Functionalized anilines are widely used in the Chemical Industry such as pharmaceuticals or cosmetics. To obtain it, perhaps the most efficient route for the preparation of aniline is the reduction of nitroarenes. Currently, the industrial process continues to be non-catalytic, which is inefficient in addition to generating a large amount of waste. Therefore, it is necessary to look for new synthesis routes that are more efficient and friendly to the environment. For this reason, there is currently intense research into the development of efficient and highly selective catalysts for said reaction. An appropriate catalyst is Pt supported on activated carbon, however it has just been reported that $Mo_2C$ based catalysts are also very efficient, especially those obtained by reactive infiltration [1].

The present investigation develops a new $Mo_2C$ that is 10 times more efficient than any $Mo_2C$ reported to date, for this we rely on the modification of HKUST, which is modified by the inclusion in its structure of Mo polyoxometalate cluster, better known as NENU-5

**Experimental/methodology.**

NENU-5 is treated in different atmospheres from He to He-20% $H_2$ at temperatures between 500 and 900 ºC depending on the atmosphere used. The material obtained has been characterized by the usual techniques (XRD, XPS, N2 adsorption, SEM, TEM) as well as by more advanced techniques (XANES-EXAFS at ALBA).

For the catalytic tests, the procedure described in [1] has been followed, a theoretical analysis based on the adsorption energy on the different crystalline faces of Mo2C has also been carried out using DFT.

**Results and discussion.**

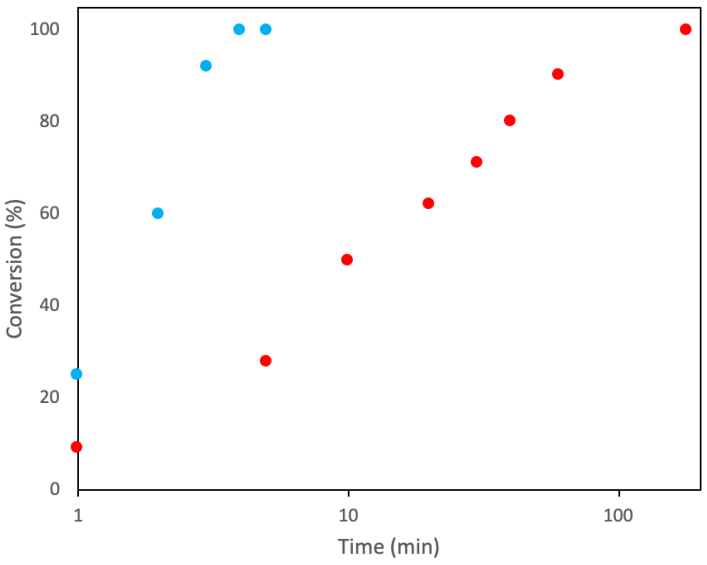

Figure 1 shows the production of para-chloro-aniline as a function of time for one of the catalysts synthesized from NENU-5, and it is compared with the data obtained in [1], as can be seen it is much more efficient, but It is also 100% selective. It is important to point out that said catalyst from the literature already showed results comparable to those obtained by a commercial Pt-C catalyst.

**Keywords:** hierarchical zeolite, Prins cyclisation, tetrahydropyranol, Florol, acid sites

**Introduction**

Hierarchical zeolites are one of the most perspective acidic catalytic materials consisting of a crystalline network that possesses not only uniform micropores, but also secondary meso- or macro-porosity, enabling transformations of bulky organic molecules [1]. The Prins cyclization reaction between biomass-derived isoprenol and isovaleraldehyde results in a commercial perfume ingredient (Florol®) [2]. Besides the desired tetrahydropyranol (THP), this reaction can also give several dehydration products (DHP) (Figure 1) capable of subsequent reactions with the initial substrates (IVA or IP) resulting in trimers.

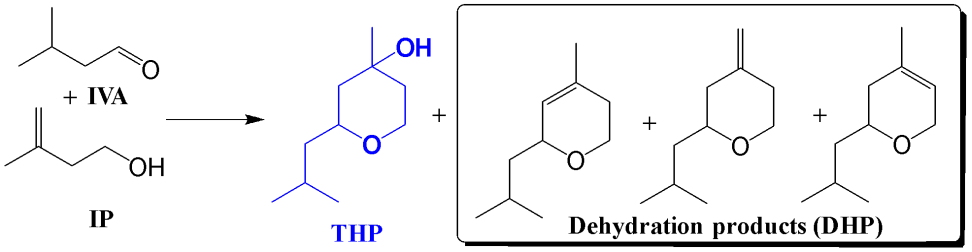

**Fig. 1. Prins cyclization of isovaleraldehyde (IVA) and isoprenol (IP) resulting in tetrahydropyranol (2-isobutyl-4-methyl-tetrahydro-2H-pyran-4-ol, THP) and side dehydration products (DHP).**

Specifically, this work was devoted to the investigation of the influence of textural and acidic properties of synthesized hierarchical beta zeolites on their catalytic activity in the Prins cyclization of isovaleraldehyde with isoprenol. Due to the presence of mesopores in the hierarchical zeolites mitigating steric limitations in converting bulky molecules exceeding the zeolite micropore size and enhancing the intracrystalline diffusion, these materials can be promising catalysts in the Prins cyclization of isovaleraldehyde with isoprenol.

**Experimental/methodology**

In this work, Prins cyclization of isoprenol with isovaleraldehyde was carried out in the liquid phase using a batch-mode operated glass reactor at mild reaction conditions (40 °C, atmospheric pressure). A set of hierarchical beta zeolites prepared from a concentrated alkali metal-free protic acid-containing zeolite gel-precursor, as well as Al-, Ga-, Fe-, B-silicate hierarchical zeolites of various structures (BEA, MOR, MFI, FER) and morphologies (nanoparticles, nanosheets or nanorods) was applied for catalysis.

**Results and discussion**

Among Beta zeolites prepared from concentrated reaction mixtures, the highest yield of the desired product (55.4%) was achieved over a catalyst possessing moderate acidity, developed mesoporosity ($V_{meso}$ 0.60 $cm^3/g$) and a high external surface area (290 $m^2/g$). Application of isomorphously substituted samples (with Ga, B) exhibiting a lower strength of acid sites contributes to an increase in selectivity towards the desired product. Catalytic results on Prins cyclization of isovaleraldehyde and isoprenol over the prepared hierarchical zeolites will be presented, showing a clear relationship between the structure and catalytic activity.

**Keywords:** continuous-flow hydrogenation, 2-methyl-3-butyn-2-ol, 2-butyne-1,4-diol, 2-methyl-2-pentenal, transition metal catalysts

**Introduction.** Sustainable development requires modern, more intense, more efficient, and environmentally friendly technologies [1]. Implementing the liquid phase continuous-flow operation instead of batch mode belongs to this trend [2]. In particular, it seems to be important in such a demanding field as the pharmaceutical industry, which focuses on achieving 100% selectivity for the desired product. Therefore the primary goal of the studies was to create a relationship between the structure of the readily available 3d transition metal catalysts and their reactivity in continuous-flow hydrogenation of the precursors of relevance to the pharmaceutical industries [3]. In our studies, the continuous-flow mode was successfully implemented, e.g. for semi-hydrogenation of 2-methyl-3-butyn-2-ol and 2-butyne-1,4-diol towards forming essential A, E and B6 vitamins intermediates, several insecticides and antitumoral chemicals. Chemoselective hydrogenation of 2-methyl-2-pentenal led to the formation of two desired products: 2-methylpentanal: an essential intermediate for dyes, resins and drugs production or 2-methylpenten1-ol: valued in perfume production.

**Experimental/methodology.** 6 wt% Cu catalysts were synthesized by different methods (grafting on the polymeric resin (TS-$NH_2$), simple impregnation (active carbon supported catalysts), or precipitation in the case of hydrotalcite derived materials). The liquid-phase catalytic selective hydrogenation was performed in the temperature range from 10 to 100°C and pressure range from 1 to 60 bar, using continuous-flow microreactor with an HPLC pump. The proper interpretation of the catalytic results was supported by physicochemical characterization using physisorption analysis, TGA, ICP OES, TPR, $H_2$-TPD, $NH_3$-TPD, $CO_2$-TPD, XRD, including XPS, in-situ TEM measurements and by DFT calculations.

**Results and discussion.** Our results show that catalysts containing small Cu content are active and stable in selective hydrogenation processes toward forming industrially relevant chemicals (2-methyl-3-buten-2-ol, 2-butene-1,4-diol, 2-methylpentanal and 2-methylpenten1-ol, respectively). Depending on the reaction conditions was possible to obtain high activity and ~ 100% selectivity towards desired products. The selectivity control, while maintaining a high substrate conversion at parameters optimal from an economic point of view, was possible thanks to the synthesis of the catalysts with the specific electronic properties, the presence or absence of the electrophilic sites and the steric effect.

**Keywords:** Hydrogenation, Alloy catalyst, Heteroaromatics

**Introduction.** Aliphatic cyclic amines are important chemicals for the synthesis of fine chemicals, pharmaceuticals and pesticides and so on, and they can be synthesized by hydrogenation of *N*-heteroaromatics with hydrogen. Hydrogenation of *N*-heteroaromatics such as pyridines and quinolines is generally difficult because the N atom of the substrates is strongly coordinated to the active metal center of catalysts. Various heterogeneous catalysts have been intensively developed [1]. Supported noble-metal catalysts such as Rh, Pd, Ru and Pt catalysts are typically more active for hydrogenation of *N*-heteroaromatics than the non-noble-metal ones, and Ir is less active among noble metals. Therefore, active non-noble metal-based catalysts are desired to be developed. In our previous works [2], we found that $SiO_2$-supported Ni-Ir alloy catalyst showed high activity for the hydrogenation of olefins. In this work, we applied the catalyst to the hydrogenation of *N*-heteroaromatics and found that $SiO_2$-supported Ni-Ir alloy showed high activity for the reaction [3].

**Experimental/methodology.** Ni-Ir/$SiO_2$ was prepared by sequential impregnation method. Ir/$SiO_2$ was synthesized by impregnating $SiO_2$ with $H_2IrCl_6$aq, and it was dried at 373 K overnight after removal of water by evaporation at 353 K. Ni was loaded on the Ir/$SiO_2$ by impregnating Ir/$SiO_2$ with $Ni(NO_3)_2$aq, followed by drying at 373 K overnight after removal of water by evaporation at 353 K. Finally, the obtained dried Ni-Ir/$SiO_2$ was calcined at 773 K for 3 h. Activity tests were conducted in a 190-ml autoclave with an inserted glass vessel. The reduced catalyst, a spinner and a mixture of pyridine and methanol were added to the glass vessel in the autoclave. After flashing air in the autoclave by $H_2$, the reactor was pressured to 1 MPa by $H_2$ at rt. Then, the autoclave was heated to 353 K and $H_2$ pressure was increased to 8 MPa.

**Results and discussion.** Fig. 1 shows the result of catalyst screening of M–Ir/$SiO_2$ (M=Fe, Co, Ni and Cu, M/Ir=1) and Ni–M'/$SiO_2$ (M'=Pd, Ru and Pt, Ni/M'=1) catalysts in hydrogenation of pyridine to piperidine as a model reaction. Ni-Ir/$SiO_2$ clearly showed high activity for the reaction, and other combinations were not effective. Ir/$SiO_2$ and Ni/$SiO_2$ also showed low activity. The activity based on the catalyst amount is about 16-fold higher than monometallic Ir and Ni catalysts. Therefore, the combination of Ni and Ir was effective for the reaction. Based on the characterization of Ni-Ir/$SiO_2$, Ni-Ir/$SiO_2$ has Ni-Ir alloy, which will be responsible for the high activity. The catalyst was applicable to the hydrogenation of other pyridines and quinolines.

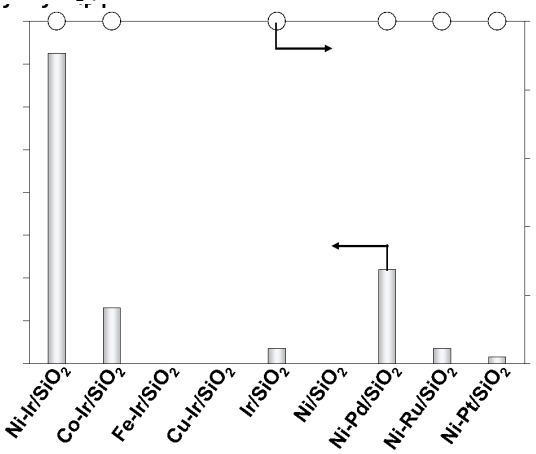

**Fig. 1.** Catalyst screening of M–Ir/$SiO_2$ and Ni–M'/$SiO_2$ catalysts in the hydrogenation of pyridine
Reaction conditions: 0.02 g catalyst (noble metal: 4 wt%), 5 mmol pyridine, 3 g methanol, 8 MPa $H_2$, 353 K, 4 h.

**Keywords:** basic catalysis, double substitution, fused ring compound

**Introduction**

Energetic materials used in the military field have attracted the interest of scientists worldwide over the past decades as important materials for the development of the weapons industry[1-3]. However, traditional energetic materials no longer met the requirements of rapidly evolving weapons. Compared to conventional energetic materials, fused ring compounds meet the high stability requirements of new energetic materials[4].4,4'-5,5'-tetranitro-2,2'-biimidazole (TNBI)[5] is a member of the common energetic materials. Its high impact sensitivity (IS: 5-6 J) makes it impossible to apply directly. The addition of alkyl groups to synthesize fused ring compounds can result in reduced susceptibility and improved safety.

**Experimental section.**

4,4'-5,5'-tetranitro-2,2'-biimidazole was used as a raw material and reacted in toluene at high temperature for 48 hours with $Na_2CO_3$ as a basic catalyst and 1,2-dibromoethane as a reactive agent. At the end of the reaction, the reaction mixture was cooled to room temperature and poured into ice water. The solid product was filtered out and rinsed with plenty of deionized water. The resulting solid dried in the air.

**Results and discussion.**

The modification of the sensitive 4,4'-5,5'-tetranitro-2,2'-biimidazole (TNBI) was catalyzed by the basic catalyst $Na_2CO_3$ and the introduction of the alkyl group with 1,2-dibromoethane, which reduces their mechanical sensitivity resulting in a thick ring product with IS > 40J.

# Regioselective N-Alkylation of 2-Amino-Azoles with Alcohols for the synthesis of 2-N-(alkylamino)azoles Catalyzed by a Ruthenium Complex Bearing a Functional Ligand

Xiangchao Xu, Yawen Tang, Jin Zhang, Feng Li*

*Nanjing University of Science & Technology, Nanjing 210094, P. R. China*
**E-mail address: fengli@njust.edu.cn (F. Li)*

**Keywords:** Regioselective, 2-N-(alkylamino)azoles, Ruthenium complex, Functional ligand.

**Introduction.** 2-N-(alkylamino)azoles represent a class of important N-containing heterocycles, which display a wide spectrum of biological activities.

Recently, considerable attention has been directed to the N-alkylation of amines with alcohols as alkylating agents based on hydrogen autotransfer process or hydrogen-borrowing strategy,[1] using Ir,[2] Ru,[3] and Pd[4] complexes. As a continuing effort in this field, we wish to describe our effort toward ruthenium-catalyzed regioselective N-alkylation of 2-amino-azoles with alcohols for the synthesis of 2-N-(alkylamino)azoles.

**Experimental/methodology.** To an oven-dried 25 mL Schlenk tube were added 2-amino-azoles (1 mmol), alcohol (1.2 mmol), catal (0.005 mmol, 0.5 mol %), base (1 mmol, 1 equiv) and *tert*-amyl alcohol (1 mL). The mixture of reaction was heated under 120 °C in an oil bath for 12 h. The reaction mixture was cooled to ambient temperature, concentrated in vacuo and purified by flash column chromatography with ethyl acetate/hexanes to afford the corresponding product.

**Results and discussion.** Our initial investigation focused on the N-alkylation of 2-aminobenzothiazole with benzyl alcohol. With the optimal reaction conditions in hand, we examined the scope of reaction with respect to alcohols and 2-amino-azoles (Figure 1). It should be pointed that apart from the desired products 2-N-(alkylamino)azoles, no isomer 3-alkyl-2-iminoazolines were found in all cases.

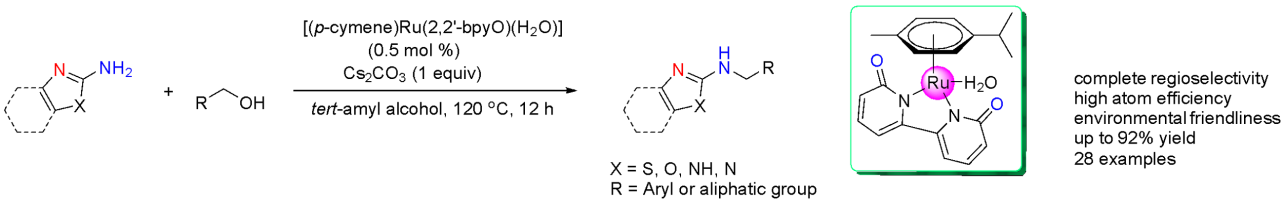

**Figure 1. N-Alkylation of 2-amino-azoles with alcohols catalyzed by a ruthenium complex**

Based on experimental results, a plausible mechanism is proposed to account for the present regioselective N-alkylation of 2-amino-azole with alcohols. Furthermore, a series of mechanistic experiments were undertaken. To demonstrate the practical potential of the present catalytic system, the gram-scale synthesis of a biologically active molecular was presented.

In summary, we have developed an efficient method for the direct synthesis of 2-N-(alkylamino)-azoles *via* the N-alkylation of 2-amino-azoles with alcohols catalyzed by a ruthenium complex bearing a functional ligand [(p-cymene)Ru(2,2'-bpyO)($H_2O$)]. Notably, this study would facilitate the progress of metal-ligand bifunctional catalysts for the hydrogen autotransfer process.

# Development of a packed bed reactor system for $CO_2$ hydrogenation to formic acid using ruthenium PNP pincer catalyst

G. Afreen[1], A. Bansode[1], K. Wada[2], M. Hirano[2], H. Matsuda[2], A. Urakawa[1*]

[1]*Catalysis Engineering, Department of Chemical Engineering, Delft University of Technology, Delft, The Netherlands*

[2]*Corporate Research and Development Division, Sustainable Technology Research Center, Nitto Denko Corporation, Osaka, Japan*

[*]*A.Urakawa@tudelft.nl*

**Keywords:** $CO_2$ hydrogenation, Packed bed reactor, Homogeneous catalyst, Formic acid

**Introduction.** The ever-increasing atmospheric concentration of carbon dioxide ($CO_2$) is a major concern regarding global warming and climate change. Among various strategies to control $CO_2$ emission into the atmosphere and/or capture $CO_2$ from the atmosphere, $CO_2$ utilization to produce C1 chemicals like formic acid (HCOOH) or formate ($HCOO^-$) is an effective approach [1]. Industrially, formic acid is a valuable commodity chemical with uses in preservatives, synthesis precursors, and most notably, as a hydrogen carrier. Its easy decomposition and reversible nature make it an exceptional liquid organic hydrogen carrier (LOHC), capable of storing hydrogen effectively. The process of formic acid formation from $CO_2$ hydrogenation is an endergonic catalytic reaction making the reaction thermodynamically unfavourable (equation 1) [2].

$$\square_{2(\square)} + \square\square_{2(\square)} \rightleftharpoons \square\square\square\square\square\square\square\square\square_{(\square)} \qquad \Delta\square^{\circ} = +32.9\ \square\square\square\square\square\square^{-1} \qquad (1)$$

$$\square_2 + \square\square_2 + \square\square\square\square\square\square \rightleftharpoons \square\square\square\square\square\square^- + \square\square\square\square\square\square\square\square^+ \qquad \Delta\square^{\circ} < 0\ \square\square\square\square\square\square^{-1} \qquad (2)$$

Many basic additives such as KOH, $NaHCO_3$, etc are used to promote the reaction and overcome the thermodynamic limitations (equation 2). Another interesting approach is direct reduction of bicarbonate to formate since $CO_2$ remains in equilibrium with bicarbonate in aqueous medium. Also, bicarbonates are easily formed from $CO_2$ and alkanol amines. Such hydrogenation reactions have been studied predominantly using homogeneous catalysts such as Ru, Rh, Ir, Co, and Fe complexes in batch reactors under high pressure conditions (~60-100 bar) [3]. However, catalyst recovery and recycle become difficult in such reactor systems.

