (MPA) improved the sintering resistance of these catalysts without appreciably changing the reaction rate of 1-hexene hydrogenation.[2] In addition, Zakem et al. demonstrated that the deposition of octylphosphonic acid on $Rh_1/Al_2O_3$ SACs modified the desorption entropy of CO by restricting the movement of $Rh_1(CO)_2$ species.[3] These studies focused on the steric, geometric, and electronic effects PA monolayers have on SACs. Relatively unexplored, however, is the addition of functionalized ligands to SACs in order to introduce additional functionality near the Rh active site.[4] The primary goals of this work were to investigate whether functionalized PA monolayers could enhance reverse water gas shift (RWGS) activity on $Rh_1/TiO_2$ SACs, to determine the effects of ligand length and functionality on catalytic activity, and to study the effects of PAs on on-stream catalyst stability.

**Experimental/methodology.** Atomically dispersed Rh on anatase $TiO_2$ was synthesized using strong electrostatic adsorption at a weight loading of 0.1-0.3 wt%. Various PA SAMs with and without amine groups were deposited to control the position of amine functionality with respect to the single-atom site. Catalysts were characterized with infrared spectroscopy after CO adsorption to confirm atomic dispersion, and a sequential $H_2/D_2$ scrambling technique was employed to estimate the number of active sites. Adsorption of $CO_2$ was monitored with infrared spectroscopy both ex situ and under reaction conditions. Reverse water gas shift activity was measured in a differential flow reactor across a range of temperatures.

**Results and discussion.** We used a combination of infrared spectroscopy and vapor-phase reaction studies to investigate the effects of amine-functionalized phosphonic acids on $CO_2$ hydrogenation with $Rh_1/TiO_2$ catalysts. We found that, depending on their tail length, deposition of amine-functionalized ligands such as aminoethyl PA (AEPA) resulted in overall improvements to $CO_2$ reduction turnover frequency (Fig. 1) and on-stream stability. Interestingly, the activity improvement was highly sensitive to the position of the amine group relative to the surface-bound phosphonate group. Conversely, deposition of alkyl ligands such as propyl PA (PrPA) resulted in blocked $CO_2$ adsorption and a complete loss of catalytic activity. A sharp reduction in methanation was also observed for phosphonic acid-modified catalysts. However, ligand deposition resulted in a loss in accessible $Rh_1$ sites, likely due to blocking by tail groups. Our results inform future investigations of ligand-modified single atom catalysts, particularly in terms of achieving ideal metal-ligand proximity.

**Introduction.** Ammonia decomposition is one of the promising routes for carbon-free and sustainable hydrogen production. Thermal decomposition by catalysis typically requires high temperatures of about 600 °C for complete conversion of $NH_3$ to the elements [1]. Although supported ruthenium nanoparticles are highly active, the high cost and scarcity of the metal prevent its use on a large scale. Catalysts based on nickel also show high activities for $NH_3$ decomposition and are an alternative to Ru [2]. In the synthesis of catalysts, we pursue the concept of incorporating the active metals into oxide host structures. The exsolution of the metal under reductive conditions then leads to highly dispersed and stable metal nanoparticles. In the present work, we systematically investigated solid solutions of Ni in MgO.

**Experimental/methodology.** $Ni_xMg_{1-x}O$ solid solutions (x=0-0.1) were prepared by calcination of mixed hydroxides $Ni_xMg_{1-x}(OH)_2$ with a brucite type structure synthesized by co-preciptation. Physical properties of the fresh catalysts were determined by XRD, Raman, STEM-EDX, and nitrogen adsorption. The exsolution and dispersion of the Ni nanoparticles was investigated by temperature-programmed reduction (TPR) with hydrogen, $H_2$ chemisorption, and X-ray diffraction. The $NH_3$ conversion over $Ni_xMg_{1-x}O$ was compared to those of other supported Ni-based materials and the changes occuring during $NH_3$ decomposition were investigated through a comparative STEM analysis of fresh, reduced and spent catalysts.

**Results and discussion.** In the entire composition range studied, the $Ni_xMg_{1-x}O$ precursors are phase-pure. However, electron microscopy indicates that the Ni is not homogeneously distributed, but slightly enriched at the rim of the plate-like nanoparticles. Exsolution of Ni occurs at about 570 °C according to TPR and in-situ XRD (Figure 1a) resulting in highly dispersed Ni metal particles with a narrow particle size distribution (4-5 nm). The minor shift in diffraction peak of $Ni_xMg_{1-x}O$ during reduction is due to thermal expansion. $NH_3$ conversion over the reduced catalysts increases with increasing Ni content (Figure 1b). The space time yield of Ni exsolved from $Ni_xMg_{1-x}O$ is much higher compared to Ni in a $NiO/Al_2O_3$-based reference catalyst (Figure 1c). The catalysts show no deactivation in a cyclic test (Figure 1b) and no change in the particle size distribution (Figure 1d). Overall, exsolution of Ni through controlled reduction of host solid solutions based on rock-salt structures is a promising method for developing active and stable $NH_3$ decomposition catalysts.

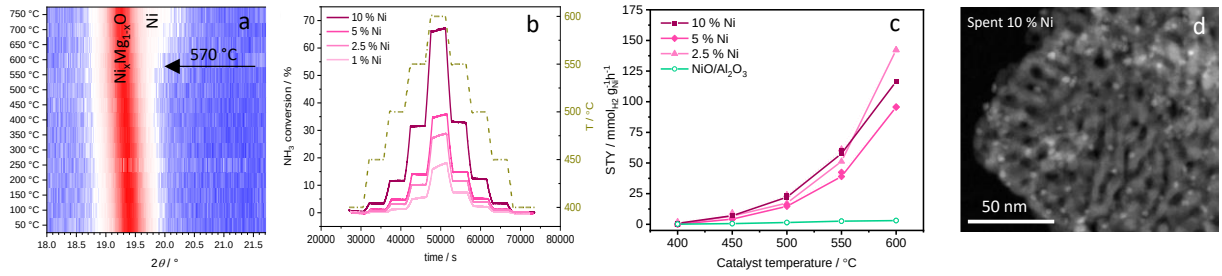

**Figure 1 Reduction of 10 % Ni-substituted MgO solid solution recorded by in-situ XRD (a), $NH_3$ conversion of Ni/NiO-MgO catalysts during heating/cooling cycles at 400-600 °C (feed: 100% $NH_3$, 600 ml $min^{-1}$ $g^{-1}$) (b), Space-time yield of $H_2$ per gram of metallic Ni (c), HAADF image of the spent catalyst showing Ni NPs after $NH_3$ decomposition (d).**