**Experimental/methodology.** We have developed a continuous flow packed bed reactor system for effective hydrogenation of bicarbonate premixed with catalyst to form formate using ruthenium PNP pincer organometallic catalyst.

**Results and discussion.** Under the reaction conditions of 40 bar and at 90 °C, a turnover number (TON) of ca. 4000 was achieved in a single pass, with a formate yield of around 30% (Figure 1). The reaction parameters such as temperature, pressure, residence time, and reactant flow rates are further optimized to improve the TON and yield remarkably. Additionally, the catalyst used in the process can be recovered and recycled for subsequent runs, making the reactor system economically appealing.

**Figure 1. Reaction scheme of bicarbonate hydrogenation in a packed bed reactor using Ru PNP pincer catalyst.**

# Non-metal doped triazine-based covalent organic frameworks as heterogeneous photocatalysts for biomass conversion

**Anise Akhundi*, Michael Wark**

*Institute of Chemistry, Carl von Ossietzky University Oldenburg, 26129 Oldenburg, Germany*

**anise.akhundi@uni-oldenburg.de*

**Introduction**. Photocatalytic conversion of biomass to fine chemicals is of great importance due to its environmental friendliness and the transformation potential to second generation fuels. 5-hydroxymethyl furfural (HMF) is a biomass-derived key platform molecule to synthesis of fine chemicals [1]. However, developing an efficient metal-free photocatalyst for HMF conversion is a challenging task. In our previous work, exfoliated carbon nitride nanosheets have been prepared by different methodologies and applied for the selective photocatalytic conversion of HMF to 2,5-furandicarboxyaldehyde (FDC) [2]. Now, we deal with synthesis of triazine-containing covalent organic frameworks (COFs) in a microwave-assisted method. We plan to create defects in the structure of the synthesized COFs by doping non-metal phosphorus element. The synthesized defected COFs will be closely characterized by $^{13}$C-NMR, FTIR, XRD, elemental analysis, and gas adsorption. The effects of defects on the band gap and energy levels of the photocatalysts will be investigated. The photocatalytic conversion of HMF to 2,5-furandicarboxylic acid (FDCA) will be conducted over the triazine-containing COFs and the activity of photocatalysts in terms of HMF conversion and selectivity towards FDCA will be assessed.

**Experimental/methodology.** Recently, g-$C_{18}N_3$-COF as a two-domensional triazine-cored COF was solvothermally synthesized upon Knoevenagel condensation using 2,4,6-trimethyl-1,3,5-triazine (TMTA) and 1,4-diformylbenzene (DFB) [3]. Inspired by this study, we use a microwave-assisted method in order to shorten the reaction time and compare the characteristics of the obtained samples with those of others. We plan to improve semiconducting behaviour of triazine-based-COFs by doping with phosphorus. The photocatalytic experiments will be conducted in a quartz glass photoreactor, under irradiation of LED lamps. After a suitable reaction time, the irradiated solutions will be analyzed by HPLC to detect products and possible intermediates of the reaction.

**Results and discussion.** The main focus of this study is the synthesis of triazine-based covalent organic frameworks, investigation of their physicochemical properties and their application in photocatalytic biomass conversion reactions. Based on our extensive experiences in synthesis and modification of the structure of g-$C_3N_4$-based nanomaterials [4], we extend similar methodology to synthesis of COFs and their modification via defect-engineering. In our previous work, exfoliation of carbon nitrides resulted in increased specific surface area and improved the conversion of HMF and the selectivity to FDC. Furthermore, achieving P-doped COFs and studying their optical and semiconducting properties is another goal of this research. Our previous study shows (Fig. 1) that phosphorus doping narrows the band gap and extends the light absorption of g-$C_3N_4$ [5].

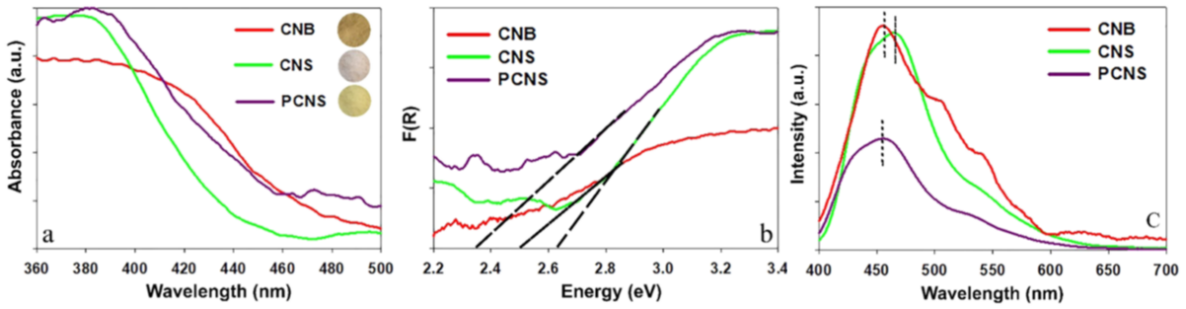

**Figure 1. (a) DRS spectra, (b) Tauc plots, and (c) photoluminescence (PL) spectra of bulk g-$C_3N_4$ (CNB), g-$C_3N_4$ nanosheets (CNS), and P-doped g-$C_3N_4$ PCNS**

**claudio.arayal@uc.cl neescalona@ing.puc.cl*

**Keywords:** Nickel Phosphide; Reductive Amination; Pyrroldiones

**Introduction.** There is an abundant amount of biomass on Earth, and it is a promising candidate to replace petrochemical-based compounds. In this line, N-methyl-pyrrolidone (NMP) is an important chemical with a worldwide production of 200-250kton/y, and has been used in petrochemical processes or plastic industry. However, NMP is highly toxic, dangerous and produces infertility and miscarriage. 5-methyl-N-substitute-2-pyrrolidones (5MPs) are an alternative to replace NMP and neither toxic nor cancerous. 5 MPs can be synthesized through reductive amination of levulinic acid plus nitrogen agent using $H_2$ as reducing agent, also that the levulinic acid can be directly obtained from biomass. This research points out synthesized pyrrolidones-derived compounds through catalytic reductive amination using supported nickel phosphides ($Ni_2P$) as a heterogeneous catalyst since nickel phosphides have shown promising results hydrogenating organic molecules [1]. **The main objective** is to understand the role of different supports such as $SiO_2$, $ZrO_2$ and $TiO_2$ in the catalytic activity.

**Experimental/methodology.** a solution of $Ni(NO_3)_2$ and $(NH_4)H_2PO_4$ is put together in acidic water in order to impregnate the support with 10% of Ni and 2:1 P/Ni molar ratio via the incipient wetness impregnation procedure. After leaving the impregnated support mature, this is calcined, reduced under $H_2$ flow and passivated. The catalyst is characterized by TPD-$NH_3$, TPR, BET, XRD and XPS. The reaction is carried out in a Parr Reactor using a stoichiometric quantity of levulinic acid and nitrogen agent (Aniline) in dioxane at 200°C and 50bar of $H_2$ using $Ni_2P/SiO_2$, $Ni_2P/ZrO_2$, and $Ni_2P/TiO_2$, with an atomic density of 3.23 at/nm$^2$ nominally.

**Results and discussion.** The preliminary results are shown in **Figure 1**, wherein $Ni_2P/SiO_2$ and $Ni_2P/ZrO_2$ do not have a significant difference in the conversion of levulinic acid, but $Ni_2P/TiO_2$ presented another behavior because it increased the selectivity of molecular intermediaries but not promoting the hydrogenation. The selectivity towards 5-methyl-phenylpyrrolidin-2-one has increased in the following order $Ni_2P/TiO_2$ < $Ni_2P/ZrO_2$ < $Ni_2P/SiO_2$ being oppositely related with the acidity of supports. Additionally, $Ni_2P/SiO_2$ was compared to $Ni/SiO_2$, and $Ni_2P/SiO_2$ suppressed the increase of γ-valerolactone in comparison with the $Ni/SiO_2$, which promotes the hydrogenation of levulinic acid to γ-valerolactone.

**Figure 1: Conversion and selectivity as a function of time**

In conclusion, $Ni_2P/SiO_2$ shows the best selectivity towards pyrrolidone in comparison with the other supports. In contrast, $Ni_2P/TiO_2$ presents the best conversion because it promotes the production of intermediaries between levulinic acid and aniline.

**Keywords:** Catalysis, Atropselective Negishi Coupling, Sustainability, Green Chemistry

**Introduction.** GDC-6036 (**1**) is a highly potent and selective KRAS G12C irreversible, covalent inhibitor, which is currently in clinical development to treat a wide spectrum of tumors.[1,2] The main synthetic challenge in the synthesis of GDC-6036 (**1**) is the installation of the stereoaxis between the aminopyridine and the quanalozine fragments (bond marked in red in Scheme 1) in a highly selective manner.

**Results and discussion.** Early R&D efforts applied non-stereoselective approaches, resulting in the need of preparative chromatographic separation techniques to isolate optically pure material.[1] Later, a first stereoselective Negishi coupling of Bromopyridine **2** and the Bromoquanazoline (*S*)-**3** using a Walphos type ligand was identified, giving up to 92% selectivity for the desired (*R*)-atropisomer (*R*,*S*)-**4,** using a ligand that is not commercially available in the required quantities.[2]

**Scheme 1: New Pd-catalyzed, atropselective Negishi coupling**

Further ligand screening activities identified an unprecedented, highly selective (95% selectivity for (*R*,*S*)-**4**), commercially available and easily accessible ligand (*R*,*R*)-Chiraphite for this transformation.[3] The implementation of this ligand and the identification of an efficient crystallization of (*R*,*S*)-**4** allowed for the development of an economic process for the production of multi hundreds of kilos of GDC-6036. Our efforts and the challenges observed to move this transformation from milligram scale in the laboratory to 125 kg batches in the production plant will be presented.

**Keywords:** Homogeneous Catalysis, Manganese, Carbene Ligands, Hydrogenation, Esters

**Introduction.** The reduction of carboxylic acid esters to alcohols is an important transformation in academic and industrial chemistry. Therefore, catalytic hydrogenation represents an environmentally and economically attractive approach compared to traditional procedures applying metal-hydrides in stochiometric quantities.

To date, many highly active homogeneous catalysts, mainly based on Ru[1], have been developed which allow for the hydrogenation of carboxylic acid esters at mild conditions. Over the last decade, efforts were made to replace noble metals in such catalysts by more abundant, cheaper, and non-toxic base metals and systems based on Mn, Fe, Co and Cu were reported. Especially Mn[2] has been studied intensely due to the remarkable stability, high activity, and versatility of its pincer complexes. However, the diversity of the known Mn catalysts is very limited since the vast majority relies on phosphine containing ligands including metal ligand cooperative sites. Over the last years it has been shown that also Mn complexes bearing more simple, non-bifunctional ligands can be efficient in hydrogenation-type reactions.[3]

**Experimental/methodology.** For that purpose, a series of structurally related bis(NHC) Mn(I) complexes **1** were synthesized via a novel synthetic procedure utilizing NHC-borane adducts in very good to excellent yields. Complexes **1** have been characterized by NMR spectroscopy, IR spectroscopy and HR-MS and in two cases additionally by elemental analysis and single crystal XRD.

**Results and discussion.** Various aromatic and aliphatic carboxylic acid esters have been hydrogenated using complexes **1** with $KHBEt_3$ as cocatalyst under mild reaction conditions (0.5 mol% catalyst loading, 60-100 °C).

***Scheme 1: Mn-catalyzed hydrogenation of carboxylic acid esters.***

Furthermore, mechanistic experiments reveal the importance of $BEt_3$ as cocatalyst, which is liberated from $KHBEt_3$ after formation of a hydrido complex. A proposed mechanism is further supported by DFT calculations.

**Keywords:** palladium−zinc, hydrogen peroxide, peroxygenase, oxidation, cascade

**Introduction.**

Supported Pd-based catalysts have shown to be effective when used in combination with an evolved unspecific peroxygenase from Agrocybe aegerita (PaDa-I variant) to selectively produce cyclohexanol and cyclohexanone (KA Oil) from cyclohexane via in-situ produced $H_2O_2$, avoiding the by-products typically generated via current industrial approaches. Producing in situ $H_2O_2$ directly with heterogeneous catalysts overcomes the downsides that incur with other methods; such as the production of unwanted byproducts and atom inefficiency found when coupling with glucose oxidase, or the addition of acid stabilizers or concentration “hot spot” generation that occurs with externally drip fed systems.[1]

**Experimental/methodology.**

Mono- and bi-metallic 1% Pd-X/$TiO_2$ catalysts have been prepared via an excess chloride co-impregnation procedure, based on the literature.[2] Cyclohexane oxidation cascade experiments were performed in a one-pot system under conditions conducive to enzyme stability.

**Results and discussion.**

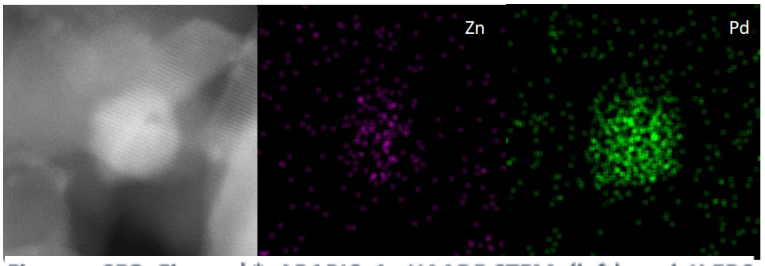

*Figure SEQ Figure * ARABIC 1. HAADF-STEM (left) and X-EDS (purple and green are Zn and Pd respectively) analyses of one of the larger particles showing alloying of the Pd and Zn.*

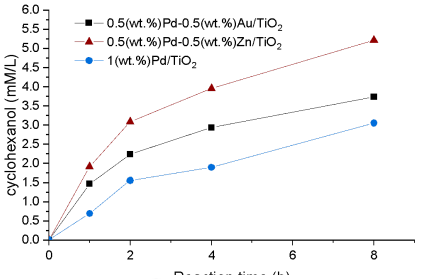

*Figure SEQ Figure * ARABIC 2. Time-on-line of the oxidation of cyclohexane (10mM) to cyclohexanol using Pd based catalysts in cascade with Pada-1*

We have investigated a range of Pd-based catalysts, for the selective oxidation of cyclohexane to KA oil, when used in conjunction with PaDa-I. The alloying of Pd with Zn in particular is found to offer improved catalytic performance compared to PdAu analogues (**Figure 2**), which have been previously reported within the literature.[3] The enhanced activity of the PdZn/$TiO_2$/PaDa-I system is attributed to the facile formation of PdZn alloys (**Figure 1**) and resulting electronic modification of Pd which offers results in increased selectivity towards $H_2O_2$ and inhibits chemo-catalyzed over oxidation of cyclohexanol. By comparison, the large population of unalloyed Pd species present in both the PdAu and Pd-only catalysts are found to be responsible for the promotion of further oxidation products and the unselective conversion of $H_2O_2$ to $H_2O$, which hampers the overall process efficiency. Additional information can be found at Brehm et al.[4] DOI: https://doi-org.abc.cardiff.ac.uk/10.1021/acscatal.2c0305

ccampos@udec.cl

**Keywords:** Tandem reaction, MCM-41, Iridium, 2-benzimidazole.

**Introduction:** 2-subtituted benzimidazoles are important organic molecules that are building blocks for the preparation of antiviral, anticancer, antiulcer, antihypertensive, antifungal, and antihistamine drugs, among others. Traditionally, these compounds are obtained by two main synthetic routes: (1) through the coupling of o-phenylenediamines with carboxylic acids or their derivatives using conditions that require high temperatures and strong acid conditions or (2) from the transfer reduction/dehydrogenation of 2-nitroaline or o-phenylendiamines with alcohols [1]. Remarkably, non-noble based catalysts demonstrate excellent results in the borrowing hydrogen reduction reaction. Among them, the use of heterogeneous Iridium formulations provides highly efficient and operational stable catalysts for this kind of reaction. However, the effect of the support displayed an important role in the dehydrogenation step [2]. This work is aimed with the effect of iridium nanoparticles (Ir NPs) supported onto titanium substituted MCM-41 structure as catalyst for the tandem production of 2-phenyl-benzimidazole (BZI) – as test reaction – from 2-nitroaniline (2NA) and benzaldehyde (BZ) using Iridium as active phase.

**Experimental/methodology.** The Ti-substitution onto the MCM-41 structure was carried out according to our previous reported methodology [3]. The obtained solid were prepared with Si/Ti mole as 0, 10, 20, 60 and 120. The deposition of the Ir NPs is carried out using Iridium (III) acetylacetonate precursor (at 0.25 wt%) in acetone as solvent, which was contacted with the and dried in vacuum to obtain the final solid. The solids were calcinated and reduced with $H_2$. The obtained catalysts were characterized by the following techniques: ICP-MS, $H_2$-chemisorption, XRD, $N_2$ adsorption-desorption isotherm, SEM-EDAX, TEM, XPS. The catalytic measurements were carried out in a stainless steel (150 mL) semi-batch Parr-type reactor at 150°C under 5 bar of $H_2$ pressure for 15 min, then the gas was changed to 5 bar of $N_2$, using 50 mg of catalyst and 2NA/Ir mole ratio of 100 in cyclohexane as solvent. The reaction products were identified via gas chromatography using a GC Clarus 680 Perkin Elmer instrument equipped with an Rtx-5 Amine column and a flame ionization detector (FID).

**Results and discussion.** The physicochemical characterization of the Ir supported catalyst displayed a uniform metal dispersion, which increased with the increase of Ti-substitution in the MCM-41 support. In line with these results, the XPS analysis showed an increase in the surface $Ir^{\delta+}$ species with the increase of the metal loading. All the catalyst showed catalytic performance for the preparation of BZI with high selectivity to the target product. Among them, the Ir/MCM-41(Ti20) catalyst displayed the higher catalytic efficiency. Also, this catalyst displayed the optimal operational stability reaching 5 recycles remaining a high conversion and selectivity to BZI production.