**Keywords:** hydrogen, methanol, fuel cell, steam reforming, copper catalysts

**Introduction.** Worldwide strategy plans for decarbonization of energy sector by 2050, are based on hydrogen and renewable sources. In order to avoid technical obstacles regarding the storage and transportation of pure hydrogen, liquid fuels can be employed as hydrogen carriers. Among these fuels, methanol is an attractive fuel, that can be produced from biomass and from green hydrogen and waste carbon dioxide. Hydrogen can be easily produced via steam reforming of methanol (SRM) over commercially available CuZn(Al)$O_x$ catalysts operating between 200 and 300°C with high hydrogen yields and very low CO selectivity [1]. However, these catalysts usually suffer from sintering and pyrophoricity phenomena. In order to avoid possible deactivation, appropriate promotion of the catalytic properties can be done either by tuning the synthesis parameters or/and doping with various metal (oxides). High dispersion and stabilization of the active metallic copper sites and operation at lower temperatures (<200$^o$C) are desired. In addition, the latter characteristic simplifies the integration of a methanol reformer with a high temperature PEM fuel cell. In this work, CuZn-based catalysts were synthesized via Flame Spray Pyrolysis (FSP) [2] and Hydrothermal (HTM) [3] methods. The obtained materials were evaluated in the SRM process and were characterized with various techniques including BET, XRD, XPS, TPR, SEM, HR-TEM, while in-situ DRIFTS were employed to elucidate reaction pathways.

**Experimental/methodology.** The catalysts were synthesized via: (i) hydrothermal method, at 120-180$^o$C for 24 h, employing metal nitrates (40wt.%CuO, 60wt.% ZnO), and NaOH or $Na_2CO_3$ as precipitating agents, followed by calcination at 300$^o$C; (ii) Double-Nozzle (DN) FSP, an easily scaled up method able to provide ultrafine CuZn oxide nanocatalysts, doped with various oxides, such as $Al_2O_3$ or/and $Ga_2O_3$. The catalysts were tested under SRM conditions within the temperature range of 160-280 ℃ ($W_{cat}$ = 0.3 g, $F_T$ = 70 ccm, S/C ratio = 1.1-1.5, MeOH = 6.5-30%, He as balance). Inlet/outled gas streams were monitored with a GC/MS system. Mapping of the physicochemical properties was done via $N_2$ adsorption, XRD, XPS, $H_2$-TPR, SEM and TEM. CO-, MeOH- and $H_2O$-MeOH in-situ DRIFTS were carried out on selected catalysts.

**Results and discussion.** Highly active and selective catalysts were obtained via hydrothermal method applied at 120$^o$C with $Na_2CO_3$ as precipitating agent. These catalysts showed better performance than the corresponding samples prepared via FSP, showing comparable activity and lower CO selctivity with the commercial HiFuelR120. Moreover, remarkable perfomance could be achieved at temperatures as low as 160$^o$C, opening new tecnological prospects in fuel processing integrated with HT PEM fuel cells. In-situ DRIFTS measurements revealed the dissociative adsorption of MeOH towards methoxy and formate species even at relatively low temperatures, while $CO_2$ and CO became emerged at higher temperatures.

**Keywords:** Supported noble metal catalyst, basic metal oxide cluster, $CO_2$ fixation reaction

**Introduction.** The supported metal nanoparticle (NP) catalysts have been used for industrial processes, and their catalytic reactivity has been developed by controlling the size, shape, and surface electronic state of the NPs. We have reported that the modification of basic metal oxide clusters (polyoxometalate, POM)consisting of Nb and Ta[1)] on the surface of supported Au NPs, and the design of a high density of POM–metal interface, lead to highly efficient hydrogenation of aromatic nitro compounds[2)]. We also reported that *N*-formylation of various amines including piperidine proceeds under $CO_2$ and $H_2$ atmosphere by using Pt-containing Nb oxide cluster $[Pt(Nb_6O_{19})_2]^{12-}$ as a catalyst[3)]. We observed Pt NPs modified with POM are formed during the reaction, so considered the bifunctional catalysis of the basicity of POM, and the redox property of Pt NPs promoted the *N*-formylation reaction. In this study, we designed the supported Pt NPs catalyst modified with basic POM ($[M_6O_{19}]^{8-}$, M = Nb, Ta) and applied them to the *N*-formylation reaction using $CO_2$ as a carbon source.

**Experimental.** Supported Pt catalysts ($Pt/Al_2O_3$) were prepared by an impregnation method. $Al_2O_3$ was dispersed in an aqueous solution of $Pt[(NH_3)_2(NO_2)_2]$ (equivalent to 5.0wt%), and then evaporated at 80°C. The resulting sample was calcined and reduced with $H_2$ at 400°C to obtain $Al_2O_3$-loaded Pt NPs ($Pt/Al_2O_3$). $[M_6O_{19}]^{8-}$-modified $Pt/Al_2O_3$ (M = Nb, Ta, M6-$Pt/Al_2O_3$) was prepared by an adsorption method. $Pt/Al_2O_3$ was dispersed in $K_8Nb_6O_{19}$ and $K_8Ta_6O_{19}$ aqueous solutions (POM/Pt atom = 4) under $N_2$ atmosphere, and the following suction filtration and drying. The N-formylation of piperidine was carried out in an autoclave (piperidine: 0.1 mmol, methanol: 2 mL, catalyst: 24.7 mg (Pt; equivalent to 5.0 μmol), $CO_2/H_2$: 1.0/2.0 MPa, reaction temperature: 130°C, reaction time: 48 h).

**Results and discussion.** STEM images of $Pt/Al_2O_3$ showed that Pt NPs were highly dispersed on $Al_2O_3$ support and the average particle size was 1.5 nm. The aggregation of Pt NPs was not observed both in Nb6-$Pt/Al_2O_3$ and Ta6-$Pt/Al_2O_3$. From the Nb K- and Ta $L_3$- edge XAS of M6-$Pt/Al_2O_3$, the Fourier transform of the EXAFS spectra indicated that Lindqvist-structure of $[Nb_6O_{19}]^{8-}$ and $[Ta_6O_{19}]^{8-}$ are maintained after the modification on the surface of Pt NPs. Figure 1 shows the product yields in the *N*-formylation reaction of piperidine with $CO_2$ as a carbon source. The yield of 1-formylpiperidine increased by the modification of $Pt/Al_2O_3$ with $[Nb_6O_{19}]^{8-}$ and $[Ta_6O_{19}]^{8-}$. The addition of $Cs_2CO_3$ (2.1 mg) to $Pt/Al_2O_3$ also increased the activity, suggesting that the modified basic POM plays an important role in the reaction. In conclusion, we found that the *N*-formylation reaction using $CO_2$ as a carbon source proceeded efficiently by the cooperation between the reducing ability of the supported Pt NPs and the basicity of the modified POM.

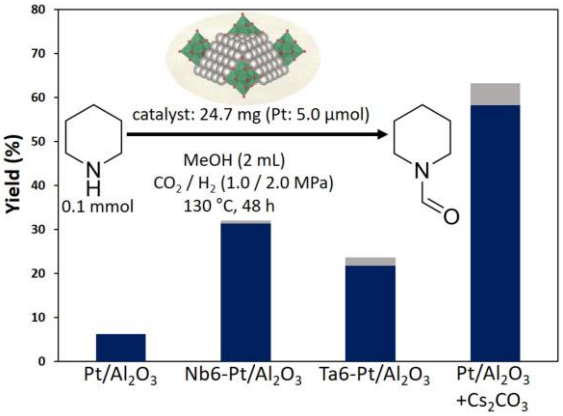

**Fig. 1.** Product yield of *N*-formylation of piperidine

**Keywords:** Metal carbonyl clusters, supported metal nanoparticles, biomass valorisation

**Introduction.** In the last decades, supported metal nanoparticles (NPs) have been widely employed in heterogeneous catalysis to obtain high-performance catalysts. Below 5 nm, chemistry of nanoparticles has lots of similarities with that of metal clusters and high-nuclearity clusters can be considered monodisperse and atomically defined metal nanoparticles. For this reason, metal carbonyl clusters (MCC) can play a role in better understanding and developing of the chemistry of ultrasmall NPs.[1] Particularly, thanks to their chemical and structural composition, MCC have been considered promising precursors for the preparation of metal nanoparticles-based catalysts. [2,3]

The main purpose of this work was to investigate the preparation of several heterogeneous Pt and Pt/Ni-based catalysts with the objective to minimise the use of Pt content, obtained by the effective decomposition of carbonyl cluster over $TiO_2$. Catalytic performances of the prepared catalysts were evaluated in the 5-hydroxymethyl-furfural (HMF) oxidation using base-free conditions and furfural reductive amination.

**Experimental/methodology.** A series of random alloy carbonyl clusters $[NBu_4]_2[Pt_{6-x}Ni_x(CO)_{12}]$ with different Pt:Ni molar ratios were synthesised and supported on $TiO_2$ by wet impregnation, under nitrogen atmosphere.[4] The final catalysts were obtained through a decomposition of the cluster under controlled atmosphere. Each catalyst was tested in the base-free oxidation of HMF, carrying out the reaction in a stainless-steel autoclave, in water under 10 bar of $O_2$. Some selected catalysts were also evaluated for the reductive amination of furfural, performing the tests in an autoclave, using a $NH_3$ solution and funder $H_2$ pressure.

**Results and discussion.**

IR spectra obtained on cluster modification during each synthetic step highlighted that carbonyl clusters were completely decomposed only after a thermal treatment at high temperature. Moreover, the Pt and Ni distribution, evaluated by TEM analysis, confirms the formation of small and well dispersed Pt NPs, with an average diameter under 2 nm and narrow distributions, while Ni species appear to be dispersed on support surface suggesting the formation of a $NiO_x$ layer. All Pt/Ni cluster-derived catalysts tested in base-free HMF selective oxidation to furandicarboxylic acid (FDCA) exhibited good performances: the presence of a Pt/Ni molar ratio of 5:1 improved HMF conversion up to 90% without the use of a base. This enhancement can be attributed to the formation $NiO_x$ during cluster decomposition. Indeed, its basic properties can improve the catalytic activity. The presence of Ni species also contributes to the catalyst stability, in fact monometallic Pt catalyst presents an activity-loss after two reaction cycles, while bimetallic Ni/Pt materials remain stable for more cycles. The catalytic performances of the samples prepared using carbonyl clusters are significantly improved for both reactions, HMF oxidation and reductive amination of furfural respect to similar systems prepared via incipient wetness impregnation of metallic salts. These results highlighted that cluster decomposition on a support can be a suitable approach to design bifunctional active and stable catalysts promoting the formation of metallic nanoparticles over metallic oxide film.

**Keywords:** Ni-BEA zeolites, silicate module, Dry Reforming of Methane

**Introduction.** The dry reforming of methane (DRM) is potentially suitable for industrial conversion of natural gas or biogas into syngas. Zeolites are a perspective group of materials to consider as carriers for catalysts with ability to ensure high dispersion of the active metal on the surface [1]. The disadvantage of zeolite catalysts is their high Brønsted acidity, which stimulates the deposition of coke on the surface of the catalyst under the conditions of the DRM process, and as a result, its deactivation. It was shown previously that Ni-BEA catalysts prepared by the two-stage post-synthesis method show high activity in the production of hydrogen by the partial oxidation of methane. It can be assumed that the stability of the catalyst for DRM at low temperatures can be improved by incorporating nickel into the vacant T-atom sites of the dealuminated zeolite BEA (SiBEA) [2].

**Experimental/methodology.** Nickel-containing BEA zeolites were prepared by a conventional wet impregnation method and a two-steps postsynthesis procedure, which allow to control the introduction of Ni-ions in the zeolite framework. As a result, a number of BEA zeolite with different degrees of dealumination were obtained, which were marked respectively to their silicate module (Si/Al): NiBEA-17, NiBEA-100, NiBEA-1700. Catalysts were characterized by XRF, SEM, XPS and IR-spectroscopy of adsorbed pyridine. The activity of obtained catalyst samples was tested in temperature range between 500 and 800 °C, the stability test was performed during 8 hours and 700 °C. The ratio of methane to carbon dioxide was 1 to 1, GHSV = 12000 $h^{-1}$.

**Results and discussion.** Results of the catalyst activity study shows, that the degree of dealumination is the determining parameter which affects the activity of Ni-BEA catalyst. The most active sample was NiBEA-1700 (Si/Al = 1700). Catalysts based on non-dealuminated zeolite showed weak actity and rapid deactivation during stability test. Instead, NiBEA-1700 retains high activity over several catalytic cycles. In particular, > 50% conversion of methane and $CO_2$ is achieved already at 700 ºC at high volumetric velocities. In the study of the DRM process, when methane is not purified from sulfur compounds, gradual deactivation of the catalyst is observed as a result of its poisoning. Roasting of zeolite catalyst at temperature of 800 ºC in air allows partial regeneration of the catalyst.