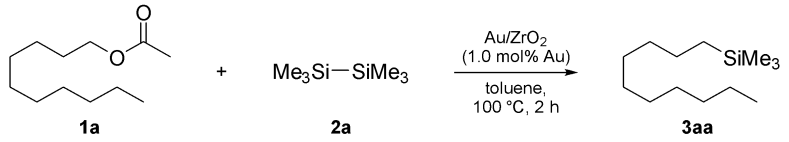
# Diverse Alkyl–Silyl Cross-Coupling via Homolysis of Unactivated C($sp^3$)–O Bonds by Supported Au Catalysts



M. Doi[1], Y. Yasui[1], H. Miura[1,2,3*], T. Shishido[1,2,3]

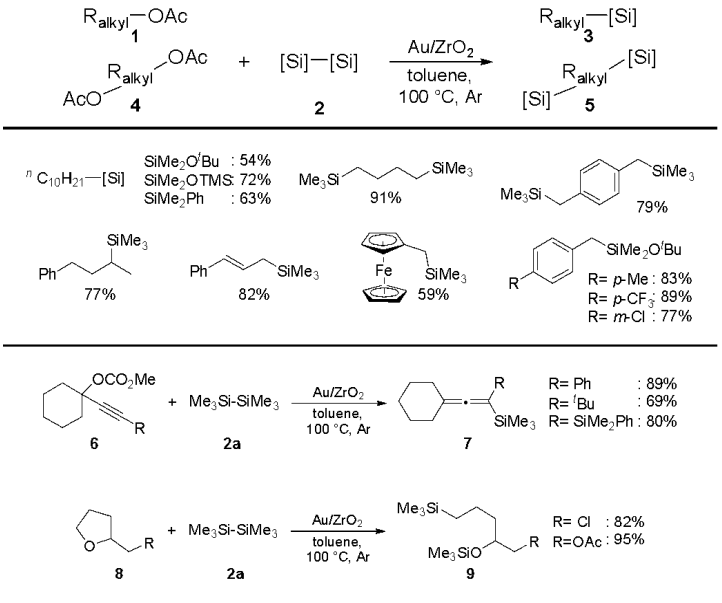
**Keywords:** Gold nanoparticles, C–O bond homolysis, silylation.

**Introduction.** Since C($sp^3$)–O bonds are a ubiquitous chemical motif in both natural and artificial organic molecules, the universal transformation of C($sp^3$)–O bonds will be a key technology for achieving carbon neutrality. Generally, sulfonyl and allyl groups, which have activated C($sp^3$)–O bonds, have been used for cleaving them. However, the general strategy for enabling alcohols, ethers, and stable esters, as a carbon electrophile to accommodate in cross-coupling reactions remains underdeveloped. Here, we report that supported Au catalysts efficiently generated alkyl radicals via homolysis of C($sp^3$)–O bonds, which consequently promoted C($sp^3$)–Si bonds formation to furnish diverse organosilicon compounds [1].

**Results and discussion.** Cross-coupling of decyl acetate (**1a**) with hexamethyldisilane (**2a**) in toluene with 1.0 mol% of Au/$ZrO_2$ catalyst at 100 °C gave the corresponding alkylsilane (**3**) in 88% yield (Scheme 1).



**Scheme 1.** Au/$ZrO_2$-catalyzed silylation of C($sp^3$)–O bond

With the optimized reaction conditions and catalysts in hand, the scope of the Au-catalyzed C–Si coupling reaction was examined. (Table 1). The reaction of primary and secondary alkyl acetate with a variety of disilanes provided the corresponding alkylsilanes (**3** and **5**) in high yields. The reaction of propargyl carbonate (**6**) also took place to give allenylsilane (**7**) in high yield. Interestingly, Au/$ZrO_2$ catalysts promoted the ring-opening silylation of cyclic ethers (**8**) to provide alkylsilnaes (**9**).

Mechanistic studies indicated that the homolysis of stable C($sp^3$)–O bonds of alkyl esters proceeded to generate alkyl radicals. The cooperation of Au nanoparticles and the amphoteric nature of the support are responsible for the generation of silyl radical and subsequent formation of alkyl radicals, thereby enabling efficient alkyl–silyl coupling to furnish diverse alkylsilanes.

**Table 1.** Substrate scope of substrates

**Keywords:** nickel, cobalt, nitroarenes, benzaldehydes, benzimidazoles.

**Introduction.** Benzimidazole nucleus occupies a prominent position among N-containing heterocycles due to its widespread use in different fields and the number of synthetic methodologies employ for their preparation. Recent trends show that the interest of the scientific community is now bending towards exploring the use of transition metal based heterogeneous catalyst for the synthesis of benzimidazoles [1]. This work is aimed at development a new class of catalytic systems obtained from $H_2$-assisted reduction of $Ni_xCo_{1-x}TiO_3$ mixed oxides to produce bimetallic $Ni_xCo_{1-x}/TiO_2$ catalysts (were x = 0.1, 0.3, 0.5, 0.7, 0.9 and 1.0). These systems were tested for the selective hydrogenation of 2-nitroaniline followed by the condensation of o-phenylenediamine with benzaldehyde to provide the corresponding 2-benzimidazole. The optimal catalyst was used for reusability test and the one-pot synthesis of 2-substituted benzimidazoles using 2-nitroaniline and other aldehydes.

**Experimental/methodology.** The $Ni_xCo_{1-x}/TiO_2$ catalysts were prepared based in a sol-gel methodology from the $Ni_xCo_{1-x}TiO_3$ mixed oxides as precursor [2]. The obtained precursors and catalysts were characterized by TPR-$H_2$, XRD, TEM and XPS techniques. The catalytic measurements were carried out in a stainless steel (150 mL) semi-batch Parr-type reactor at 150°C under 10 bar of $H_2$ pressure for 30 min, then the gas was changed to 5 bar of $N_2$, using 25 mg of catalyst and the amounts of substrate needed to attain a $mol_{2\text{-nitroaniline}}$:$mol_{metals}$ ratio of 100 in ethyl acetate. The stirring speed was kept at 700 rpm to avoid mass transfer limitations. The reaction products were identified via gas chromatography using a GC Clarus 680 Perkin Elmer instrument equipped with an Rtx-5 Amine column and a flame ionization detector (FID).

**Results and discussion.** The characterization of the $Ni_xCo_{1-x}TiO_3$ mixed oxides showed a unique reduction temperature between 500-600°C for all systems. The increase of the Ni composition in the as-prepared materials displayed a change in the reduction profile, resulting in a shift to lower temperatures as the nickel content increases. The study of these systems demonstrates that after 5 h of reduction at 550°C all the system produced the corresponding metallic $Ni_xCo_{1-x}/TiO_2$ catalysts. The XRD results agree with previous result, showing that the bimetallic phase is formed in all the proposed catalysts. TEM micrographs indicates that the mixed oxides precursors possess a nanorods structure and after the reduction treatment the catalyst preserved this shape. The XPS analysis displayed that the Co and Ni metals are almost in zero valent state for all system studied. The catalytic activity showed that all the catalysts were active in the tandem synthesis of 2-benzimidazole and the yield to the target product is function of the Ni content. The most efficient and selective system was $Ni_{0.1}Co_{0.9}/TiO_2$, due to the composition of the bimetallic alloy. Furthermore, $Ni_{0.1}Co_{0.9}/TiO_2$ exhibited a high operational stability in the test reaction reaching 5 catalytic cycles without losing its activity. Finally, the catalytic activity of $Ni_{0.1}Co_{0.9}/TiO_2$ was tested in the one-pot synthesis of 2-substituted benzimidazoles from 2-nitroaniline and aldehydes, showing high activity and selectivity to the desire 2-substituted benzimidazole. The balance of Ni-Co metals in the catalyst's formulation provides an optimal balance in the tandem reactions to produce the target product.

# Reactive distillation for continuous production of Ethyl chloro acetate

G.Chhavi[1*], M. Sanjay[2]

[1]*Indian Institute of Technology Bombay, Mumbai,India*
[2]*Indian Institute of Technology Bombay,Mumbai, India*
[*]*gpta.chhavi@gmail.com*

**Keywords:** Process Intensification, Reactive Distillation, Green engineering

**Introduction.** Fine chemicals are high-value chemical products with ample potential for advancement in manufacturing processes, especially in process development and green practices. Numerous fine chemicals follow the basic chemistry of esterification reactions, often limited by equilibrium, affecting the final yield[1].Removal of the undesired product in the reaction can push the equilibrium in forward direction. Reactive distillation (RD) is a process intensification technique which could overcome these limitations by providing reaction and separation in a single unit [2]. The scope of this work entails the application of RD for continuous production of Ethyl chloro acetate (ECA), a widely used organic solvent used in pharmaceuticals, plant protection chemicals and heterocyclic compounds production. ECA is produced by the esterification of Mono-chloro acetic acid (MCA) and ethanol (EtOH) in the presence of an acidic catalyst [3]. The catalyst employed in this study is amberlyst-15, an ion exchange resin which can be reused for multiple reaction runs, thus minimizing the neutralizing and separation requirements [4].

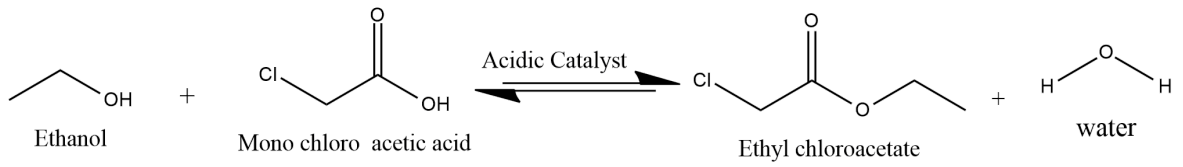

Figure 1: Esterification of Ethanol and Mono chloro acetic acid to form Ethyl chloro acetate

**Methodology.** To delve into various aspects of getting a synergistically coordinated reaction and separation scheme for RD, understanding of various aspects such as reaction kinetics, vapour liquid equilibrium, and careful catalyst selection are required. The reaction kinetics was studied by varying the reaction conditions, such as temperature, feed molar ratio, stirring speed, and catalyst loading etc., in a batch reactor. The results were fitted to a suitable model equation to obtain the reaction parameters. Theoretical studies for RD were performed using ASPEN plus RADFRAC module. Meticulous selection of RD configuration and distillation policy, such as number of stages, feed location, feed flow rates, reflux ratio and reboiler duty, is required for the desired product yield which is not only complex but possibly have multiple solutions. Initial simulations were performed for twenty stages, out of which four stages were part of the reactive section. All the missing parameters were estimated using the UNIFAC method. As the reactive section comprises Amberlyst-15 catalyst, a temperature constraint of 393 K is set to avoid catalyst deactivation.

**Results and discussion.** The conversion of MCA achieved is 100%. However, there remains a potential to increase the recovery of ECA as a part of it is carried along to the top with the vapour stream due to the formation of the azeotrope. Another challenge is the removal of water and recovery of ethanol due to its azeotropic mixture with water. A sensitivity analysis with varying feed molar ratios, reflux ratio and catalyst loading could provide better foresight to improve the overall product yield.

**Keywords:** propane dehydrogenation with $CO_2$, Zn(Ga)-BEA zeolites, acid-base characteristics.

**Introduction.** Oxidative dehydrogenation of alkanes, in particular propane to propene mediated with $CO_2$ ($CO_2$-PDH), is considered a promising alternative to the oil-based cracking processes of olefins production [1]. Among the promising catalysts for $CO_2$-PDH are those based on BEA zeolite with incorporated heteroelements [2]. An effect of acid-base characteristics of Zn(Ga)-BEA zeolites on their catalytic performance in the $CO_2$-PDH processs is presented in this work.

**Experimental/methodology.** The catalyst samples, prepared by two-step post-synthesis procedure [3], including full dealumination of BEA specimen followed by introducing $Zn^{2+}$, $Ga^{3+}$($Nb^{5+}$, $Ta^{5+}$) cations into T-positions of zeolite framework, were characterized using the XRD, XPS, MAS NMR, low-temperature $N_2$ ad/desorption, $C_3H_8$/$C_3H_6$ ($CO_2$, $NH_3$)-TPD, TPO-$O_2$, and FTIR-Py techniques. Catalytic experiments were carried out in a flow-type quartz reactor at atmospheric pressure, at a temperature of 823–923 K, and a gas hour space velocity (GHSV) of 6000 $h^{-1}$. The reaction mixture composition for $CO_2$-PDH was 2.5 vol. % of $C_3H_8$ and 15 vol. % $CO_2$ in He.

**Results and discussion.**

The adjustment of acid–base characteristics of BEA zeolite-based catalysts by preliminary dealumination of the original zeolite (Si/Al = 17) followed by the incorporation of heteroelement cations ensures the formation of MSiBEA compositions (Si/Al = 1000) with significantly reduced overall acidity and basicity.

The content of gallium in the zeolite matrix has a significant effect on the acid–base characteristics of catalysts. Weak and medium-strength Lewis acid sites of Ga(III)-O(H)-Si structure formed by isolated gallium atoms play a key role in the target process over Ga(Ta,Nb)SiBEA catalysts. Propylene yield reaches 37% (873 K) in the presence of $Ga_{4.0}$SiBEA catalyst. At the same time, a higher propylene formation selectivity of 70-77% was achieved over $Ga_{2.0}Ta_{2.0}$SiBEA (Table).

Propylene selectivity of 74% and yield of 22% was achieved over the $Zn_{1.0}$SiBEA catalyst, which is characterized by the presence of mainly medium-strength acid (LAS are $Zn^{2+}$) and basic ($O^{2-}$ anions and oxygen vacancies) sites on the surface of [Zn–O–Si] structures. An important factor in the selectivity of the $Zn_{1.0}$SiBEA catalyst is the absence of Bronsted acid sites on its surface capable of protonating the formed olefin, intensifying the further side cracking processes with carbonization of the catalyst surface.

**Table. $CO_2$-PDH process parameters over Zn,Ga(Ta,Nb)-BEA catalysts**

| Catalyst | $X_{C3H8}$, % | $S_{C3H6}$, % | $Y_{C3H6}$, % | TOS, min |
|---|---|---|---|---|
| $Zn_{1.0}$AlBEA | 37–11 | 23–42.5 | 9–5 | |
| $Zn_{1.0}$SiBEA | 32–27,5 | 73–76 | 23–21 | |
| $Ga_{1.0}$SiBEA | 28–27 | 71–74 | 20 | |
| $Ga_{2.0}$SiBEA | 31–27 | 63–62 | 19,5–17 | 20–120 (150) |
| $Ga_{4.0}$SiBEA | 57.5–45 | 64–73 | 37–35 | |
| $Ga_{2.0}Ta_{2.0}$SiBEA | 29–26 | 77–76 | 22–20 | |
| $Ga_{2.0}Nb_{2.0}$SiBEA | 20–19 | 70–71 | 14–13 | |

*T* = 923 K is for Zn-containing catalysts, *T* = 873 K is for Ga-containing catalysts.

Thus, propylene production with acceptable selectivity and yield parameters in the process of propane dehydrogenation with $CO_2$ over M-BEA zeolite catalysts is achieved at the balancing of their acidic and basic characteristics.

# Preparation of esters of tertiary alcohols

M.Kotova, A. Šnebergerová a T.Vargina

*Department of Organic Technology, University of Chemistry and Technology, Prague, Czech Republic*
**maria.kotova@vscht.cz*

**Keywords:** esters of tertiary alcohols, Lewis acids, acetylation

**Introduction.**

Esters are a large class of organic compounds widely used in many fields of chemical industry. Most esters have a characteristic, pleasant smell and are therefore often used in the fragrance industry [1]. The development of efficient synthetic routes to carboxylic acid esters is still of great interest because fine chemicals often contain ester unit as the functional group [2]. The usual methods involve the condensation reaction between an alcohol and a carboxylic acid in the presence of a mineral acid. This synthetic approach results in good yields with primary alcohols, limited yields with secondary alcohols, and poor yields with tertiary ones. The main goal of the work was to find a simple and efficient way for the direct synthesis of esters of tertiary alcohols and to optimize reaction conditions (catalyst, catalyst amount, solvent). Dimethylbenzylcarbinol and 1adamantanol were chosen as model alcohols.

**Experimental/methodology.**

Various synthetic procedures such as Fischer esterification, Steglich esterification, and acylation with functional derivates of acetic acid catalyzed by Lewis acids and basic catalysts to obtain esters of tertiary alcohols were tested. The preparation of esters by Fischer and Steglich esterification was performed according to literature procedures [1]. Acylation of alcohols with functional derivates of acetic acid catalyzed by Lewis acids and basic catalysts was performed the following way: to a mixture of tertiary alcohol (1 mmol), dichloromethane (10 ml), and catalyst ( 0.1 mmol) acetic anhydride or acetyl chloride (10 mmol) was added. The mixture was stirred at room temperature for 1-6 h. Samples were taken at different intervals during the reaction to determine conversion and selectivity. The samples were neutralized with a 5% solution of sodium bicarbonate and analyzed using GC (DB-5, non-polar column, FID) or GS/MS (column: DB-5-ms, length: 35 m, diameter: 0.20 nm, thickness: 0.33 μm) in order to identify the products.

**Results and discussion.**

It was found that in reactions under conditions of Steglich and Fischer esterification good results were not achieved. In the case of Fischer esterification of acetic acid with dimethylbenzylcarbinol only the undesired product of dehydration 2-methyl-1-phenylprop-2-ene was obtained. Fischer esterification of acetic acid with 1-adamantanol didn't take place. Although under conditions of Steglich esterification, the desired product was formed, the conversion of alcohols in both cases was only 52-56 % after 24 hours. Acylation with functional derivates of acetic acid catalyzed by basic catalysts (4-dimethylaminopyridine, triethylamine, pyridine) had given good results (total conversion, selectivity up to 95 %), and no side products were detected in the reaction mixture. Acylation with acetic anhydride catalyzed by hard Lewis acids ($AlCl_3$, $FeCl_3$, $ZnCl_2$) took place with high selectivity (over 99 %) to the desired ester. On the other hand, acylation under the same conditions with acetyl chloride tended to either undesired dehydration of dimethylbenzylcarbinol to give alkene or nucleophilic substitution of hydroxyl group in 1-adamantanol leading to the formation of 1-chloradamantane. According to the obtained results, we can conclude that Lewis acids and 4-dimethylaminopyridine are useful catalysts for the acetylation of tertiary alcohol by acetic anhydride.

**Keywords:** Hydrogenation, Nitrobenzene and Nanotubes

**Introduction.**
The selectivity production of primary amines is a global target, and this market represents a mundial production of four million tons per year [1]. The hydrogenation of nitrobenzene (NB) to obtain aniline (AN) is one of the model reactions to evaluate the efficiency and operational stability of new catalysts formulation. In this field, the nanomaterials-based heterogeneous catalysts arise as a hot-topic due to structural properties conferred by quantum effects. Among them, the noble metals supported onto nanotubes provide a unique environment to produce highly active and stable catalysts mainly by the confinement effects onto their inner surface. This research proposes a comparison between two different kinds of supports: carbon nanotubes (CNT) and $TiO_2$ nanotubes (TNT) to prepare Iridium (Ir) supported catalyst for the heterogeneous hydrogenation of NB to produce AN.

**Experimental/methodology.**
Nanotube supports were prepared according to our previous reports [2, 3]. Different metal loadings (0.25, 0.5, 1.0 and 2.0 wt %) were prepared using $Ir(acac)_3$ as metal precursor. The obtained solids were calcined at 623K and reduced using $H_2$ at 573K. The catalysts were labelled as xIr/CNT or xIr/TNT, respectively, where x correspond to Ir loading. The physicochemical properties of the catalyst were analyzed by XRD, $N_2$ adsorption-desorption isotherms, $H_2$-TPR, $H_2$-chemosoprtion, TEM and XPS characterization techniques. The catalytic activity was measured in a batch stainless steel batch reactor with 50 mg of catalyst, a molar ratio NB/Ir of 250 in ethanol as solvent at 303 K, 10 bar of $H_2$ pressure and constant stirring to avoid diffusional control. The periodic samples of the reaction were analysed in a GC with FID detector.