**Table 1. Catalytic experiment results**

| | Ni-BEA-17 | | Ni-BEA-100 | | Ni-BEA-1700 | |
|---|---|---|---|---|---|---|
| T, ºC | X(CH4),% | X(CO2),% | X(CH4),% | X(CO2),% | X(CH4),% | X(CO2),% |
| 600 | 4 | 5 | 13 | 25 | 22 | 31 |
| 700 | 6 | 9 | 26 | 47 | 48 | 58 |
| 800 | 14 | 17 | 59 | 75 | 79 | 80 |
| 850 | 20 | 34 | 75 | 84 | 96 | 95 |

Investigation of the acid characteristics of zeolite catalysts with IR-spectroscopy of adsorbed pyridine indicates that with an increase in the level of dealumination, the number of Brønsted acid sites (BAS) and Lewis acid sites (LAS) will decrease. In particular, on the surface of the catalyst with Si/Al = 1700, there is a complete absence of BAS. On the surface of the catalyst there LAS are formed with the participation of aluminum and nickel cations.

Overall, increasing of dealumination degree of Ni-BEA zeolites leads to increasing of their catalytic activity in DRM and resistance to carbonization. The Ni-BEA-1700 sample showed highest activity and stability during several catalytic cycles.

# Encapsulated Ni-$CeO_2$ nanoparticles with $SiO_2$ shell for dry reforming of methane

Jae Hyeon Kwon[1], Jong Wook Bae[1*]

[1]*School of Chemical Engineering, Sungkyunkwan University (SKKU), 2066 Seobu-ro, Jangan-gu, Suwon, Gyeonggi-do 16419, Republic of Korea*

**Keywords:** Dry reforming of methane (DRM), Ni-$CeO_2$ nanoparticles, Core-shell catalysts, Ceria promoter

**Introduction**

Dry reforming of methane with carbon dioxide ($CH_4 + CO_2 = 2H_2 + 2CO$, DRM) have been largely investigated to produce syngas using Ni-based heterogeneous catalysts and product gases can be recycled with subsequent conversions to liquid fuels and chemicals [**1,2**]. Generally, Ni nanoparticles having a comparable activity as novel metals can be easily sintered to form less active and larger aggregates with more facile coke deposition natures for dry reforming of methane [**3,4**]. Cerium oxide can be used to activate $CO_2$ with its oxygen vacant sites, which enhance the gasification of the adsorbed coke precursors. Moreover, core-shell structure can impart the thermal stability of Ni nanoparticles with spatial confinement effect. In the present study, the strategies for stabilizing the Ni-$CeO_2$ nanoparticles with less coke depositions are explained by introducing core-shell-structured Ni-Ce@$SiO_2$ in terms of their resistances for cokes and aggregations.

**Experimental**

Ni-$CeO_2$ nanoparticles having different Ce/Ni molar ratios were coated with $SiO_2$ shells by using the modified reverse microemulsion methods in the Brij C10 / cyclohexane solution (denoted as Ni-$Ce_x$@$SiO_2$). Catalytic activity of the reduced Ni-Ce@$SiO_2$ catalysts were evaluated by using a fixed-bed tubular Inconel reactor with an outer diameter of 9.53 mm. The DRM reaction was carried out with a mixed gas of $CH_4/CO_2/N_2$ (molar ratio) of 1/1/2 at a gas hourly space velocity (SV) = 30,000 mL/($g_{cat}$·h), T = 800 °C and P = 0.1 MPa. The effluent gases were analyzed with an on-line gas chromatography (YL6500 GC, Younglin) equipped with a thermal conductivity detector.

**Results and discussion.**

TEM images of the reduced and used core-shell Ni-Ce@$SiO_2$ are displayed in **Figure 1(A)**, which clearly showed the uniformly dispersed Ni-$CeO_2$ nanoparticles were encapsulated with $SiO_2$ shells. As displayed in **Figure 1(B)**, the conversions of $CH_4$ and $CO_2$ on the Ni-$Ce_1$@$SiO_2$ (Ce/Ni molar ratio of 1/1) with thermally stable core-shell structures were found to be kept for 250 h on stream. This was also attributed to the highly dispersed Ni nanoparticles during the high temperature DRM reaction.

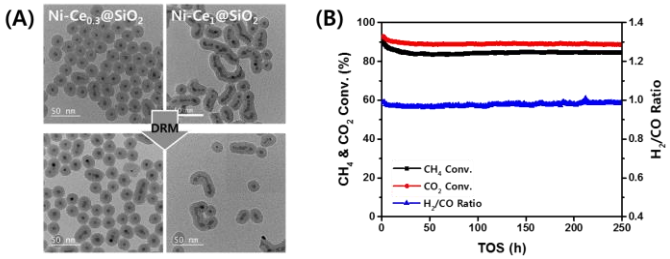

**Figure 1.** (A) TEM images of reduced and used Ni-Ce@$SiO_2$ and (B) long-term catalytic stability on the Ni-$Ce_1$@$SiO_2$.

The positive contributions of cerium oxides can be enlarged by increasing Ce/Ni ratios on the Ni-Ce@$SiO_2$ catalyst due to a more abundant supply of lattice oxygen to oxidize the carbonaceous species. The highly dispersed and intimately interacted oxygen vacancies of $CeO_2$ promoter seems to efficiently suppress the coke depositions as well as structural deformations with the help of the $SiO_2$ shells.

# Carbon nanofiber growth from methane over carbon-supported NiCu catalysts: Two temperature regimes

S. Schoemaker[1], T. Welling[1], D. Wezendonk[1], B. Reesink[2], A. van Bavel[3], P. de Jongh[1]*

**Keywords:** carbon nanofibers; growth mechanism; methane; thermogravimetric analysis

**Introduction.** An attractive route towards $CO_2$-free production of hydrogen is the thermocatalytic decomposition of methane. Next to hydrogen, valuable carbon nanomaterials can be formed.[1] The carbon nanomaterials have interesting properties, e.g. high electron conductivity and mechanical strength.[2] The properties depend strongly on the carbon structure. To tune the properties, it is key to understand the carbon formation, and how it is influenced by the catalyst properties or reaction conditions.[1,2] Many different kinetic properties or optimal conditions have been reported in literature but there is no detailed conceptional framework yet. In this work, the carbon growth was studied in-situ gravimetrically. We focussed on how the reaction parameters influenced the carbon formation over carbon-supported NiCu catalysts.

**Experimental.** Ni-Cu catalysts were prepared via incipient wetness impregnation. The decomposition experiments were performed in a thermogravimetric analyzer. The catalysts were reduced *in-situ* after which the sample was heated to reaction temperature and $CH_4$ gas was introduced. Experiments were performed at varying temperature or with varying methane partial pressure.

**Results.** We identified two distinct temperature regimes. Operating in the different regimes yielded different kinetic properties (activation energies and reaction orders) and formation of different carbon nanostructures. We offer an explanation by considering a change in the rate limiting step upon operating in different regimes: methane dissociation at lower temperature or carbon formation at higher temperature. A maximum carbon yield was obtained at the transition between the regimes, as here the catalytic system is best balanced. Our results offer understanding of the importance of in which regime one is operating in order to understand how reaction conditions influence the catalytic lifetime and what carbon nanostructures are formed.

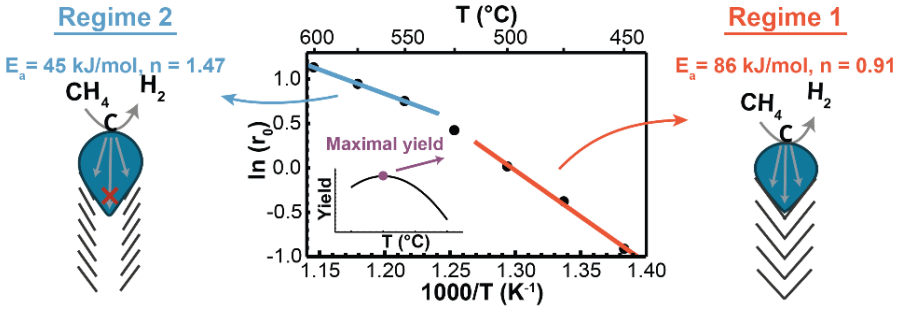

**Figure 1 Graphical illustration of carbon growth in two regimes. A maximal carbon yield is obtained at the transition between the regimes.[3]**

# Developing alumina-based cobalt catalyst for efficient hydrogen production via the ethanol steam reforming process

G. Grzybek[1]*, M. Greluk[2], A. Kierys[2], A. Sienkiewicz[2], J. Lupa[2], G. Słowik[2], M. Rudzińska[1], D. Potyczka[1], P. Stelmachowski[1], A. Kotarba[1]

**Keywords:** cobalt catalyst, alumina support, alkali doping, ethanol steam reforming, hydrogen production, carbon deposit removal.

**Introduction.** Production of hydrogen, considered a fuel of the future, is becoming essential in the light of ongoing energy transformation. It can be produced from bioethanol in the catalytic steam reforming process (ESR). A wide range of catalytic systems was investigated in ESR, among others the cobalt phase dispersed over oxide supports [1]. Unfortunately, they suffer from poor stability, mainly due to coke formation upon ethanol dehydration path, which leads to undesired $C_2H_4$ [2]. This path can be, however, significantly reduced or even eliminated by a controlled modification of the catalyst surface acidity and/or active phase dispersion. In the case of alumina-based systems low acidity may be achieved by using the alpha alumina polymorph [3], while the adjustment can be achieved by alkali doping. Also, the specific surface area of the catalyst is an important factor. To develop an efficient catalyst based on an alumina support, the compromise between its phase composition and internal structure has to be found. In turn, the optimal dispersion of the active phase can be gained by optimizing a method of introduction.

**Experimental/methodology.** We synthesized a series of cobalt catalysts based on alumina supports varying in phase composition and morphology (different synthesis methods). In addition, we optimized the method of cobalt active phase dispersion over $Al_2O_3$ and verified the effect of potassium modification. The samples obtained via the incipient wetness impregnation method, sonochemical synthesis, and hydrothermal synthesis were compared. The prepared samples were characterized with a wide range of methods (e.g. XRD, *in situ* XPS, SEM, TEM/EDX, $H_2$-TPR, RS, TG/DSC) and tested in the ethanol steam reforming process (500°C, EtOH:$H_2O$ 1:12, 21 h). The state of the potassium promoter was studied using a unique thermal alkali desorption method (SR-TAD).

**Results and discussion.** We compared two series of cobalt catalysts based on $Al_2O_3$ supports, one pure alpha phase ($\alpha$-$Al_2O_3$) and the second containing 79% of alpha and 21% of gamma phase ($\alpha\gamma$-$Al_2O_3$). The cobalt active phase in the amount of 10 wt% was loaded using three different methods (mentioned above). First of all, using catalysts from both series assured almost no $C_2H_4$ production (< 1%). The samples based on $\alpha\gamma$-$Al_2O_3$ show a significant advantage over those containing $\alpha$-$Al_2O_3$ in terms of ethanol conversion. Moreover, we observed significantly higher ethanol conversion for catalysts prepared using the sonochemical and hydrothermal method for cobalt dispersion. Adding a potassium promoter allowed for achieving 100% conversion of ethanol. Thus, the adjustment of the alumina support properties (phase composition and internal structure), the method of cobalt introduction, and the loading of potassium promotor allow us to get an efficient ESR catalyst. The observed performance of the catalysts was discussed in terms of the cobalt dispersion, cobalt oxidation state, active phase-support interactions, catalyst surface acidity, and the resistance to deactivation of the catalyst.

**Introduction.** $CeO_2$ is a well-defined support in heterogeneous catalysis that can stabilize very disperse metal species under real reaction conditions due to its special electronic properties.[1] In this sense, the analogous subnanometric cerous oxide units presented in a MOF structure can serve also as support of actives metal single sites for many catalytic processes, including, the low-temperature CO oxidation reaction,[2] due to the presence of oxygen vacancies.[3]

**Experimental/methodology.** The synthesis of the single-atom Pt supported on the UiO-66(Ce) material was carried out by a wet-based impregnation methodology under basic conditions. 150 mg of the as-obtined Pt/UiO-66(Ce) were loaded into a conventional tubular plug-flow reactor for the catalytic test.

**Results and discussion.** We have made a post-synthetic Pt-MOF functionalization based on an efficient electrostatic deposition. The hydroxyl groups present on the $CeO_x$ clusters after the missing-linker process, can be deprotonated under basic conditions and consequently interact with the cationic Pt species (see scheme in Figure 1). In this sense, and thanks to the combination of different techniques, we claimed the success incorporation of Pt-single sites. Ce $L_3$-edge XANES and FTIR spectroscopies indicate a consumption of $Ce^{4+}$ species and consequently an increment of $Ce^{3+}$ after the Pt deposition. Moreover, Pt $L_3$-edge XANES and CO-FTIR spectroscopies confirm the cationic nature of the supported $Pt^{\delta+}$ ($2+<\delta<4+$) on the Ce-MOF. The co-existence of $Ce^{3+}$ sites, able to activate oxygen molecules, and $Pt^{\delta+}$, that can activate the CO molecules, suggested us the possibility to apply this material on the catalytic CO oxidation reaction.