**Results and discussion.**
The physicochemical characterization of the Ir supported catalyst displayed that the nanotubes surface area remains constant after the metal deposition. In addition, the $H_2$-chemosorption showed a decrease of the metal dispersion with the increase of metal loading. The presence $Ir^{\delta+}$ surface species – detected by XPS – increased with the increase of the metal loading particularly in the xIr/TNT catalysts. The catalytic performance showed that all the NB conversion profiles fitted a pseudo-first kinetic model and high selectivity to the desired product was found. Intermediary products such as nitrosobenzene, N-phenyl-hydroxylamine or other condensation products were not detected. Among the different catalytic systems xIr/CNT catalysts series displayed a higher efficiency in comparison with the xIr/TNT catalysts. Furthermore, the best catalytic efficiency was shown by the 1.0Ir/CNT catalysts reaching 5 continuous catalytic cycles remaining the maximum of conversion and selectivity to AN production.

**Keywords:** flow chemistry, homogeneous carbonylation, iron (II) tetracarbonyl bromide

**Introduction.**

The carbonylation transformation has not yet gained widespread adoption in research and industry. The main reason is the reluctance of scientists to work with the highly poisonous gas - carbon monoxide. Utilisation of CO surrogates can reduce safety risks, but such approach relies on the compatibility between the conditions for gas generation and its consumption, which can complicate post-reaction processing. Iron pentacarbonyl has been successfully applied as an *in situ* CO donor in the oxycarbonylation of unsaturated alcohols [1,2]. However, its further application in the carbonylation transformation of aryl bromides has proven difficult due to the problematic isolation of products [3]. The use of iron (II) carbonyl halide compounds can avoid such problems.

**Experimental/methodology.**

Herein, we apply iron (II) tetracarbonyl bromide [4] as an *in situ* CO surrogate in the continuous Pd-catalyzed carbonylation of aryl bromides (Fig. 1). Pd-catalyzed carbonylations were performed within a 40-minute residence time using a stainless steel coil reactor. The NMR, HPLC-MS, and GC-FID techniques were used for the analysis of conversions and yields of products.

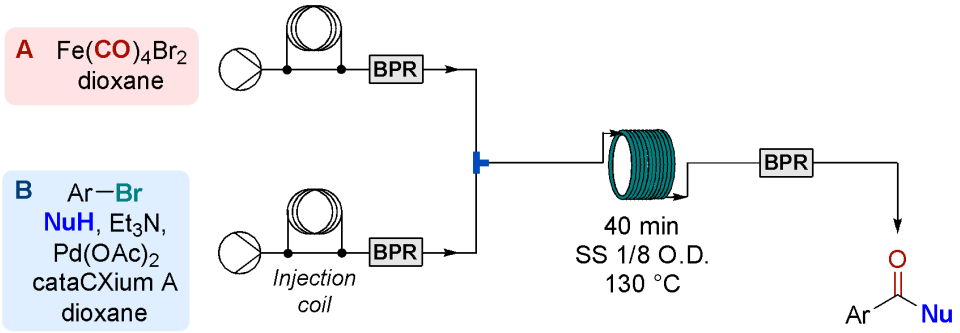

*Figure 1.* Experimental setup for the continuous carbonylation of aryl bromides.

**Results and discussion.**

The initial experiments performed on 4-bromoanisole in screw cap vials yielded high amounts of the desired amide, as determined by GC-FID. Further optimization of the parameters for the flow system, such as temperature, pressure, catalyst and ligand loading, and residence time, resulted in process-intensified reaction conditions for the Pd-catalyzed Heck-type carbonylation. Iron(II) tetracarbonyl bromide was successfully used as the CO donor in nearly stoichiometric amounts. A variety of carboxylic acid derivatives were also prepared on a multigram scale by a direct pumping of stock solutions using the HPLC pumps. Additionally, our procedure was applied in the synthesis of moclobemide, a drug used to treat depression and social anxiety.

# Impact of O-defects and Ru species on aerobic oxidation of benzyl alcohol on high-surface-area Ru/$TiO_2$ catalysts

Van Hung Mac[1,2], Katja Neubauer[1], Ali M. Abdel-Mageed[1*]

[1]*Leibniz-Institut für Katalyse e. V., Albert-Einstein-Str. 29a, 18059 Rostock, Germany*
[2]*Hanoi University of Science and Technology, 100000 Ha Noi, Viet Nam*
[*]Ali.abdelmageed@catalysis.de

**Introduction.** The selective oxidation of alcohols is a major step for the production of wide range of chemicals, in particular the solvent-free selective oxidation of benzyl alcohol using oxygen.[1] Ru has attracted considerable interest in catalysis not only because of its relatively low cost compared to commonly studied and industrially applied noble metals such as Au, Pt, Pd, but also due to its tunability by different support effects, especially in combination with $TiO_2$.[2] In this work, we focused on the systematic study and optimization of supported catalyst on high specific-surface-area (SSA) $TiO_2$ supports for the liquid-phase aerobic oxidation of benzyl alcohol at ambient pressure. Here, we aim at the identification of structure-reactivity descriptors for controlling the activity and selectivity by screening different structural features, focusing in the beginning on the impact of O-vacancy defects and the nature of the Ru species.

**Experimental.** Ru/$TiO_2$ catalysts with a similar amount of Ru were prepared by impregnating $TiO_2$ supports doped with varying amounts of $SiO_2$ (supplied by Venator) using $RuCl_3.xH_2O$ salt.[3] Prior to measurement and characterization, the catalyst was pretreated at 200 °C under a flow of $H_2$. The catalytic measurements were carried out in a three-neck round bottom flask with 10 ml of benzyl alcohol under magnetic stirring without further addition of a solvent. Reaction mixtures are analyzed with GC-MS and confirmed using $^1H$ and $^{13}C$ NMR. Catalysts were studies before / after reaction with different characterizations

**Results and discussion.** Catalytic measurements are done after reductive treatment which results in the formation of highly dispersed Ru nanoclusters and measurable fraction of isolated $Ru^{3+}$ ions (see previous results in Ref.[3]). The catalytic activity of Ru/$TiO_2$ catalysts for the selective aerobic oxidation of benzyl alcohol depends significantly on the level of $SiO_2$ doping. Based on previous studies on similar catalysts, the increase of $SiO_2$ leads to the decrease of the concentration of O-defects.[4] By plotting the conversion of benzyl alcohol versus the amount of $SiO_2$ in the catalyst we see an inverted volcano type dependence of rate of conversion on the amount of $SiO_2$ (Figure 1), and thus on the concentration of O-defects, with the highest conversion for $SiO_2$-free Ru/$TiO_2$ catalyst (highest O-defect concentration). Selectivity for benzaldehyde, in contrast, reaches highest value at a doping level of 4% $SiO_2$, which was previously correlated with moderate support reduction (O-defects concentration). We observed another major product confirmed, by 1H NMR measurements, as dibenzyl ether. The quantity of this product is similar to benzaldehyde but follows a trend similar to the changes in benzyl alcohol conversion (directly proportional to conversion). Interestingly the selectivity toward dibenzyl ether was increasing with the decrease of reaction temperature in the range between 150 and 80 °C while at the same time selectivity to benzaldehyde goes in the opposite direction. Origin of the activity and selectivity on these catalysts shall be discussed in the light of additional results on Ru/$TiO_2$ catalysts based dominantly on loading Ru in an atomically dispersed form and based on detailed structural characterization with different spectroscopic and microscopic tools.

**Keywords:** Florol, Prins cyclization, zeolite, mesoporous material

**Introduction.** Prins cyclisation of isoprenol with isovalerladehyde for production of tetrahydropyranol (THP), known as a commercial fragrancy product Florol®, was investigated over acidic heterogeneous micro-and mesoporous catalysts (Fig. 1a) with the special interest on revealing the effect of the textural properties on catalyst performance. In addition, to support the experimental observations, also DFT calculations were performed to unravel the possible reaction mechanism.

**Experimental/methodology.** Several heterogeneous catalysts including H-Beta zeolites with varying $SiO_2/Al_2O_3$ ratio, microporous H-USY-30 and its alkali treated counterpart as well as micro-mesoporous Beta zeolite-MCM-41 hybride materials and iron modified Beta zeolite were tested. The catalyst were charaterized by several methods, such as nitrogen adsorption, acidity by pyridine adsorption-desorption FTIR, SEM and TEM. Prins cyclisation of isovaleraldehyde (IVA) with isoprenol (IP) was investigated in a glas reactor using dimethylcarbonate as a solvent. In a typical experiment 10 mmol of IP and 50 mmol of IVA were used together with 0.15 g catalyst and a high stirring speed and small catalyst particles were used to suppress mass transfer limitations. DFT calculations with Perdew-Burke-Ernzerhoff method were performed.

**Results and discussion.** The results demonstrated that mildly acidic H-Beta-300 afforded the highest selectivity to THP (72%), while more acidic zeolite catalysts exhibited more prominent deactivation and lower selectivity to THP. Dehydration of THP also occurred in some extent forming dihydropyrans (DHP).

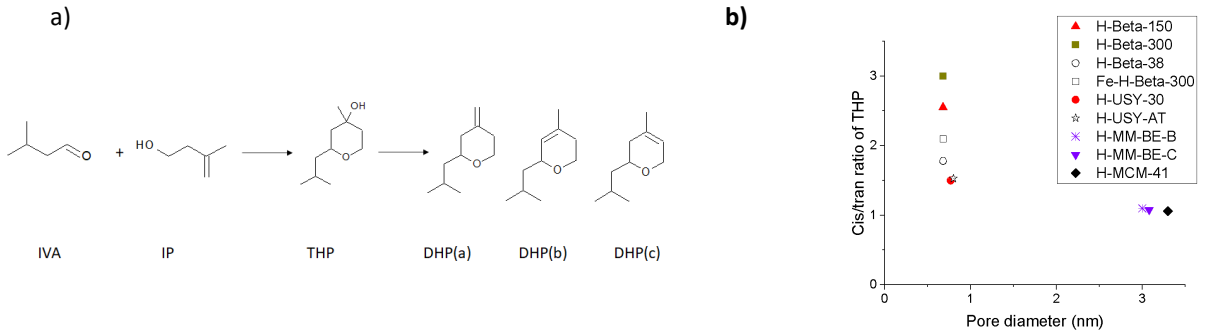

**Fig. 1. a) A simplified reaction scheme for Prins cyclisation of isoprenol (IP) with isovaleraldehyde (IVA) for production of tetrahydropyranol (THP) and its dehydrated counterparts, dihydropyrans (DHP), b) cis/trans ratio of THP isomers as a function of the catalyst pore size.**

The most interesting result was the effect of the pore size on the cis/trans ratio of THP (Fig. 1b), namely a high cis/trans pyranol ratio was obtained over microporous zeolites, while opposite results were seen for mesoporous materials produced lower cis/trans pyranol ratio. In the final work the effect of reaction conditions, such as temperature and reactant ratio will be discussed. Furthermore, a special emphasis will

be put on correlation of catalyst properties with their performance. Finally a plausible reaction mechanism proposed based on DFT calculations will be discussed.

# Layered Double Hydroxides as catalysts for Baeyer-Villiger oxidation

O. Gorlova[1], I. Paterová[1*], J. Kocík[2], K. Peroutková[2], Z. Tišler[2]

**Keywords:** hydrotalcite, hydrogen peroxide, Baeyer-Villiger oxidation, LDH, myrtenal, β-cyclocitral

**Introduction.**

Baeyer–Villiger (BV) oxidation is one of the most important tools for the synthesis of esters from ketones or aldehydes using peroxides or peroxyacids as oxidizing agents [1, 2]. It should also be underlined that the ester may not be the main desired product. Under suitable reaction conditions, subsequent hydrolysis of the resulting ester to a more valuable ketone or aldehyde can be performed [3]. It is known from the literature that catalysts modified with e.g. tin [3] or iron [4] are very active for BV oxidation. One of several types of catalysts that can be used for this reaction are double layered hydroxides (LDH), or hydrotalcite-like compounds [5]. The course of BV oxidation also depends on the structure of the starting substance [1-5]. To compare this effect, 2 substances with different structures were chosen, namely myrtenal as a representative of bicyclic compounds and β-cyclocitral as a representative of monocyclic substances. BV oxidation was carried out in the presence of hydrogen peroxide as an oxidizing agent and LDH with different contents of tin and iron as catalysts.

**Experimental/methodology.**

LDH with different molar ratios of Sn/Fe/Mg/Al (Sn/Zn/Mg/Al) ions were synthesized by co-precipitation method at constant pH value (pH = 9.5) and constant temperature (T = 60 °C). The solution of metal precursors was precipitated with a basic solution of potassium hydroxide and carbonate. The precipitated solid was filtered off, washed, dried overnight and subsequently transformed by calcination in air at 400 °C for 5 h to mixed oxides. The Baeyer-Villiger oxidation was carried out in a 25 ml magnetically stirred round bottom flask equipped with a reflux condenser, containing a mixture of 0.1 g of catalyst, 0.5 g of starting material, 3 g of solvent and tempered to the desired temperature. Hydrogen peroxide (3.2 eq.) was gradually dosed to the mixture at 10-minute intervals in 12 doses.

**Results and discussion.**

All prepared materials were characterized by different analytical methods. Mixed oxides were tested as catalysts for Baeyer-Villiger oxidation of myrtenal and β-cyclocitral and for subsequent hydrolysis of the resulting formates to the desired products. The effect of the type and amount of incorporated metal (Sn, Fe), and the starting substance structure was evaluated. The activity of MgAl, ZnAl and ZnMgAl mixed oxides was compared. Mixed oxides based on ZnAl hydrotalcites, both tin-modified and unmodified, appeared to be the most active ones. After 5 h of reaction, almost 100% conversion of myrtenal and 95% selectivity to nopinone was achieved. Mixed oxides containing iron in the structure were not as active as those ones containing tin. The maximum myrtenal conversion achieved did not exceed 40 %. The selectivity to nopinone was also quite low - only 30 %.

# Isolated Copper Sites on Graphite Nanoplatelets for Ullman-type C-O Coupling

Vincenzo Ruta,[1] Dr. Mark A. Bajada,[1] and Prof. Dr. Gianvito Vilé*,[1]

[1]*Politecnico di Milano, Piazza Leonardo da Vinci 32, 20133 Milano (Italy)*
[*]*Corresponding author email: gianvito.vile@polimi.it*

**Introduction.** For the past 20 years, cross-coupling reactions have been crucial in organic and pharmaceutical synthesis, as they allow for the formation of C-C, C-O, and C-N bonds in a single step [1]. Among the most widely used reactions, Ullmann condensations play a significant role in the formation of C-O bonds, enabling the synthesis of variously substituted diaryl ethers using inexpensive copper catalysts. However, the reaction also has its drawbacks, including harsh reaction conditions, the need for bulky and expensive ligands, and the low efficiency of existing protocols [2].
We introduce herein a novel single-atom Cu catalyst supported on tetraethylenepentaminopyrrole-functionalized graphite nanoplatelets ($Cu_1$/TEPAP-GNPs) that has been synthesized in a controlled manner, thoroughly characterized, and demonstrated in Ullmann-type condensation reactions.

**Experimental/methodology.** Catalyst preparation was performed in a two synthesis approach, via graphite nanoplateletes synthesis and metal immobilization. A battery of structural and spectroscopic analysis (ICP, XRD, XPS, XAS, TEM, FTIR, NMR) was applied to elucidate the main catalysts properties. For the catalytic tests, the phenol (0.5 mmol) and aryl bromide (0.75 mmol) were dissolved in a glass tube in 2 mL of solvent, and the catalyst (8 mg) was added. The tube was sealed and heated at the specific temperature, ranging from 90 to 150 °C. The reaction mixture was analyzed via high pressure liquid chromatography, determining conversion, selectivity, and product yield. DFT calculations (VASP code) were applied to determine the reaction mechanism.

**Results and discussion.** We began our work by conducting the copper-promoted coupling of phenol and bromobenzene, optimizing the process in terms of catalyst amount, solvent, and reaction. By correlating these results with the catalyst structural properties, we found out that the presence of the polyaminic linker on the catalyst surface allowed improved activity and selectivity (reaction rate = 201 $mmol_{prod}mol_{Cu}^{-1}h^{-1}$, product selectivity >90%), while its absence was detrimental to the process (reaction rate = 20 $mmol_{prod}mol_{Cu}^{-1}h^{-1}$). This pointed to the role of the polyaminic linker as a ligand, stabilizing and activating the isolated metal center. The flexibility of our protocol was confirmed by testing variously decorated phenols and aryl bromides, showing the excellent catalytic performances of our materials. Moreover, time-on-stream studied confirmed the stability of this materials over 24 h of operation. DFT calculations were finally applied to postulate a reaction mechanism on the Cu isolated sites, showing that the interaction between the catalyst and reactants is thermodynamically favorable and provides a reasonable explanation for the observed kinetics.

***Figure 1.*** *HRTEM of the catalysts (a), schematic representation of the Ullmann coupling reaction on the heterogeneous catalyst (b), XPS spectra of C 1s (c), N 1s (d), Cu 2p (e) of the catalyst; and XANES spectra (f).*

# Simulation based design of Simulated Moving Bed Reactor for the production of 2-phenyl Ethyl Acetate

Kapil Satya Pal Singh*, Sanjay M. Mahajani

*Department of Chemical Engineering, IIT Powai, Mumbai-400076*
Corresponding Author: Kapil Satya Pal Singh (kapiljayantt@gmail.com)

**Keywords:** Simulated-moving bed reactor, Triangle theory, Pareto plot

**Introduction.** Simulated moving bed reactor (SMBR) is a single-unit operation that have four sections and each section have specific number of beds. In this, adsorption and desorption occur concurrently with the reaction and separation. That makes it a viable option for equilibrium limited reactions, to achive complete conversion of limiting reactant. It has a total thirteen number of degrees of freedom i.e., feed and desorbent concentrations, and their flow rates, raffinate and extract flow rates, four sectional flow rates, switch time and column dimensions which makes its dsign a challanging task. The complete process of SMBR is followed by desorption recovery from both raffinate and extract phases, which mainly governs the operating cost. On the other hand, the capital cost depends on productivity.[1-2] Therefore, the objective of this study is to get minimum solvent requirement and maximum productivity using a simplified approach. Instead of mathematical optimization clubbed with simulation which is computaionally exhaustive. For design optimisation, the reaction of interest undertaken is 2-phenyl ethyl acetate synthesis by reacting 2-phenyl ethyl alcohol with acetic acid, in the presence of catalyst/adsorbent Amberlyst-15.

**Methodology.** The solution methodology aodpted is based on Triangle theory which is well developed for simulated moving bed (SMB) without reaction.[2] It uses linear adsorption isotherm and puts constaints on flow rate ratios (namely as $m_1$, $m_2$, $m_3$ and $m_4$ ) to ensures complete conversion of limiting reaction, raffinate, and extract purity. This theory is further extended to SMBR (SMB with reaction). The SMBR model equation was solved in MATLAB with suitable boundary conditions. To begin with the design optimization, column area, feed and desorbent concentration, feed flow rate and SMBR configuration were assumed.