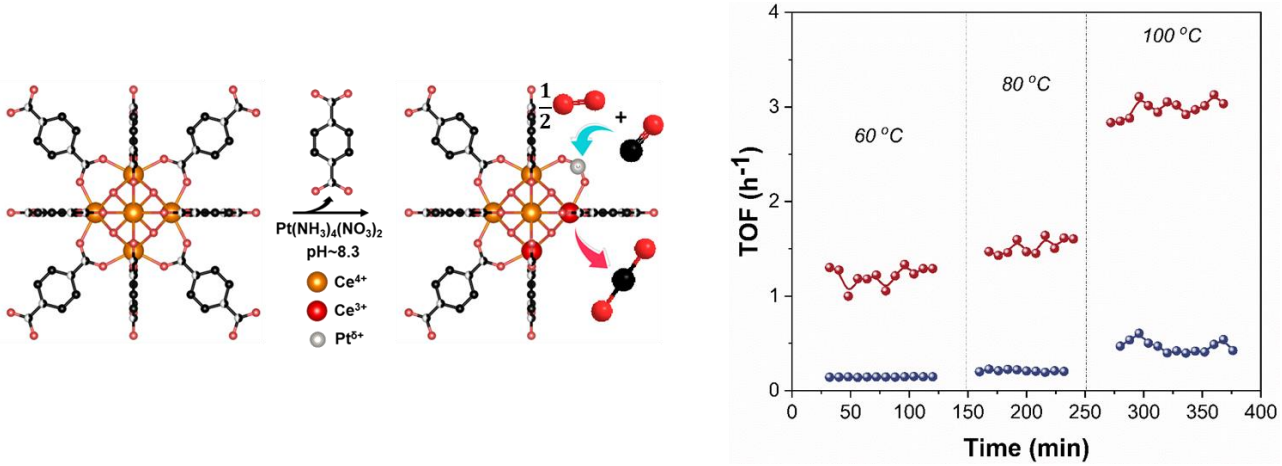

**Figure 1.** Temperature-programmed CO oxidation obtained for Pt/UiO-66(Ce) (red circles) and Pt/*n*$CeO_2$ materials (blue circles).

In fact, the Pt/UiO-66(Ce) synthesized in this work shows an increment of ~6-fold in comparison with the traditional Pt/*n*$CeO_2$ material in the low-temperature range (60-100ºC) studied (see Figure 1). Moreover, its catalytic activity could be preserved at least 14h at 100ºC without any evidence of deactivation. Finally, the material recovered after the catalytic process was characterized by different techniques. X-ray diffraction and Pt $L_3$-edge XANES spectroscopy show that the crystalline and Pt nature, respectively, were maintained during the catalytic test.

[2] *Dow Inc., 1776 Building, Midland MI 48674 (USA)*

[*]*GPollefeyt@dow.com*

**Introduction.** Over the last years, the development of polyfunctional tandem catalysts, using oxygenates as a chemical intermediate, has gained attention for the direct conversion of syngas to light hydrocarbons.[1, 2] In such a hybrid catalyst, a methanol synthesis component (typically a mixed metal oxide) is coupled with a methanol conversion component (typically a molecular sieve). Recent work showed that for olefin production from syngas, CrZnOx-based bifunctional catalysts are very stable with respect to CO activation, however they suffer from gradual loss in olefin yield because of restructuring of the catalyst [3]. This work studied the technical feasibility of stabilizing the catalyst structure and catalyst performance through the addition of trivalent dopants such as Aluminum, Gallium, Iron and Manganese [4].

**Experimental/methodology.** Various Fe, Mn, Al and Ga-promoted CrZn-based mixed metal oxides were prepared by co-precipitation. After drying and calcination, the microstructural and physicochemical properties of the catalysts were characterized by XRF, XRD, TPR, XPS, XAS and TEM. The hybrid catalyst was prepared by mixing the desired amounts of mixed metal oxide and SAPO-34 sieve fractions (40-80 mesh). Syngas conversion was performed in stainless steel fixed-bed reactor systems (i.d. 3 - 7.7 mm) at 20 bar and $H_2/CO = 2$, GHSV 1200-3600 $h^{-1}$. The outlet gas composition was measured using online GC (Maxum).

**Results and discussion.** The promotion of CrZn methanol synthesis catalysts by the addition of a third element such as aluminum, gallium, iron or manganese can effectively increase the initial $C_2$-$C_3$ olefin yield as well as stabilize this high olefin yield over time (Figure 1). Detailed characterization via XAS revealed that incorporating trivalent elements into the spinel phase, stabilizes this structure upon exposure to syngas, leading to higher olefin yield stability. Interestingly, this stabilization effect for iron and mangenese-doped materials is only observed when calcining the materials at low temperature, whereas for aluminum and gallium the stabilization persists up to high calcination temperatures. This work demonstrates the necessity of rational catalyst design, and a perspective will be given on future development options.

**Keywords:** Biomass valorization, $CO_2$ reduction, electrocatalysis, Cu nanoparticles

**Introduction.** In the context of a circular economy there is the possibility of increasing the economic value of wastes, such as biomass, using them as precursors to carbon supports for electrocatalytic application.
The virtuous recovery of citrus waste forms the basis of the following research studies. It is known that such industrial wastes contain added-value chemical compounds such as phenols , flavoniodes and in particular ascorbic acid, used as a capping agent and reducing agent. This study aims to demonstrate the practicality of directly utilizing citrus waste in a one-pot synthesis of C-supported Cu nanoparticles and their application in $CO_2$ electroreduction.

**Experimental/methodology.** Catalysts were prepared by means of microwave-assisted hydro-thermal synthesis; Cu precursor was dissolved in distilled water at 50 °C. Then the peels were finely ground and suspended in the $CuSO_4$ solution and diluted with distilled water afterward thus irradiated with microwaves at 68 °C. The prepared catalysts were thermally annealed in Ar at 500 °C. An ink, was obtained by mixing together catalyst, Nafion, and absolute ethanol by sonication for 2 hours. Then the so prepared ink was deposited on GDL by spray coating. The obtained electrodes, acting as working electrodes, were tested by chronoamperometric detection using a three-electrodes setup cell at two different potential (-1.8, and -2 V vs Ag/AgCl) for 2 hours in a variety of electrolyte (KOH, $KHCO_3$, $K_2SO_4$) and solution saturated with $CO_2$.