**Results and discussion.** Initially, the mass flow rate ratios $m_1$ and $m_4$ were assigned a high value (as per constraints) so that extract purity is satisfied.It was reduced slowly to come up with the best design. Although, $m_2$ and $m_3$ had a range of values as per constraints. The feasibility of $m_2$ -$m_3$ pairs were studied and they were plotted on triangle digram,as shown in Figure 1(a). Further, the effect of various

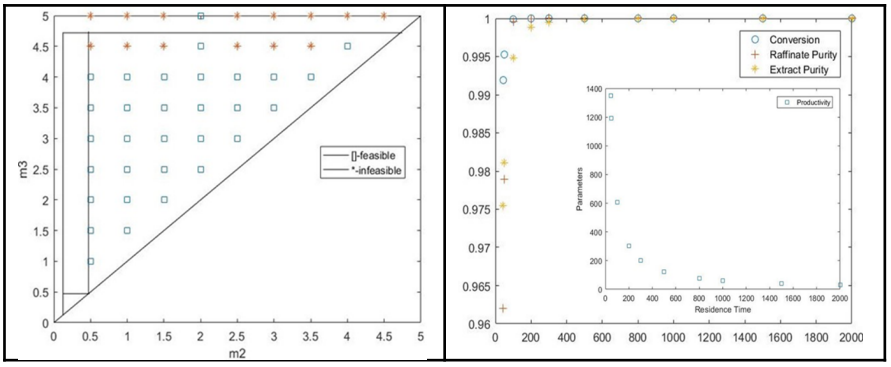

**Figure 1. (a)** Triangle theory diagram (b) Effect of residence time

parameters were studied such as effect of residence time (as shown in 1(b)), flow rates of all four sections, pseudo solid velocity etc. The parameters were optimized for $m_2$-$m_3$ feasible pairs through diferent paths that gave minimum desorbent and maximum productivity. Productivity vs desorbent values were plotted to arrive at a plot similar to Pareto plot which shows maxium productivity and corrosponding mimimum value of desorbent required.

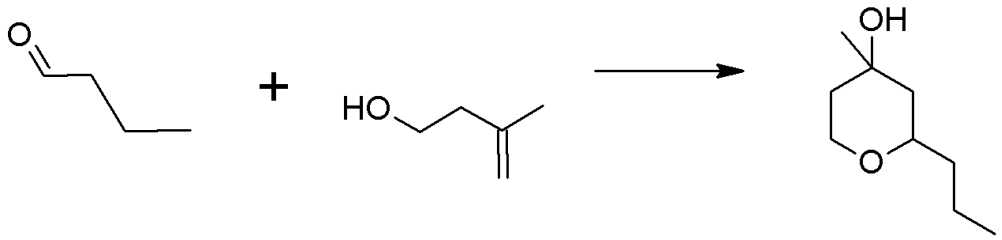
# $MoO_3$-MCM materials as effective catalysts in Prins reaction of isoprenol with butanal

E. Vrbková[1], L. Dolejšová Sekerová[1], E. Vyskočilová[1*]

[1]*Dpt. of organic technology, University of Chemistry and Technology Prague, Prague, Czech Republic*
[*]*eliska.vyskocilova@vscht.cz*



**Keywords:** Prins reaction, 4-methyl-2-propyltetrahydro-2*H*-pyran-4-ol, MCM-41

**Introduction.** Prins reaction of isoprenol with butanal provides important an intermediate (4-methyl-2-propyltetrahydro-2*H*-pyran-4-ol), which can be acylation to 4-methyl-2-propyltetrahydro-2*H*-pyran-4-yl acetate desired fragrance with fruity and rose scent known, e.g., as Clarycet®[1]. Lewis acids are suitable catalysts for this reaction [2,3].

**Experimental/methodology.** Materials were prepared by wet impregnation method using commercially available MCM-41 and water solution of ammonium molybdate. Catalytic testing was performed in batch arrangement, and samples of the reaction mixture were analyzed using gas chromatography (FID, non-polar column).

**Results and discussion.** Within this work, we prepared MCM-41 modified with different $MoO_3$ amounts. These materials were thoroughly characterized (nitrogen physisorption, acidity – temperature programmed desorption, elemental composition, etc.). The activity of prepared materials was tested in the Prins reaction of isoprenol with butanal. The influence of various reaction conditions (catalyst type, solvent, water addition) was tested. It was shown that modification of MCM-41 with $MoO_3$ led to a significant increase of catalytic activity (butanal conversion at 4 hours of reaction: 7% for MCM-41 compared to 93% for material 5wt.% of $MoO_3$-MCM-41). Water addition to the reaction mixture positively influenced the selectivity to desired substituted tetrahydropyranol (4-methyl-2-propyltetrahydro-2*H*-pyran-4-ol). The next step will be the production of the product in a higher amount followed by acylation.

**Keywords:** C($sp^3$)–O activation, Gold catalyst, Silylation, Hydrosilane

**Introduction.**

Deoxygenative transformation of C–O bonds attracts much attention since reducing the oxygen content of biomass-derived molecules is important from the viewpoint of carbon resource circulation. Deoxygenative silylation of C–O bond are an ideal method for synthesizing organosilicon compounds which are widely used as chemical intermediates in organic synthesis and resources of silicon polymers. Hydrosilanes are a promising source of silyl moiety owing to their high stability, low price, and commercial availability. Nevertheless, cross-coupling between carbon electrophiles with hydrosilanes to give organosilicon compounds is still rare due to high nucleophilicity of hydride of hydrosilane, consequently resulting the formation of reduced hydrocarbons.

Herein, we describe that supported Au catalysts showed high activity toward deoxygenative silylation of inactive C($sp^3$)–O bond in alkyl acetate to give alkylsilanes.

**Experimental/methodology.**

Supported Au catalysts were prepared by precipitation method using $HAuCl_4$ as a precursor. Au was deposited on the support by adding a metal oxide and urea as a pH adjuster to an aqueous $HAuCl_4$ solution. The resulting powder was calcined in air and reduced in at 200 °C for 1 h to obtain the supported Au catalyst.

**Results and discussion.**

The deoxygenative silylation of decyl acetate (**1a**) with triethylsilane (**2a**) was carried out in the presence of $TiO_2$ supported Au catalysts. The corresponding alkylsilane (**3a**) was obtained in 92% yield. The reaction did not proceed by using supported Ni, Cu, Pd, Ag and Pt catalysts. Furthermore, the supports for Au nanoparticles were important for highly selective C–Si bond formation, and surface Lewis acidic property of supported catalysts was essential for the activation of alkyl electrophiles. Various alkyl esters and propargyl carbonates participated in the Au-catalyzed deoxygenative silylation with hydrosilanes to give the corresponding alkylsilanes and allenylsilanes. (Figure 1) Detailed mechanistic investigation revealed that generation of silyl radical via the single-electron transfer from hydrosilane to Au nanoparticles is responsible for unusual reactivity of hydrosilanes.

**Keywords:** alpha oxygen, binuclear iron centers, $O_2$ activation.

**Introduction.** According to the theoretical prediction, binuclear iron sites in various zeolitic matrices are expected to split $O_2$ with a formation of α-O.[1] The unique property of α-O lies in the ability to oxidize highly stable molecules (methane) already at ambient temperature.[2] Direct application of $O_2$ for transforming hydrocarbons into value-added oxygenates, being a platform for chemicals and energy vectors, is of paramount importance for sustainable catalysis. Yet, the formation of fully functioned iron sites (capable of splitting $O_2$ and oxidizing methane with α-O) was confirmed experimentally for FER and very recently also for Al-rich *BEA zeolites. The occurrence of these active sites requires a high population of Al pairs (Al-O-Si-O-Al sequences in one zeolitic ring) which can stabilize divalent cations and their proper geometrical arrangement in two axial rings in the vicinity of ~7 Å.[1,2].Both of those conditions are met in the FER and *BEA topologies. However structural differences local geometry of divalent cation, distance between iron sites, and Al atoms organization) of FER and *BEA matrix may affect the final performance of binuclear Fe(II) sites in splitting $O_2$ and subsequent oxidation reactions. These differences were confirmed in the value of calculated energy barrier of $O_2$ activation, which is form Fe-*BEA varies (31.4 kcal/mol) significnaly higher that for Fe-FER(24.9 kcal/mol).[1] This work compares the redox behavior of binuclear Fe(II) sites in *BEA and FER topologies during $O_2$ activation studied by in-situ XAS and Mössbauer spectroscopies and subsequent interaction with methane as a testing reaction.

**Experimental/methodology.** Two zeolites of FER (Si/Al 8.5) and *BEA (Si/Al 5) topology with hight population of Al pairs were studied in their Fe-forms (Fe/Al ~0.05, impregnation from the organic solution of $FeCl_3$) by in-situ by Mössbauer and X-ray adsorption spectroscopy and activity tests with FTIR and mass spectrometry detection of the reaction products.

**Results and discussion.** Mössbauer and XAS spectral characteristics of evacuated Fe-FER and Fe-*BEA confirmed the presence of atomically dispersed Fe(II) cations, however the local geometry of iron sites in the plane of the rings is slightly different – square-planar in the case of Fe-FER and rather square-pyramidal for Fe-*BEA, which is in agreement with the DFT results. Interaction of both samples with $O_2$ reveals significant differences in samples behavior, indicating formation of a new band at Mössbauer spectra with parameters typical for α-O. In the case of Fe-FER not only the oxidation state but also the geometry of the iron sites is strongly affected by the interaction with $O_2$, which is reflected on XAS spectra. In-situ XAS spectra registered after the interaction of α-O formed over Fe-FER and Fe-*BEA with methane confirmed that the redox cycle occurred and Fe active sites were restored. Activity tests with mass spectrometry detection revealed the presence of oxidation products, methanol and $CO_2$ (attributed to signals m/z 31 and 44 respectively), directly in the gas stream. Both samples were stable in three consecutive redox cycles. The presented study proved the differences in the behavior of binuclear iron sites formed in FER and *BEA topologies in both steps of the redox cycle, the activation of $O_2$, and the employment of formed α-O in the oxidation reaction. Manifested discrepancies in the activity of binuclear iron sites in FER and *BEA are in line with a slightly higher energy barrier of the $O_2$ splitting over Fe-*BEA.

# Nonoxidative Dehydrogenation of Methanol to Dimethoxymethane over Cu/Hβ-zeolite Bifunctional Catalysts with Tailored Acidic Sites

Chalachew Mebrahtu[1]*, Ruiyan Sun[1], Christian H. Gierlich[1], Regina Palkovits[1]*

**Introduction.** Transportation is one of the main sectors contributing to global greenhouse gas emissions. Therefore, considerable effort is still required for sustainable mobility. Recently, various $CO_2$-based compounds such as oxymethylene ethers (OME) have been suggested as potential diesel fuel additives, owing to their excellent ability in reducing soot formation and good compatibility with diesel engines [1]. Among the OMEs, dimethoxymethane (DMM) is the simplest compound and its current production relies on an oxidative reaction route with the formation of $H_2O$ leading to low $H_2$ efficiency. Therefore, recently, our group presented a novel gas-phase DMM synthesis strategy via the nonoxidative methanol (MeOH) dehydrogenation with the formation of $H_2$ instead of $H_2O$ [2]. This approach appears to be highly attractive due to the potential closed $H_2$ circulation, thus improving the overall energy efficiency of the process. However, for selective DMM synthesis via nonoxidative dehydrogenation of methanol, a suitable bifunctional catalyst with both acidic and dehydrogenation sites is necessary.

**Experimental/methodology.** Herein, Cu/Hβ-zeolite with different acidic sites is employed as a bifunctional catalyst for selective DMM synthesis via nonoxidative dehydrogenation of MeOH. The acidic sites of Hβ-zeolite (Si:Al = 25) were first tailored via dealumination using 2, 4, 8, and 12 M $HNO_3$ (at 80°C). After the dealumination, 1 wt.% of Cu was introduced using incipient wetness impregnation [3]. Finally, the effect of acidic sites on DMM formation was investigated using a gas-phase fixed bed reactor and the prepared catalysts were rigorously characterized to understand structure-activity relationships.

**Results and discussion.** Among the prepared catalysts, the sample dealuminated with 8 M $HNO_3$ (1%Cu/Hβ-DeAl8) presented highest activity and selectivity towards DMM (Fig. 1a). 81.5% DMM selectivity was achieved with a MeOH conversion of 3.7% at 1 atm and 200°C. Removal of Brønsted acidic sites (Fig. 1b) via dealumination allowed to suppress dimethyl ether (DME) formation. Interestingly, an induction period featuring a remarkable rise in DMM selectivity from 41 to 81.5% with time on stream occurred [3]. Detailed characterization results indicate adaptation of Cu species and Lewis acidic sites under reaction conditions resulting in the decisively weaker dehydrogenation and condensation ability for high DMM selectivity.

# In-situ synthesis of SAPO-34 on γ-$Al_2O_3$ microspheres: a suitable fluidized-bed catalyst for methanol conversion to light olefins

**Ghavipour, M.**[1], **Kopyscinski, J.** [1,*]

*Chemical Engineering Department, McGill University, 3610 University Street, Montreal, Canada*
**jan.kopyscinski@mcgill.ca*

**Introduction**

Considering the environmental regulations and concerns, researchers have focused on developing green technologies based on a closed-loop carbon cycle. This, for instance, can be done by steam-reforming or partial oxidation of plastic wastes to synthetic gas, which in turn will be converted to methanol and subsequently to light olefins for plastic production. Methanol conversion to light olefins (MTO) is a key step within this cycle and recently has attracted researchers' attention [1]. Narrow-pore silica aluminum phosphate (SAPO-34) is known as the optimum catalyst for the MTO reaction with complete methanol conversion and over 80% light olefin selectivity. The only drawback is the fast catalyst deactivation due to coke formation, which is why a fluidized-bed reactor with continuous regeneration is employed.

Hydrothermally synthesized SAPO-34 zeolite has cubic particles with a size range of 1-5 μm (Fig 1 left) whereas, for the fluidized-bed application, particles of 50-100 μm are required. The traditional spray-drying method cannot be employed as the microporous structure of the SAPO-34 catalyst tends to be blocked by the binder and its physicochemical properties will be affected negatively. Our aim here is to develop a synthesis method in which SAPO-34 particles are synthesized on γ-$Al_2O_3$ microspheres. By employing this method, the precious SAPO-34 particles will not bury in the middle of the agglomerates, instead, they will be in the outer layer accessible to the reactants. To adhere the SAPO-34 particles to the support, the alumina precursor required for SAPO-34 preparation would be provided from the γ-$Al_2O_3$ microspheres' outer surface.

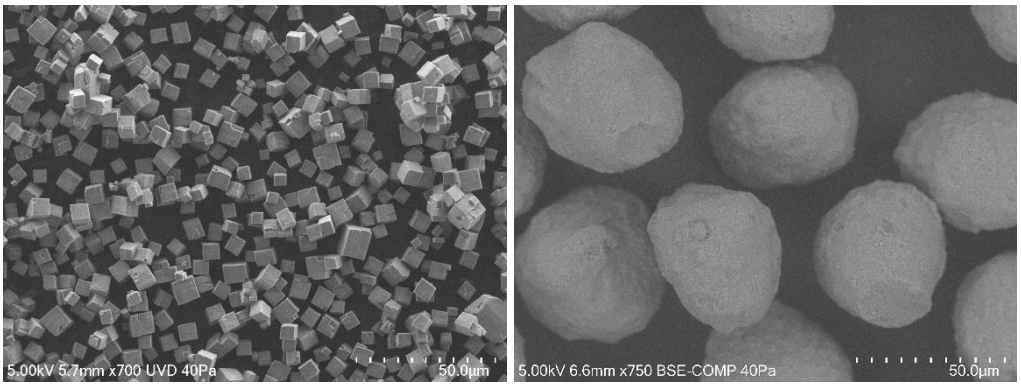

Fig 1 SEM images of left) as-synthesized cubic SAPO-34 crystals, right) bare γ-$Al_2O_3$ microspheres

**Materials and Methods**

SAPO-34 was hydrothermally synthesized on γ-$Al_2O_3$ microspheres (dry support/gel mass ratio of 0.4) with mixed-template (TEAOH and DEA). Activity tests were performed in a fixed-bed microreactor at 420°C, atmospheric pressure, and WHSV of 1 $h^{-1}$. Different synthesis procedures and treatment methods were employed to activate the outer layer of the γ-$Al_2O_3$ microspheres and fully cover it with the SAPO-34 phase.

**Results and Discussion**

While keeping the microspheres intact, the outer layer of alumina was activated successfully to react with other precursors to form the SAPO-34 outer shell. Comprehensive catalyst characterization tests (such as XRD, BET, SEM, SEM-EDX, $NH_3$-TPD, and TGA techniques) were employed to characterize the supported catalyst. Activity tests (based on the SAPO-34 content of the supported catalyst) were conducted and the results showed that the catalyst lifetime and product distribution are similar to those of pure unsupported SAPO-34. The supported catalyst underwent an abrasion test in a simulated fluidized-bed chamber for 10 days while monitoring the catalyst's weight loss and morphology. The results indicated good mechanical strength of the developed catalyst. In conclusion, the in-situ SAPO-34 synthesis over γ-$Al_2O_3$ microspheres seems to be an effective catalyst for the fluidized-bed reactor application.

**Keywords:** Fischer-Tropsch, Biomass to liquids, cobalt, poison.

**Introduction.** Biomass to liquids (BTL) via gasification and Fischer-Tropsch synthesis (FTS) is an interesting technology for fuels and chemicals production. With the use of biomass comes the opportunity to use waste as feedstock and improve efficiency of different industries while reducing the $CO_2$ emissions. However, there are several challenges to overcome to do BTL feasible. One of the most important is the syngas gas cleaning before further utilization. Biomass has a wide range of inorganic species [1] that will end up as volatiles in the gas phase after the gasification [2]. There have been several studies [3] regarding the effect of the most common species present in biomass as S, alkali metals, nitrogen compounds in the FTS. However, phosphorus has not received much consideration. In this context, our study is focused on test the effect of the addition of phosphorus to cobalt-based catalysts in the FTS.

**Experimental/methodology.** Three different cobalt-based catalysts supported on $Al_2O_3$, $TiO_2$ and $SiO_2$ were prepared by incipient wetness impregnation. To screen the effect of phosphorus in the catalysts, different loadings of phosphorus were added to the catalysts, from 1700 to 6700 ppm. The catalysts were characterized by TPR, $N_2$ adsorption-desorption, $H_2$ chemisorption and XRD. The FTS was performed in a tubular fixed bed reactor with 1g of catalyst and 19g of SiC; at 240 ºC and 5 bar.

**Results and discussion.** The activity of the catalysts was compared in by CO conversion and site-time yield during the first 24 h. After this time, the CO conversion was adjusted to 50 % to compare the selectivity. In Figure 1, it is depicted the CO conversion during the first 24 h on stream for the cobalt catalysts supported on $Al_2O_3$, $TiO_2$ and $SiO_2$.