**Results and discussion.** The synthesized samples were thermally treated in Ar to enhance the graphitization of the C support, which is required for electrons conduction. The chronoamperometry results show the production of formic acid (FA) and oxalic acid (OA) at both voltages and for both electrocatalysts investigated even if the main product is $H_2$. The best performances are seen for the Cu-Orange thermally treated electrode with Faradaic efficiency (FE) to FA of about 22% at -2 V vs Ag/ AgCl. The prepared catalyst were characterized by X-ray fluorescence analysis that revealed the presence of : C, N,O,S and Cu. SEM studies highlight a porous support homogeneously decorated with round Cu nanoparticles with an average particle size about 370±60 nm. Finally the XPS analysis of the fresh and thermally treated samples provides more information on the surface chemical composition, consisting mostly of Cu, O, and C. Several differences were found between treated and fresh one samples because the thermal treatment induces marked structural modifications mainly on the C electronic structure. Therefore, it is clear that the use of such waste allows not only their re-use, but shows a double positive effect: I) a support that allows good dispersion of the metal and II) the natural presence of chemical compounds with a reducing function such as ascorbic acid. Concluding, the reported procedure can be applied to the preparation of orange peel derived C-supported metal electrocatalysts for other electrocatalytic reactions of relevance in storage and energy conversion.

# Effect of support on methanol selectivity in low-temperature $CO_2$ hydrogenation to methanol over iridium-based catalysts

Ahmad Alrefaei[1], Atul Bansode[1], Atsushi Urakawa[1*]

[1]Catalysis Engineering, Department of Chemical Engineering, Delft University of Technology, Delft, 2629 HZ, The Netherlands

**Introduction**: The conversion of $CO_2$ into a chemical energy carrier, such as methanol (MeOH), is a promising approach to minimize emissions and provide alternative energy sources. The process of converting $CO_2$ to MeOH is thermodynamically favorable at high pressure and low temperature [1]. However, due to $CO_2$ stability, a catalytic system is required to activate it at low temperature. Recent research shows that a binuclear iridium (Ir) molecular complex exhibits high activity toward MeOH in low-temperature $CO_2$ hydrogenation [2]. The high activity is attributed to the Ir species, which forms multiple hydride complexes in the presence of $H_2$ and are responsible for $CO_2$ activation via formate formation [2]. In addition, the Ir- based catalysts behavior in terms of the hydrogenation process, interaction with support, activity, and product selectivity can vary depending on the nature of the support [3]. The present work investigates the effect of support in the Ir-based catalytic system in low-temperature $CO_2$ hydrogenation to MeOH.

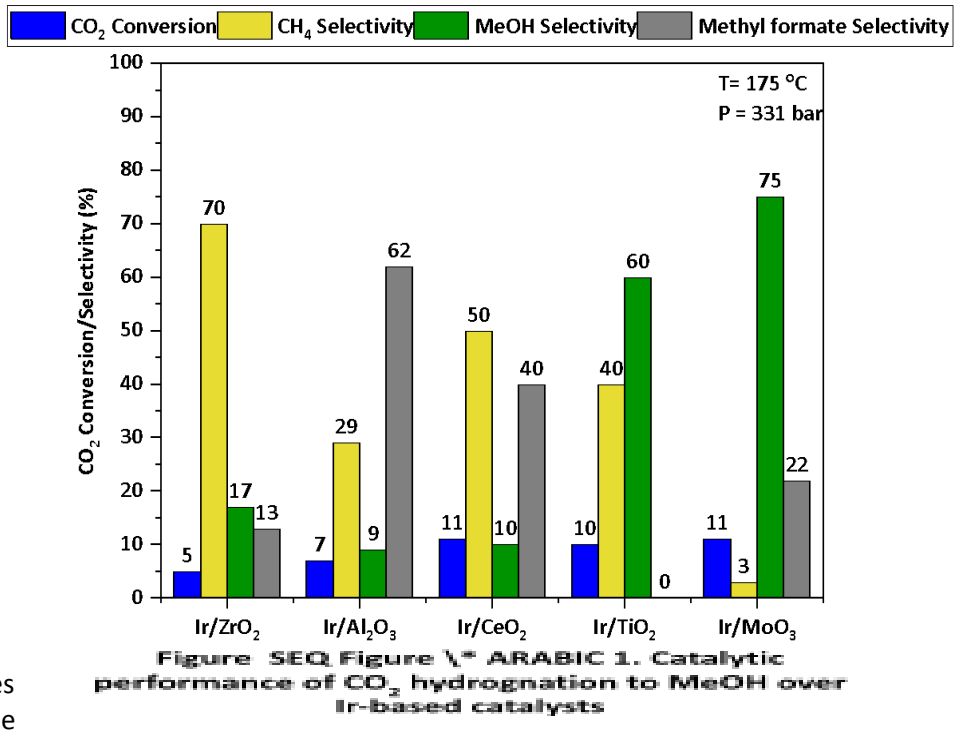

Figure SEQ Figure * ARABIC 1. Catalytic performance of $CO_2$ hydrogenation to MeOH over Ir-based catalysts

**Methodology**: 1.5 wt% of iridium metal was impregnated on $TiO_2$, $ZrO_2$, $MoO_3$, $Al_2O_3$, and $CeO_2$ to study the catalytic activity and the MeOH selectivity. The activity was examined in a fixed-bed reactor at a temperature of 175 °C, a pressure of 331 bar, and $H_2/CO_2 = 3$.

**Results and discussion**: The catalytic activity results depicted in Figure 1 demonstrate that the conversion of $CO_2$ over reducible supports ($TiO_2$, $CeO_2$ and $MoO_3$) is better than non-reducible ($ZrO_2$ and $Al_2O_3$), emphasizing the importance of support nature in enhancing $CO_2$ conversion. However, the support's nature did not have a clear trend on MeOH selectivity as evidenced by the result of both $CeO_2$ and $MoO_3$ (reducible supports). Characterization of catalysts by $H_2$-TPR showed different types of Ir reduction peaks depending on the support used, which highlights the existence of different Ir – support interactions. Furthermore, a noticeable change in product selectivity was observed after several hours, suggesting a possible restructuring of the catalyst. The catalytic performance revealed that Ir/$MoO_3$ catalyst exhibited remarkable MeOH selectivity at low temperature among others, in comparison with Cu/ZnO/$Al_2O_3$ (Commercial catalyst), which yielded the same MeOH selectivity at 260 °C and $H_2/CO_2 = 10$ [1].