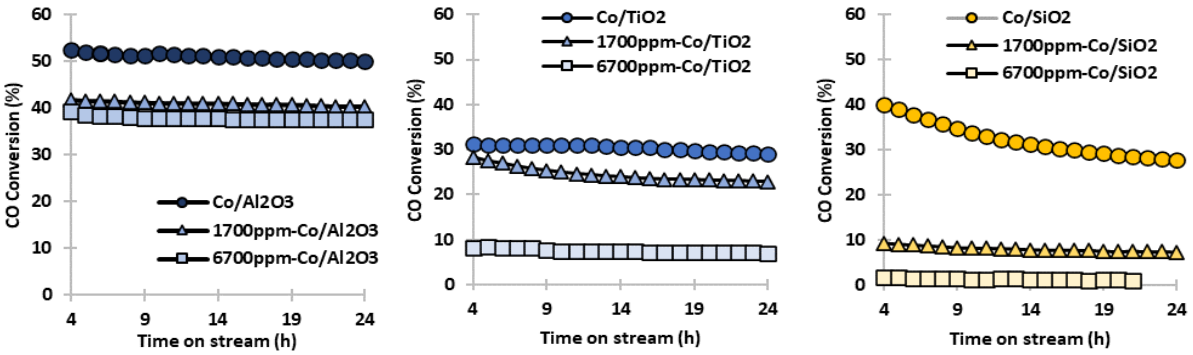

**Figure 1: Effect of P on the CO conversion during the first 24 h on stream for the cobalt catalysts. Left: Supported on $Al_2O_3$, centre: supported on $TiO_2$ right: supported on $SiO_2$.**

The addition of phosphorus led to a small decrease in metallic dispersion as well as a decrease in cobalt reducibility. Furthermore, this contamination reduced the activity of the catalysts in different degrees. In the case of $Al_2O_3$ support, the deactivation was less pronounced compared to $TiO_2$ and $SiO_2$, to the extent that both catalysts showed no activity with the higher P loading. This difference might be due to different metal-support interactions. Regarding the selectivity, it was affected by the poisoning of P with an increase in methane and paraffins while reducing the light olefins and $C_{5+}$ products.

**Keywords:** heterogeneous catalysis, methane partial oxidation, esterification, manganese, cobalt

**Introduction.** The direct partial oxidation of methane to primary oxygenates such as methanol suffers from impractically low product yields due to the facile over-oxidation of the desired product to $CO_2$ under the reaction conditions necessary for methane activation [1-3]. Protecting methanol within a less reactive, oxidation-resistant methyl ester is an effective product protection stratety that breaks through this selectivity-conversion trade-off, thereby obtaining high methane-based yields and product concentrations [1, 4]. Despite the high yield and productivity of methane-to-methyl-ester systems, there are a number of critical shortcomings left unaddressed that preclude their practical applicability, including: the reliance on molecular Pt-group catalysts, economically infeasible oxidants (e.g. $K_2S_2O_8$), and the use of corrosive, fully concentrated acid solvents [5].

**Experimental/methodology.** Cobalt and manganese precursors were deposited on various oxide supports ($SiO_2$, $Al_2O_3$, $TiO_2$, etc.) via incipient wetness impregnation and liquid deposition. The catalyic performance was screened in a stirred batch reactor with a diluted TFA mixture at 215°C (described in [6] in detail). Metal leaching and homogeneous contributions to activity were evaluated through ICP and hot filtration of the reaction filtrates. Solid catalysts were characterized using various methods (e.g. XRD, TEM, BET, XAS etc.).

**Results and discussion.** In this work, we introduce a number of improvements to methane-to-methyl-ester systems that alleviate some of the major shortcomings in catalysts, oxidants, and the acidic reaction medium. Importantly, we report the first heterogeneous catalysts for this reaction that are compatible with $O_2$ as a terminal oxidant and do not utilize Pt-group metals. Under our improved reaction conditions, $Co/SiO_2$ and $Mn/TiO_2$ display competitive performance on the basis of turnovers and ester production rates (up to 245 and 613 μmol $g_{cat}^{-1}$ $h^{-1}$, respectively) in comparison to previously reported, homogeneously-catalyzed systems that employ stronger oxidants and higher methane partial pressures. The metal leaching and homogeneous contributions from these catalyst were neglible, confirming the heterogeneous nature of the catalysis. Furthermore, we find that high metal dispersion is associated with high activity in this system, and the most efficient utilization of cobalt or manganese is realized at the lowest loading. Through a combination of characterization techniques, correlaitons between catalytic activity and the presence of specific metal species present in the catalyst can be derived. The conclusion of the contribution underscores impactful directions for the further development of high-yield methane conversion processes through more holistic consideration of catalysts, reagents, and operating conditions, with a focus on current work toward a novel continuous flow system for methane-to-methyl-ester chemistry.

**Keywords:** Methane, partial oxidation, Ni catalysts

**Introduction.** While different catalytic routes have been studied for $CH_4$ conversion to more efficient feedstocks, partial oxidation has been widely investigated as a potential and promising route due to advantages that include its exothermic reaction, and producing syngas in high yields with a $H_2$/CO ratio very close to 2, as desired for gas-to-liquid technology [1,2]. While the most active catalysts for these processes are based on expensive noble metals, Ni-based catalysts have attracted significant attention due to their abundancy and lower costs [3]. However, the reaction over most of the studied catalysts, to date, suffer major drawbacks including catalyst's sintering and coke formation.

In the present study, Ni/γ-$Al_2O_3$ catalysts were modified by incorporating $Fe^{3+}$ ions in the bulk of the support to introduce redox functionality to enhance coke oxidation and removal. The results revealed that Fe ions in the support resulted in textural modification and a significant enhancement of the catalyst coking resistance.

**Experimental.** Fe-doped γ-$Al_2O_3$ was prepared via a sol-gel method using aluminum sec-butoxide and Fe(III) nitrate in 2-propanol. Ni catalysts with 10 wt% Ni loading were prepared by wetness impregnation method followed by calcination at 700 °C. Catalysts were prepared in Fe/Al+Fe molar ratio in the range of 0.01-0.15, which will be referred to as Ni/FeX where X represents the molar ratio (Fe/Al+Fe) x 100. The catalysts were characterized by various techniques including, XRD, XPS, HR-TEM, $N_2$-sorption, $H_2$-TPR, $CO_2$- and $NH_3$-TPD, TGA, and Raman spectroscopy. Catalytic activity tests were conducted at 700 °C and 1 atm using a continuous-flow fixed bed reactor. The reaction feed was composed of $CH_4$ (30%), $O_2$ (15%) and $N_2$ (55%) with a total flow rate of 50.8 mL $min^{-1}$.

**Results and discussion.** Concentrations of Fe(III) as high as 10% could be well dispersed in the alumina matrix while higher concentrations promoted the formation of the binary oxide phase, $NiFe_2O_4$, which upon reduction resulted in the formaiton of $FeAl_2O_4$. The catalysts with Fe(III) concentrations of 1-5% exhibited a significant enhancement in coking resistance during partial oxidation of methane to synthesis gas, where negligible amounts of crystalline carbon formed and stable performance was exhibited during 100 hrs on-stream. The significantly enhanced coking resistance was referred to the role $Fe^{2+}$ ions, that were found to be the dominant iron state upon reduction, in a possible redox cycle that promoted the oxidation of carbon preventing its accumulation on the catalysts. In addition, the presence of the iron in the support enhanced the γ-phase stability and was associated with enhanced catalysts' porosity, which has contributed to the removal of carbonaceous species by enhancing internal mass diffusion. The results of this study hold a great promise for developing robust and durable catalytic materials for methane reforming.

**Keywords:** Fe-Mn catalysts, Mesopourous $Nb_2O_5$, Fischer-Tropsch Synthesis, Low $CO_2$, High $C_{5+}$ and $C^=/C^-$

**Introduction.**

Fischer-Tropsch Synthesis (FTS) has been growing interest due to its relevance on providing biofuels such as biojet and green diesel. Catalysts promoted with manganese can favor the growth of the carbon chain, in addition to generating products with greater added value [1]. Thus, this work has designed, characterized and evaluated the performance of Fe promoted with Mn catalysts on mesoporous niobia in the FTS.

**Experimental/methodology.**

Iron (15 wt.%) was deposited on mesoporous niobia by wet impregnation and precipitation-deposition methods [2]. Then they were dried overnight and calcined at 400°C at 5°C/min before adding manganese (1, 3 and 5% wt%) by incipient wetness impregnation followed the same drying and calcination procedures. The catalysts were characterized by N2-physisorption, $H_2$ and CO-TPR, MEV, DRS-UV-Vis, XRD, Mossbauer, and CO-TPD. The Fischer-Tropsch reaction was carried out in a stainless-steel fixed-bed reactor. The catalyst (400 mg) was mixed with quartz sand (400 mg) and then reduced in situ using high purity $H_2$ at 400 °C, time in flow=12h, and atmospheric pressure. After reduction, the catalytic tests were carried out at 20 bar, 250-300 ºC and GHSV 500-1500 $h^{-1}$, TOS=30 h and $H_2$/CO ratio=1 and 2.

**Results and discussion.**

The selectivity and conversion of the catalysts applied in the SFT at 250 ºC, 20 bar, and 500 $h^{-1}$ of GHSV are shown in Figure 1. The selectivity for the products obtained in the SFT demonstrates that the presence of manganese as a promoted phase in an iron catalyst reduces the formation of methane (from approximately 25% in 15Fe/Nb2O5m to approximately 12% in 3Mn-15Fe/$Nb_2O_5$m) and carbon dioxide. In addition, there was a greater selectivity for heavy hydrocarbons ($C_{5+}$). It is noted that the CO conversion is reduced at low and high Mn concentrations, indicating that this metal significantly influences the obtaining of the desired products and the olefin/paraffin ($C^=/C^-$) ratio. The characterization results demonstrated that oxycarbides are formation are responsible of the catalytic performance evolution.

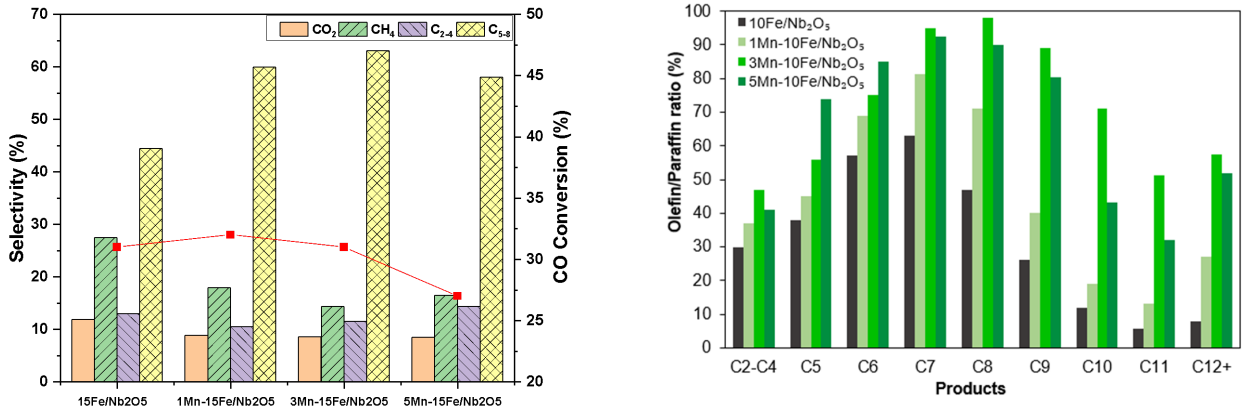

**Figure 1. CO conversion, selectivity and olefin/paraffin ratio under Fe-Mn/$Nb_2O_5$ catalysts in the FTS at 250 ºC, 20 bar, and GHSV=500 $h^{-1}$.**

# Effect of $CO_2$ content in feed gas mixture for Fischer-Tropsch Synthesis over $Co/SiO_2$ catalyst

S. Satokawa*, N. Wachi, H. Konno, A. Yanagita, K. Tashiro

[1] *Seikei University, 3-3-1 Kichijoji-kitamachi, Musashino-shi, Tokyo 180-8633, Japan*

**Keywords:** Fischer-Tropsch synthesis, $Co/SiO_2$ catalyst, $CO_2$ content

**Introduction.**

Technology for synthesizing liquid fuels by $CO_2$ hydrogenation has attracted attention toward the realization of carbon neutrality. This can be achieved by combining the reverse water gas shift (RWGS) reaction, which converts $CO_2$ to CO, and the Fischer-Tropsch synthesis (FTS) reaction, which converts CO to hydrocarbons. Here, since the former RWGS reaction is governed by thermodynamic equilibrium, the ratio of CO and unreacted $CO_2$ contained in the exit gas ($CO/CO_2$) depends on the reaction temperature. Therefore, the FT catalyst in the latter stage is required to have the performance of selectively reacting only CO even under the condition that $CO_2$ is contained in the reaction gas [1]. In this study, we conducted an activity test of the FTS reaction over $Co/SiO_2$ catalyst with mixed gases containing CO and $CO_2$ of various compositions. In addition, effects of reaction temperature, pressure, and $H_2/CO_x$ mixed ratio were also conducted.

**Experimental**

$Co(20wt\%)/SiO_2$ catalyst was prepared by impregnation method. An aqueous solution containing cobalt (II) nitrate hexahydrate was added to a commercially available $SiO_2$ carrier (CARiACT Q-10, Fuji silysia chemical), and mixed in a mortar for 20 min. Then, it was dried overnight at 110 °C and calcined in the air at 400 °C for 6 h. The FTS activity test was carried out using a high pressure fixed bed flow reactor. First, a mixed gas of $H_2/N_2$ = 1/4 was passed at 50 mL $min^{-1}$ at 350 °C for 2 h to reduce the catalyst. After that, under the conditions of 220 °C, 1.0 MPa, and $H_2/CO_x$ = 2-3, feed gases with different $CO/CO_2$ ratios were flowed at 60 mL $min^{-1}$. The obtained gas was analyzed with a gas chromatograph (MCGC990, agilent), and the liquid components were collected with a gas-liquid separator and then analyzed with a gas chromatograph mass spectrometer (GCMS-QP2010, shimadzu).

**Results and discussion**

Fig. 1 shows the $CO_x$ conversions and product selectivities in the feed gas with different contents of CO and $CO_2$ at 220 °C and 1.0 MPa. The COx conversion in the case of mixed gas condition was higher than those with synthesis gas and $CO_2$ mixed gas ($CO_2/(CO_2+CO)$ = 0 and 1.0) conditions. In addition, it was found that the COx conversion rate and the methane selectivity increased as the $CO_2$ concentration in the mixed gas increased. The selectivity and yield of the liquid hydrocarbons ($C_{5+}$, others) were maximum at $CO_2/(CO+CO_2)$ = 0.3 and 0.5, respectively. $CO_2$ was not consumed during the FTS reaction using the mixed gas feed. Therefore, when CO and $CO_2$ are mixed in an appropriate ratio, the efficiency to obtain the liquid fuel increases.

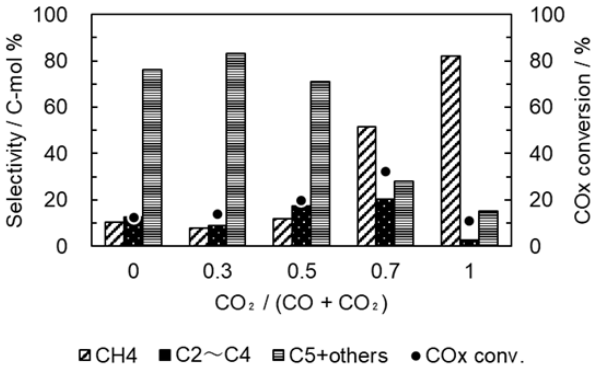

**Fig. 1 Effect of CO and $CO_2$ mixed ratio for FTS reaction activity over $Co/SiO_2$ at 220 °C and 1.0 MPa.**

**Keywords:** Zeolite; liquid fuels; chemicals; $CO_2$ reduction; bifunctional catalysis; hydrogen storage

**Introduction.** The growing environmental concerns and increasing demand for carbon feedstocks have stimulated recent research activities on the transformation of $CO_2$. Bifunctional catalysis opens a new strategy for the selective hydrogenation of carbon dioxide ($CO_2$) into hydrocarbon fuels and chemicals using green hydrogen, which not only utilizes abundant $CO_2$ as a carbon feedstock but also enables the storage of hydrogen.[1] In this work, we investigate the direct hydrogenation of $CO_2$ to gasoline-range hydrocarbons and olefins over a series of bifunctional iron-zeolite catalysts operated at high temperatures (> 300 °C).[2] This process may efficiently utilize $CO_2$ discharged from industrial combustion and green $H_2$ produced by high-temperature solid oxide electrolytic cells (SOEC).

**Experimental/methodology.** Iron oxides promoted by a series of alkaline metals were synthesized by a sol-gel method. H-SSZ-13, H-MOR, H-Beta, H-Y, H-ZSM-35, H-MCM-22, H-ZSM-22, H-ZSM-5 and H-ZSM-48 were commercial products. The iron oxides and zeolites were integrated with different proximity.

**Results and discussion.** The bifunctional catalysts, composed of FeMnK oxide and nine zeolites with different topologies, have been investigated for $CO_2$ hydrogenation at high temperatures. FeMnK+H-ZSM-5 offered a 70% selectivity of $C_5$–$C_{11}$ hydrocarbons together with a 17% selectivity of $C_2$–$C_4$ olefins (Fig. 1). A volcano trend was obtained between the pore size of zeolites and the selectivity of $C_5$–$C_{11}$ hydrocarbons. The 10MR zeolites favored the formation of $C_5$–$C_{11}$ hydrocarbons, while both 8MR and 12MR zeolites could not promote the C–C chain growth. As the temperature increased from 320 °C to 400 °C, $CO_2$ conversion increased significantly from 32% to 51% while CO selectivity was kept at low levels of around 15%. Besides, the yield of aromatics increased more than doubled over the FeMnK+H-ZSM-5 catalyst. Moreover, the key factors determining the catalytic performances, dynamic evolution of active sites, and reaction network have been intensively investigated and clarified.

**Keywords:** Methane, Zeolites, Copper, Partial Oxidation, Methylation, Alkenes, Aromatics

**Introduction.**

Direct partial oxidation of methane into methanol (DMTM) has been in the focus in research for the chemical industry for several decades. Copper exchanged zeolites have shown potential for this by utilizing a chemical looping protocol [1-3]. Zeolites have also been utilized as catalysts for the Methanol-to-hydrocarbons (MTH) reaction [4]. By combining the DMTM and the MTH reactions, hydrocarbons can be synthesized directly from methane, limiting the scale and the cost for industrial processes.

Among the most promising zeolites for DMTM is the mordenite (MOR) type, while ZSM-5 has long been utilized for the MTH reaction [1,5]. In this study, Cu-, Na-exchanged and protonated MOR, ZSM-5 and CHA zeolites were tested for the step-wise methylation of ethylene, propylene and benzene.

**Experimental/methodology.**

Tests were carried out with a laboratory scale gas feed reactor set-up, with the effluent being analyzed by an online MS and quantifications done with a GC FID. By varying sample composition, zeolite framework type and reaction conditions, screening of methylation reactions was carried out. The reaction protocol consisted of three steps: oxidation of the Cu zeolite at 773 K in $O_2$, activation of methane at 473 K and extraction with either 100% ethylene, 100% propylene or 10% benzene/He at 473 K. All samples were characterized, both before and after testing.

**Results and discussion.**

Results suggest that two separate reactions occur when the adsorbed methoxy species are extracted with ethylene: methylation forming propylene, and oligomerization and cracking yielding a mixture of $C_4$-$C_7$ hydrocarbons. Extraction with propylene revealed that the same two competing reactions occurred. However, a higher affinity towards the oligomerization reaction was seen, with $C_6$ as the main product. The sample showed signs of coke formation after reaction, that could be burned off afterwards.

Benzene methylation yielded only toluene. The toluene yield was about 40 % relative to the yield of methanol observed with steam extraction. The MOR framework was the most active, while CHA framework did not show any activity.

The lower amount of toluene produced indicates that not all the methoxy species formed when activating methane can be accessed by the large benzene molecule. Benzene cannot enter the CHA pores, and will be highly restricted in the 8 rings of MOR. This might give a new insight into how the methoxy species behave inside the zeolite framework during the reaction.

# Investigation of the deactivation mechanism of iron-based catalysts for use in low-temperature Fischer-Tropsch-Synthesis

Sascha Bredow[1*], Erik Reichelt[2], Matthias Jahn[3]

[1]*Fraunhofer IKTS, Dresden, Germany*
[2] *Fraunhofer IKTS, Dresden, Germany*
[*]*Sascha.tim.bredow@ikts.fraunhofer.de*

**Introduction**

Depending on the applied catalytic material Fischer-Tropsch-Synthesis (FTS) can be used to produce short and long-chained hydrocarbons and oxygenates. Compared to cobalt-based catalysts iron-based catalysts have the advantage of higher selectivity towards oxygenates and especially higher alcohols[1] which are linear 1-alcohols with a chain length of more than four carbon atoms. The synthesis of higher alcohols via a sustainable pathway is of high interest since they are a demanded industrial product. Utilizing sustainably sourced syngas in FTS an alternative green route to higher alcohols could be achieved[2].

Responsible for the catalytic activity of those FT catalysts are numerous iron carbides which is generally agreed upon in the scientific community[3]. However their chemistry is not yet fully clarified, even though iron-based catalysts are becoming more and more attractive for research and industrial applications[1,3]. Studies concluded that different carbide phases influence FT activity and are able to shift the product composition[4,5]. In addition the composition of iron-based catalysts is known to change during FT synthesis due to mainly four different deactivation mechanisms[1,6]. Because of this complex and dynamic nature of the iron carbide phases and their composition on the catalyst surface make it challenging to find correlations between the catalyst performance and its composition[3].

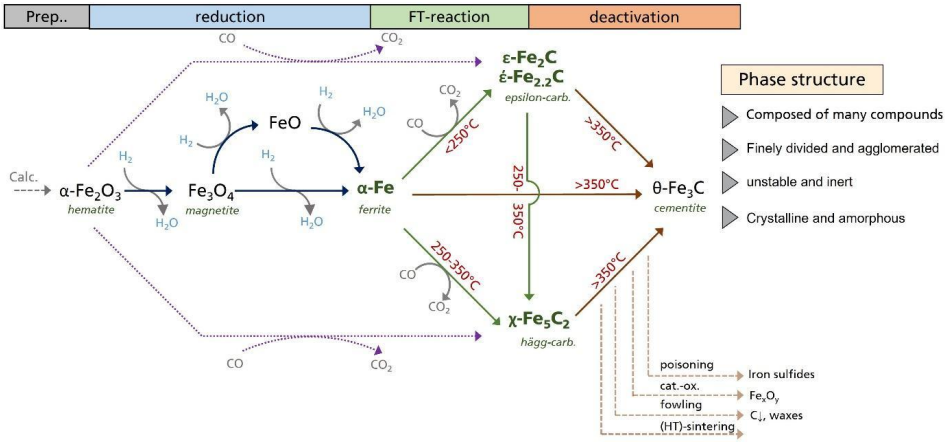

Figure 1 - Evolution of iron phases in FT catalysis (adapted from de Smit et al.[4])

**Experimental/methodology.**

In order to elucidate the not yet fully known connections between catalyst performance, phase composition and the associated degradation behavior it is purposeful to synthesize phase-pure iron carbide catalysts. These catalysts are then exposed to syngas under FT conditions and their phase composition as well as the yielded product spectrum are analyzed at different stages of the reaction. For that purpose, also accelerated aging is a valuable tool. According to this approach it should be possible to investigate the deactivation behavior of different iron carbide phases. Furthermore, it could give insight into the individual catalytic activities of different carbide materials, especially regarding their influence on product distribution.

**Keywords:** Fischer Tropsch Synthesis, catalysis, cobalt, $CO_2$, clean fuels.

Carbon capture and conversion of industrial flue gasses into aviation fuel range hydrocarbons is an appealing technology considering the large energy demand of the aviation sector and the few available alternatives [1]. The conversion of CO into long chain hydrocarbons over cobalt-based catalysts has been extensively investigated, but the conversion of $CO_2$ over these type of catalysts produces mainly methane [2]. Industrial flue gases e.g. typical steelwork off-gases are mainly composed of CO, $CO_2$, $H_2$ and $N_2$ and therefore a reverse water gas shift and gas separation step would be needed to convert these flue gases into synthesis gas [3]. However, if the Fischer Tropsch process would be tolerant for $CO_2$, a one-step conversion of flue gas into long chain hydrocarbons could be achieved. The performance of cobalt-based catalysts for mixed feed Fischer Tropsch is debated as some research claims the $CO_2$ to be an inert whereas others claim the $CO_2$ to be hydrogenated into methane along with the CO [4,5]. Surprisingly when a 50/50 $CO_2$/CO feed was used over a cobalt on titania P25 catalyst a $C_{5+}$-selectivity of almost 80 % could be achieved. These results are difficult to compare with state-of-the-art literature because in mixed feed experiments, the ratio of $H_2$/atomic carbon is often different which affects the conversion level and besides, an increase in $CO_2$ content changes the $H_2$/CO ratio which affects the CO conversion as well [6]. In Figure 1, the $C_{5+}$-selectivity versus CO outlet partial pressure is given for various H/atomic carbon ratios and with a sufficient CO-partial pressure available, a high $C_{5+}$-selectivity can be achieved. In this work the CO conversion level and hence the CO outlet pressure is tuned for different $CO_2$/CO mixtures by varying the GHSV. Based on these results, the highest possible $CO_2$-concentration in a mixed feed Fischer-Tropsch process for the efficient production of synthetic aviation fuels is determined.

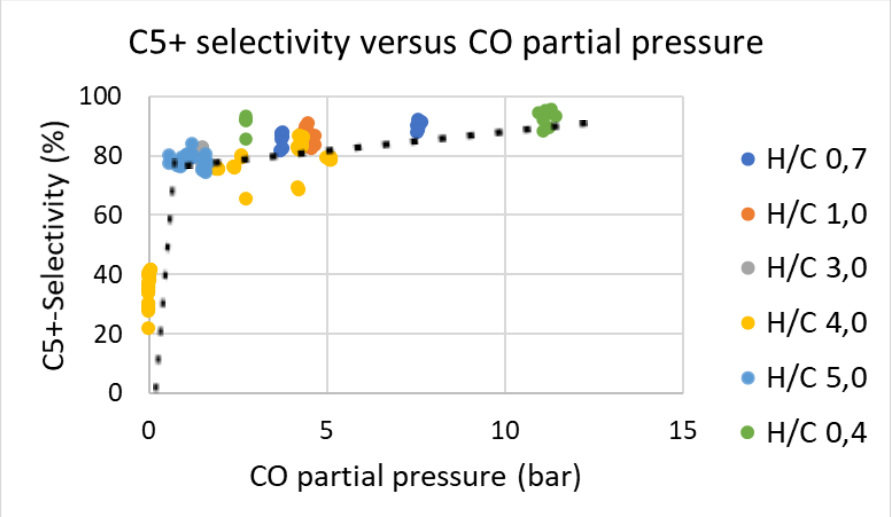

**Figure 1 $C_{5+}$-selectivity versus CO partial pressure in the outlet for various CO and CO/$CO_2$ Fischer Tropsch experiments with varying $H_2$/atomic carbon ratios. The reactions are performed in a PBR at 220°C 20 barg with argon as internal standard.**

# Bench-scale FT crude production from $CO_2$ using a two-step rWGS-FT process

Author's Name: Christian Frilund[1], Pekka Simell[1]

[1]VTT Technical Research Centre of Finland, Espoo, Finland

**Keywords.** CPOX, rWGS, Fischer Tropsch, P2X

**Introduction.** Catalytic reverse water-gas shift (rWGS) has the potential for high volume $CO_2$ valorization to chemicals. With the use of renewable hydrogen and $CO_2$ in for example power-to-X applications rWGS unlocks a wide range of syngas reactions, inlcuding Fischer Tropsch (FT) synthesis for the fossil-free production of hydrocarbons. The thermodynamics show that for feasible $CO_2$ conversions very high reaction temperatures are required, for which the heat can be either supplied directly or indirectly. In this research, the focus is on a two-step $CO_2$ to FT process where the FT off-gases (unreacted $H_2$,CO, $CO_2$ and C1-C5) are re-circulated to an rWGS stage with oxygen feeding (in-situ combustion) and hydrocarbons reacting by catalytic partial oxidation (CPOx). Here we present results of a bench-scale implementation of this coupled 2-stage process concept.

**Experimental/methodology.** A compact tubular CPOx/rWGS reactor was constructed, consisting of an in-house prepared noble-metal catalyst coated on FeCrAl monoliths, designed to be operated at FT pressure (up to 20 bar) and high temperature (up to 900 C). The process was downstream coupled to an existing bench-scale FT process, including FT gas reciruclation to the CPOx/rWGS stage. Industrial-grade bottled gases were fed to the CPOx/rWGS using thermal MFCs. Gas analysis was performed using a TCD/FID-GC. Condition screening factorial tests were designed using MODDE Pro software. Thermodynamic equilibrium calculations were performed using HSC Chemistry.

**Results and discussion.** *Standalone CPOx/rWGS tests.* The CPOx/rWGS reactor outlet gas composition was compared to the equilibrium gas composition. The results are shown in Figure 1.

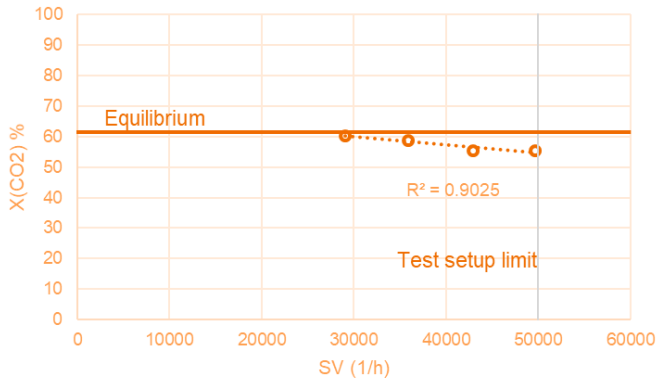

Figure 1. $CO_2$ conversion as a function of gas hourly space velocity.

At around SV 30 000 1/h the thermodynamics predicted equilibrium gas composition in the outlet is almost fully achieved. Even at SV 50 000 1/h the output gas has not drifted far from the equilibrium, thus verifying that rWGS can be performed at high throughput conditions. Condition screening is performed using a 4 factor and 2 level experimental design, with controlled factors reaction temperature, $CO_2$ feed rate, feed $H_2/CO_2$ ratio and reaction pressure. The condition screening highlighted the effect of a higher $H_2/CO_2$ leading to a higher $CO_2$ conversion, but also higher methane (methanation) selectivity. A higher reaction temperature promoted the formation of CO instead, both in terms of a higher CO selectivity as well as higher $CO_2$ conversion.

*Coupled CPOx/rWGS tests.* Extended duration coupled CPOx-FT tests with an approximately 20 % recycle ratio were performed. The results showed that the CPOx/rWGS is able to fully decompose C2+

hydrocarbons, but a very small C2 portion remained in the outlet gas. The system was operated for over 300 h (non-continuous) with an average specific activity of 300 mmolCO/$cm^3$cat*h.

# Balancing between OCM catalyst deactivation and activity through design and controlled composition

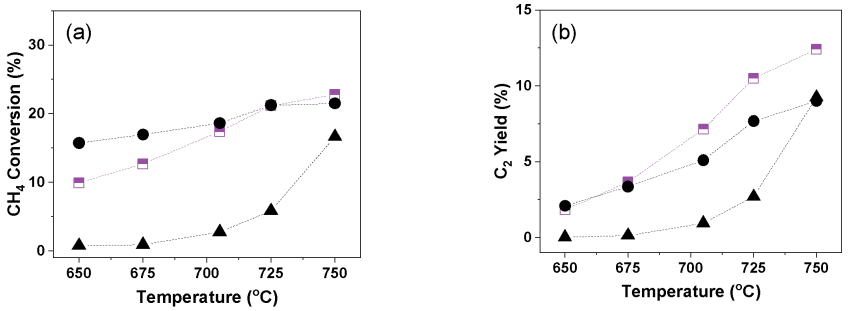
Baoting Huang, Jin Wang, Dina Shpasser and Oz M. Gazit*

[1]*Technion - Israel Institute of Technology, Haifa, Israel*
**ozg@technion.ac.il*

**Keywords:** $La_2O_3$, $Na_2WO_4$,

**Introduction.** The Mn-$Na_2WO_4$/$SiO_2$ (MnNaWSi) catalyst for the oxidative coupling of methane (OCM) has been and still is regarded as the most promising catalyst for OCM with reports showing $CH_4$ conversion ~25% with a $C_2$ selectivity of ~80% (@ >800 °C) over long periods of time. Despite the remarkable performance of the MnNaWSi catalyst, recent reports show that structural changes and deactivation in the multi-metal oxides material occur under reaction condition.[1,2] Distinctly it is the melting of crystalline Na2WO4 at 698 °C that is believed to impose instability in the catalyst structure due to its strong interaction with the silica support and the MnOx phase as well as its evaporation at the high reaction temperature.

**Experimental/methodology.** The catalysts were tested using a single-pass fixed-bed flow reactor made of quartz with an inner diameter of 7 mm. In each run of reaction, 50 mg of catalyst was loaded and packed inside the reactor. Two pieces of quartz wool were loaded and packed on both ends of the catalyst bed like a sandwich configuration to stabilize the reactor bed. Prior to catalyst loading the sample was sieved and collected within 60-100 mesh. The reactor bed was packed to be consistently 5 mm long. The feed gas composition and flowrate were controlled by mass flow controllers (Brooks SLA5850). Typically, the feed gas mixture had a total flow of 50 ml $min^{-1}$ STP with composition of 4:1:1:4 $CH_4$:$O_2$:$N_2$:Ar, which results in GHSV (gas hourly space velocity) of 60,000 ml $h^{-1}$ $g^{-1}$.



**Results and discussion.** we the demonstrate the promotion of OCM over a two-domain catalyst bed composed of a $La_2O_3$/MgO catalyst and the MnNaWSi catalyst. We show that the OCM mechanism is promoted by the synergistic interactions between the two catalysts when the former is stacked on top of the latter. Our results show that a catalyst bed composed of 10 wt% La/MgO stacked on-top of 90 wt% MnNaWSi (La/MgO-MnNaWSi_0.1s) is able to give ~10% methane conversion and ~19% $C_2$ selectivity at ~650 °C, whereas at the same temperature the MnNaWSi is inactive and the La/MgO gives only 13% selectivity. Increasing the temperature to ~705 °C the La/MgO-MnNaWSi_0.1s catalyst is found to give ~6-fold higher or similar methane conversion compared to the MnNaWSi catalyst and La/MgO catalysts, respectively. However, the selectivity of the La/MgO-MnNaWSi_0.1s was 41%, which is higher by a factor of 1.5 for the La/MgO and 1.2 for the MnNaWSi, **Figure 1**. Interestingly, increasing the size of the La/MgO top-part of the bed showed diminished OCM performance, suggesting that the promoting catalytic effect is dictated by the lifetime of intermediate radicals. Data supporting our claim and relevant charechterization will be presented.

**Figure 1.** Temperature dependencies experiment (650-750 °C) for:

▬La/MgO-MnNaWSi_0.1s;

**Keywords:** $CO_2$ to fuels, Fischer-Tropsch synthesis, iron-based nanocatalysts, zeolites

**Introduction.** Transportation, as well as other industries, is faced with a challenge of reducing the use of fossil fuels and lowering $CO_2$ emissions. Particularly challenging this is in aviation that contributes to 2-3 % of global $CO_2$ emissions. For this purpose, use of synthetic liquid fuels produced directly from $CO_2$ and $H_2$ is proposed. To advance this technology and improve the effectiveness from current processes, 4AirCRAFT project utilizes electro, chemo and biocatalysts combined in a single multistep catalytic reactor for production of sustainable aviation fuel.[1] Presented work focused on one of the steps of the process. It is based on the development of inorganic nanocatalysts and their performance evaluation for the CO hydrogenation to fuel-length hydrocarbons via Fischer-Tropsch process.

**Experimental/methodology.** We focused on bifunctional catalysts composed of iron oxide ($Fe_3O_4$) supported onto zeolite HZSM-5 ($SiO_2/Al_2O_3$=91) [2], denoted as $Fe_3O_4$/HZSM-5(91). The $Fe_3O_4$ nanoparticles were synthesized by precipitation and incorporated into HZSM-5 by two methods denoted as physical mixing and dry impregnation. For this, $Fe_3O_4$ was mixed with the zeolite in a mortar (dried, physical mixing) or in a form of a slurry (dry impregnation). We also tried a wet impregnation approach in which a solution of iron salt was impregnated on the zeolite followed by calcination. Catalytic tests were performed in an automated continuous fixed-bed reactor with control of gas flow, temperature, and pressure. Products were analyzed by gas chromatography. In addition, the effect of support acidity in CO conversion and product selectivity was evaluated, using zeolite materials with different $SiO_2/Al_2O_3$ ratios (from 52 to 371) generating the catalysts $Fe_3O_4$/HZSM-5(52), etc.

**Results and discussion.** Prepared $Fe_3O_4$/HZSM-5 catalysts were designed to target a tandem reaction of CO hydrogenation and chain growth on the Fe sites, and oligomerization/cracking secondary reactions on the acid sites of the zeolite support, leading to formation of longer-chain hydrocarbons. Our transmission electron microscopy data shows catalysts of $Fe_3O_4$ supported on HZSM-5 with morphologies consisting of clustered $Fe_3O_4$ nanoparticles deposited onto the zeolite. The XRD displayed diffraction peaks for the HZSM-5, $Fe_3O_4$ and α-$Fe_2O_3$ phases, whereas in wet impregnated catalyst, no iron species were detected. The catalyst prepared by dry impregnation showed smaller Fe crystallite size, compared to the physical mixing. The catalysts prepared by the different methods and different zeolite acidities were then tested in the Fischer-Tropsch reaction. The best results were obtained for the $Fe_3O_4$/HZSM-5(91) catalyst, with CO conversion of up to 89% at 350°C and lower $CO_2$ selectivity. Main products of the catalytic reactions were light hydrocarbons with approx. 25 % of liquid products in the gasoline range ($C_4$-$C_8$).

Overall, our data shows that the $Fe_3O_4$/HZSM-5(91) catalyst was active towards the hydrogenation of CO to hydrocarbons, and both the acidity of the zeolite and the synthesis method influenced the performances. A more detailed kinetic analysis as well as further optimization of the catalysts in terms of morphology and composition are under investigation to target higher-chain hydrocarbons and lower temperature conditions.