**Keywords:** glucose hydrogenolysis, layered double hydroxides, biomass, hydrogenation

**Introduction:** In the last decade the use of biomass as a resource for the chemical industry has become of high interest to reduce the dependence of fossil resources and lessen carbon emissions.[1] One important type of biomass is cellulose, which makes up 30-50 % of the biomass.[2] Due to the complex reaction network of the glucose-hydrogenolysis, a catalyst has to be multifunctional to synthesize ethylene glycol (EG) and propylene glycol (PG) effectively. Catalysts have to balance the activity for hydrogenation and retro aldol reaction to produce less hexitols or other side products.[3] Recent developments focused on the use of a hydrogenation metal (e.g. Ni, Ru, Cu, Pd) together with a retro aldol catalyzing metal oxide (e.g. $WO_x$, $La_2O_3$).[1,4] In our work, we synthesized a novel, modifiable Ni/$WO_x$-layered-double-hydroxide (LDH)-based catalyst, which exhibits a high dispersion of active sites. Additionally, different cations could be incorporated into the LDH-Matrix to tailor the activity and selectivity of the final catalyst. Using this catalyst, the kinetics of the reaction network were investigated and structure activity correlations were established.

**Experimental/Methodology:** The synthesis of the LDH is done using a hydrothermal route with nickel- and aluminium-nitrate. Other cations such as $Mg^{2+}$ or $La^{3+}$ can be incorporated into the LDH-Matrix. Metatungstate is added into the LDH-structure via a pH dependent anionic exchange using diluted $HNO_3$ as acid. The anion exchanged LDHs are calcined in air, followed by reduction in a hydrogen stream. The catalysts are evaluated in the hydrogenolysis of glucose to EG and PG. The reaction is performed in aqueous solution at 180 °C and 50 bar.

**Results and Discussion:** The addition of tungstate anions into the LDH-structure was proven by XRD and XRF measurements. Presenting Ni and $WO_x$ contents each with ca. 40 wt%, whereas the $WO_x$-content was tailored by the choice of pH during the anionic exchange. XRD-measurements of the catalyst showed low intensities, indicating small crystallite sizes. Physisorption experiments revealed an increase of the BET-surface from the LDH (ca. 150 $m^2\ g^{-1}$) to the catalyst (up to 200 $m^2\ g^{-1}$). The high metal loadings together with the high BET-surface areas show the raney-like character of this catalyst system. Ammonia-TPD measurements revealed an increase if the amount and strength of acidic centers, when increasing the $WO_x$ content. TPR-measurements with different $WO_x$-contents showed a decrease in the reduction temperature with increasing $WO_x$-content, indicating strong electronic interactions between NiO and $WO_x$.

In the catalytic experiments, high activities and selectivities towards ethylene glycol were obtained. A study on the $WO_x$-content showed that an increased $WO_x$ content enhances the glycol yields as well as diminishes hexitol yields. By incorporating Mg into the LDH-structure a decrease in the hydrogenating activity could be achieved, showing/proving the modifiability of this catalyst system. Additionally a thorough kinetic study was performed yielding activation energies as well as information about the reaction system.

# Selective Catalysis using Metal Nanoparticles Confined in Porous Materials

D. Iltsiou[1], M. K. Larsen, J. Mielby[1], S. Kegnæs*[1]

**Keywords:** catalysis, zeolites, hydrogenation

**Introduction.**

In spite of the great technological, environmental, and economic interests, general methods for stabilizing metal nanoparticles against sintering are missing. Although for some specific systems, it has been achieved by optimizing the interaction of nanoparticles with a support material or by encapsulation of the metal particles [1-3]. However, these known catalytic systems are, in general, rather expensive and difficult to synthesize, and they cannot be produced on an industrial scale. Therefore, developing novel sintering stable heterogeneous nanoparticle catalysts, which find use in the chemical industry, is very important.

Recently, we have developed several different catalytic systems where metal nanoparticles are confined in different porous materials, including zeolites [3,4,5], porous polymers (POP) [6], and carbon materials [7]. Here, we give an overview of the progress which has been made in the synthesis of metal nanoparticles confined in different porous materials and their application in catalysis. The encapsulation of metal nanoparticles in porous materials often prevents the metal nanoparticle from sintering during a high-temperature catalytic reaction. Furthermore, the porous materials can also contribute actively to the catalytic reaction by improving the catalyst's activity or selectivity, for instance, by controlling the accessible or type of activity sites [3,5]. For instance, we have shown that the metal nanoparticles encapsulated in zeolite materials are only accessible through the pores, which highly favor size-selective reactions [3].

**Results and discussion.**

We have tested the produced materials as catalysts in different selective oxidation and hydrogenation reactions. For example, nickel-encapsulated nanoparticles in zeolites are highly active in the methanisation of carbon dioxide to methane [5,8]. Furthermore, the location of the metal particles has a great influence on the catalyst activity. Additionally, the encapsulated other metal nanoparticles, like Cu, Ru, Pd, and Pt, were demonstrated to be highly active and selective in various gas-phase reactions, including catalytic oxidation of ethanol to acetaldehyde and hydrogenation of alkenes [9,10]. Furthermore, we have characterized the materials with various techniques, including SEM, in situ TEM, STEM, TEM tomography, XPS, XRF, BET, and XRD, among others.

**Keywords:** Cu(I)-based catalyst, mixed metal oxide, hydrogenation

**Introduction.** For most of hydrogenation reactions, the heterogeneous catalysts with expensive noble metals such as Pt, Pd, Rh, and Ru are essential to use. On the viewpoints of elemental strategy, catalysts composed of relatively abundant base metal elements such as Cu and Ni are desirable. Especially, as for the hydrogenation catalyst, $H_2$ activation at mild condition is requested. For example, $Cu/Al_2O_3$ catalyst exhibits the activity for hydrogenation of unsaturated hydrocarbons at relatively low temperature and pressures (80°C and 0.4 MPa, respectively)[1)]. The mixed metal oxides containing two-coordinated Cu(I) and secondary metal species (Al, Fe, Nb, Ta, and Ga) are expected to have unique catalytic activity due to their electronic structures and coordination environments. In this study, we synthesized those Cu(I)-based metal oxides by a solid-state reaction (SSR) method and applied them to catalytic hydrogenation of styrene.