**Keywords:** Methane oxidation, ZSM-5, Carbon coating

**Introduction.** Methane, the simplest saturated hydrocarbon, is the main component of natural gas and shale gas. In spite of its abundance, it is currently used as fuel and its application as a chemical feedstock is rather limited. The current methane-based chemical process is based on an indirect pathway via syngas, a mixture of CO and $H_2$. Since this syn gas synthesis process is energy-intensive, only large-scale process is cost-competitive so that small-scale methane resource cannot be exploited. In order to overcome this weak point of an indirect methane conversion, the direct conversion of methane has been studied. Several methodologies are reported for the direct conversion of methane, including aromatization, coupling, pyrolysis, and partial oxidation of methane into oxygenates [1]. However, the strong C-H bond in methane makes it hard to convert methane directly into value-added products under mild condition [2]. In last decade, many researchers reported the selective oxidation of methane in an aqueous solution using $H_2O_2$ as an oxidant [3]. Xiao et al. proposed a "molecular fence" strategy that modifies the surface of the zeolite catalyst with hydrophobic organosilanes to control the diffusion of hydrophilic hydrogen peroxide and trap it inside [4]. In this study, the external surface of zeolite was modified with carbon originated from furfuryl alcohol (FA) and then a partial oxidation reaction of methane was performed.

**Experimental/methodology.** The experiment was performed in a glass liner inside an autoclave with a total volume of 120 mL. Hydrogen peroxide was added to water for its concentration to be 0.277 M. Methane was charged to the pressure of 31 bar. The product gas was separated with a Carbosphere packed column (Agilent) in an online gas chromatograph (Younglin), which was passed through a methanizer, methane from $CO_2$ was measured by a flame ionization detector. The liquid mixture was filtered with a microfilter (Millex) for nuclear magnetic resonance (NMR) analysis and hydrogen peroxide quantification. $^1$H NMR was measured at room temperature via a Jeol Resonance ECZ600R, using 0.1 % trimethylsilylpropanoic acid (TMSP, Na salt)/$D_2O$ (Euriso-top) as the standard.

**Results and discussion.** The physicochemical properties of the prepared catalysts were determined from $N_2$ physisorption data, $NH_3$-TPD, and contact angle measurement. As the content of carbon increased and then the external surface of zeolite decreased rapidly. The hydrophobicity of the surfaces was confirmed by water-droplet contact angle tests. When the carbon content is zero, the contact angle was 17.2 °. Also when the carbon content was 4.84 wt.%, the contact angle was 29.5 °. As the carbon content increases, the contact angle also increased, which means an increase in hydrophobicity. At 50 °C, H-ZSM-5 showed a total product yield of 401 μmol, C-H-ZSM-5 with a carbon content of 0.22 ~ 1.78 wt.% showed a total product yield of 500 μmol to 630 μmol. At 30 °C, 0.50 wt.% Fe-ZSM-5 showed a total product yield of 300 μmol, C-0.50 wt.% Fe-ZSM-5 with a carbon content of 0.27 ~ 3.41 wt.% showed a total product yield of 380 μmol to 650 μmol. The gain factor, which is defined as [moles of total products]/[moles of $H_2O_2$ consumed] for each catalyst was determined and was almost double over C-H-ZSM-5 than that over H-ZSM-5.

*Ceria has a wide range of applications on catalysis and energy categories. Inclusion of certain aliovalent dopants in the ceria can improve the catalytic performance by increasing the strain force of the latticeand generating more oxygen vacancies.We investigate the effect of synthesis parameters on the reaction activity, such as pH value, Sm/Ce ratio in SDC, and irradiation strength in a microwave synthesis. The result shows that the catalyst exhibiting high activities toward syngas production (i.e., a CH4 conversion > 90 % at 700 °C) requires a medium Ni-SDC interaction with a Sm/Ce ratio of about 1/9 to 2/8. As reported, optimum oxygen vacancies and adequate ion diffusivity in these SDCs, also displays the highest ion conductivity for fuel cell applications.*

**Keywords:** Ceria, methane oxidation, oxygen vacancies, microwave synthesis, SDC

**Introduction.**

Partial oxidation of methane (POM) is an effective way for conversion of natural gas to valuable chemicals. Methane, a major component in natural gas, is partially oxidized in the POM to syngas with a suitable H2/CO ratio for methanol and Fischer–Tropsch synthesis. Compared with steam reforming of methane, the POM is mildly exothermic, thus avoiding highly endothermic reaction with a smaller reactor size and reduced capital cost [1]. Besides, a higher efficiency can be achieved when the POM is combined with a membrane reactor to produce hydrogen for electric power generation [2].

Several studies have focused on metal oxides such as doped ceria (Ce) for conversion of methane . Ceria, an excellent electronic and ionic conductor, has been shown to be an effective catalyst for methane oxidation because of high resistance to sintering and coking. In addition, ceria doped with trivalent cation such as samarium (Sm) exhibits mixed-valence states of Ce4+ /Ce3+ as a redox couple in the POM. Accordingly, doped ceria may play a synergistic role and provide additional pathways for redox reaction to improve the POM activity [3].Many preparation methods have been applied to prepare a metal/doped ceria system for catalytic applications, such as microwave, hydrothermal, co-precipitation, sol–gel techniques and so on [4]. Several nickel/ samarium doped ceria (Ni/SDC) systems prepared by a microwave method are shown to exhibit smaller crystallites with high activity in comparison with those in the conventional process. In the present study, we obtained SDC nanopowders via a microwave method and made Ni/SDC catalysts by combination of SDC with nickel via different routes. The effect of preparation methods and synthesis parameters on the POM activity was investigated. Our results showed that different methods and parameters lead to changes in morphology and particle size, which are crucial for the catalytic activity.

**Experimental/methodology**

Catalyst preparation

The synthesis of samarium doped cerium oxide (SDC) was achieved by a microwave (MW) assisted method in a two-step process of, (i) MW irradiation of precursor solution, and (ii) crystallization of the fluorite structure by heat treatment [5]. In a typical preparation, cerium (III) nitrate hexahydrate ($Ce(NO_3)_3{\cdot}6H_2O$) and samarium(III) nitrate hexahydrate ($Sm(NO_3)_3{\cdot}6H_2O$) as precursor salts were dissolved in ethanol with Sm/Ce molar ratio according to a composition of $Ce_{0.1}Sm_{0.9}O_{1.95}$. The mixture was dropwise added with 10 M NaOH for adjustment of pH value and then placed inside a conventional household

microwave. The synthesis was conducted by irradiating the solution with different microwave strength (Low = 133W、Med = 532W、High = 798W) in an on/ off cycle (10 sec on and 20 sec off) for 10 min. The precipitate from the irradiated solution was collected and washed with distilled water to remove soluble species. The sample was further rinsed with ethanol and then calcined at 600 ℃ for 4 h to yield the product (SDC).

Characterization

Catalytic activity on methane oxidation was evaluated by temperature-programmed reaction with an on-line mass spectrometer. Mass/electron ratio (m/e) in the MS were selected for $H_2$ (2), He (4), $CH_4$ (15), $H_2O$ (18), CO (28), $O_2$ (32), and $CO_2$ (44). The phase composition of crystalline components on the catalyst was investigated by X-ray diffraction (XRD) analyses. The assignment of the various crystalline phases was based on the JPDS powder diffraction file cards. The morphology of the as-synthesized Ni/SDC catalyst was characterized by scanning electron microscope (SEM) equipped with an energy-dispersive X-ray spectrometer (EDX) and transmission electron microscope (TEM).

**Results and discussion.**

Figure 1 shows X-ray diffraction (XRD) patterns of the as-synthesized catalyst. The XRD pattern of SDC on all catalysts was found to match well with the cerium oxide and indexed to a cubic fluorite structure. There were no peaks detected for the dopant samarium oxide, indicating that the dopant ion is fully substituted in the $CeO_2$ lattice to form a solid solution. Figure 2 presents MS profiles of eluting gaseous products from methane oxidation on the CMW catalyst prepared at different pH values. The result of temperature-programmed surface reaction shows that syngas are main products. The catalyst prepared at a low pH value produced more syngas with a higher MS intensity, whereas the catalyst prepared at a high pH value gave rise to a more stable activity. CMW catalysts yield syngas in methane oxidation and the highest activity is achieved on the lowest pH made catalyst, i.e., pH = 9.

**Keywords:** Partial oxidation of methane, In situ $H_2O_2$, Methanol, Formic acid

**Introduction.** The direct conversion of methane to its oxygenates is known as one of challenging reactions. The current methane conversion into the value-added products is based on the indirect energy-intensive multistep processes in which methane is first converted into a syngas, a mixture of carbon monoxide and hydrogen, at high temperatures. Therefore, this indirect process can be industralized in a large scale to get its economic competitiveness. In order to utilize small-scale methane resources, it is important to develop efficient direct methane conversion technologies including direct partial oxidation, dimerization, and chlorination at low temperatures[1]. However, the chemical inertness of methane and its more stable C-H bond than that of its oxygenates make it difficult to obtain high yields of desired products during direct methane conversion[2]. Hutchings et al. reported the partial oxidation of methane over Fe/ZSM-5 catalysts using $H_2O_2$ as an oxidant[3]. In our previous work, we reported the partial oxidation of methane over Fe/ZSM-5 and Pd/C catalysts. Pd/C catalyst was used for the synthesis of $H_2O_2$ in situ from $H_2$ and air($O_2$)[4]. The pH of the reaction liquid was adjusted using sulfuric acid to obtain a higher $H_2O_2$ concentration despite of leaching of the active metal. In this work, we conducted partial oxidation of methane using air, which is more economic than $H_2O_2$, as an oxidant and $H_2$ as a reducing agent. The $H_2O_2$ was synthesized in situ from the air($O_2$) and $H_2$ and utilized for the conversion of methane. The commercial Pd on activated carbon was used for $H_2O_2$ synthesis and Fe/ZSM-5 was used for the partial oxidation of methane. To increase the yield of $H_2O_2$, various halide anions including KF, KBr, and KCl were used without any liquid acids. The effect of some reaction variables such as reaction temperature, reaction time, and the concentration of halide anions on the catalytic performance was also investigated.

**Experimental/methodology.** The Fe/ZSM-5 catalyst was prepared with a wet impregnation method using $FeCl_3$ as a Fe precursor and $NH_4$-ZSM-5 as a support. 1%Pd/C catalyst was purchased from Sigma Aldrich and used as-received. The liquid-phase partial oxidation of methane was conducted in an autoclave. Typically, 50 mg of Fe/ZSM-5, and 50 mg of 1 wt.% Pd/C were added into 30 mL of water including halide anions with various concentrations(0-10 mM). The reactor was sealed and reactant gases were charged ($CH_4$:$H_2$:Air=15:3:10 bar).

**Results and discussion.** The yield of methane oxygenates and $H_2O_2$ was the highest when KBr was used as an additive. As the concentration of KBr increased, the amount of total product and $H_2O_2$ after the reaction increased. However, the use of KBr at high concentrations caused the leaching of active metals from the catalysts, even though the fraction of leached metal didn't exceed 0.5% of the introduced amount. When the reaction time was increased from 30 min to 2 h, the amount of total products increased gradually but the residual $H_2O_2$ and methane oxygenates selectivity decreased. Increasing reaction temperature from 30 to 50 $^{o}$C resulted in higher methane oxygenate yield but lower methane oxygenates selectivity. Under optimal reaction conditions, the conversion of methane reached 0.4 % with methane oxygenates selectivity of 88 %(reaction time= 4h, temperature= 30 $^{o}$C, [KBr]= 10 mM).

# Determining bifunctionality of mesoporous Co/Zeolite catalyst for direct synthesis of liquid fuel by Fischer-Tropsch reaction

Sungtak Kim[1*]

[1]*Department of Chemical Engineering and Applied Chemistry, Chungnam National University, Daejeon, South Korea*

**Keywords:** Fischer-Tropsch, Cobalt catalyst, Mesopore Zelite

**Introduction.**
Fischer-Tropsch (FT) synthesis from natural gas is one of the most promising technology for the production of clean fuel that is served as an alternative of traditional petroleum oil. In general, additional upgrading process such as mild hydrocracking or isomerization is accompanied for the production of liquid fuel from solid wax. To simplify the processes, dual-function catalysts that exhibited activities for both chain growth and isomerization reaction have been suggested for the single FT process. For this purpose, a ZSM-5 zeolite was proposed as a support material due to its wide presence of acid site that is capable of cracking and isomerization of long-chain hydrocarbons. Utilization of mesoporous ZSM-5 is one of the most potential solution for the above issue.1 However, microscopicrole of mesoporosity on the activity and selectivity of the Co/ZSM-5 catalyst for the FT reaction are still elusive. Therefore, in this work, the effects of mesoporosity and acidity of Co/zeolite catalysts on the activity and selectivity for the FT synthesis were systemically studied.

**Experimental/methodology.**
Mesoporosity was implemented to HZSM-5 by two different methods, so-called the bottom-up and top-down methods. The bottom-up method refers to providing mesopores by controlling the degree of crystallization during when hydrothermal synthesis ofsynthesizing HZSM-5 crystal. For instance, HZSM-5 synthesized at 120 °C exhibited a low degree of crystallinity accompanying mesopores with 22 nm of pore size, while that synthesized at 160 °C exhibited a high degree of crystallinity without mesopores. In the present study, the low crystalline mesoporous HZSM-5 and the high crystalline HZSM-5 are denoted as bm-HZSM5 and b-HZSM-5, respectively. The top-down method refers to the alkali treatment that randomly de-silicatesetches the parent HZSM-5 structurecrystal, resulting in a creation of mesopores.

**Results and discussion.**
Mesoporous Co/HZSM-5 exhibited higher activity than conventional-structure Co/HZSM-5 and produced liquid form hydrocarbons. The mesoporous ZSM-5 zeolite was accompanied with large external surface area, which led to an effective Co dispersion. Since the FT synthesis conducted in the present study was not a case of diffusion-limited reaction, the mass-transfer enhancement induced by the mesoporosity was not responsible for its high activity. Cracking and isomerization abilities were linearly correlated to the number of acid site present on the zeolite support but independent to its mesoporosity.

**Keywords:** Direct $CO_2$ conversion, Fischer-Tropsch synthesis, cobalt catalyst, La-doped ceria, oxygen vacancy

## Introduction

The conversion of $CO_2$ to liquid fuels via catalytic reactions has attracted great attention to the realization of a carbon-neutrality. Regarding this, two subsequent catalytic reactions: the reverse water gas shift (RWGS) reaction followed by Fischer-Tropsch synthesis (FTS) is a promising strategy. The former reaction produces CO from $CO_2$, and the latter affords hydrocarbons from CO. Our next stage is the development of a highly active catalyst for one step conversion of $CO_2$ ($CO_2$-FTS) to simplify the process design.[1] In general, cerium oxide ($CeO_2$) can generate oxygen vacancies which act as $CO_2$ adsorption sites by doping trivalent cations such as $La^{3+}$.[2] We synthesized cobalt catalysts, promoting alkyl-chain growth, on La-doped $CeO_2$ (LC) with the expectation that LC and cobalt become the reaction fields for the RWGS and the FTS, respectively.

## Experimental/methodology

Lanthanum (III) nitrate hexahydrate and cerium (III) nitrate hexahydrate were dissolved in deionized water. The solution was dropped into a continuously stirred 10% $NH_3$ solution and kept stirring at room temperature for 24 h. The resulting precipitate was collected by filtration and then dried at 110°C overnight. The obtained powder was calcined at 400°C for 5 h. The material in which *x* mol% of $Ce^{4+}$ is replaced by $La^{3+}$ is denoted as LCx. The cobalt was loaded on LCx by impregnating to prepare catalysts (Co/LCx), and then calcined at 400°C for 6 h. The obtained Co/LCx catalysts were reduced with $H_2$ at 400°C for 2 h and catalytic activity was evaluated at 1.0 MPa, $H_2/CO_2$ = 3, 260–300°C. The outlet gas was analyzed using a gas chromatograph.

## Results and discussion

Fig. 1 shows the $CO_2$ conversion and the selectivity of products on $CO_2$-FTS at 260°C. Although, the $CO_2$ conversion was decreased gradually as the molar fraction of $La^{3+}$ increased in the support, the "$C_{5+}$, Others" selectivity was increased accompanied with a decreasing in "$CH_4$" selectivity. The surface oxygen vacancies in the obtained LCx were analyzed by XPS spectra of O 1s orbitals. The peaks derived from O 1s can be resolved into oxygen atoms in the $CeO_2$ lattice ($O_L$) and hydroxyl groups adsorbed in oxygen vacancies on the surface ($O_V$).[3] The area ratio $O_V/O_L$ of these peaks became larger as the amount of the doped $La^{3+}$ increased, indicating that $La^{3+}$-doping formed oxygen vacancies. These results demonstrate that the formation of oxygen vacancies in $CeO_2$ by $La^{3+}$-doping is a promising strategy for the execution of $CO_2$-FTS in one step.

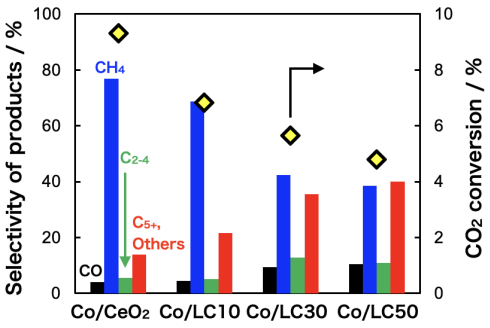

**Fig. 1 $CO_2$ conversion and selectivity of products on the $CO_2$-FTS at 260°C. $C_n$ and Others imply hydrocarbon with carbon numbers of *n*, and products except for hydrocarbons**

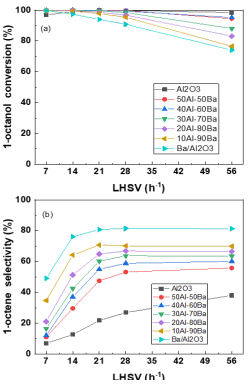
# Optimization of dual-bed catalyst system for linear alpha olefin production in alcohol dehydration



Y. Kim[1,2], U. Jung[1], D. H. Chun[1], M. H. Youn[1], K. B. Lee[2], K. Y. Koo[1*]

**Keywords:** linear alpha olefin, alcohol dehydration, dual-bed system

**Introduction.** Linear alpha olefins (LAOs) are olefins with a double bond at the end of the linear carbon chain. They are used as raw materials in the chemical industry as a co-monomer of polyolefins, synthetic luricants, plasticizer alcohols, and surfactants. The demand for C4-C8 LAO accounts for more than half of the total LAO demand. Hence, alcohol dehydration has recived increased attention owing to its high selectivity of specific LAOs which are used for LLDPE co-monomers. Generally, weak acidic metal oxide catalysts are utilized in alcohol dehydration reactions because their acidic sites serve as active sites. As the acidity of the catalyst increases, the concentration of active sites on the catalyst surface also increases, resulting in increased 1-alcohol conversion. However, side reactions (dehydration-hydration-dehydration) entail the formation of double-bonded isomers, which cause problems in the downstream separation process [1]. Both alcohol dehydration and isomerization can occur at the acidic sites of the catalyst; hence, there exists a trade-off between 1-alcohol conversion and LAO selectivity, and this correlation surpresses the LAO yield. In this study, we applied $Al_2O_3$ catalysts (Al) with high acidity and $Ba/Al_2O_3$ catalysts (Ba) with high LAO selectivity in a dual-bed system and investigated the optimum Al-Ba bed ratio for catalytic performance in the 1-octanol dehydration reaction.

**Experimental.** The commercial $Al_2O_3$ sphere (Sasol, 1 mm) precalcined at 500 °C was used as the catalyst. The 1.5 wt% $Ba/Al_2O_3$(Ba) was prepared using the incipient wetness method. The chracteristics of the catalysts were investigated by ICP-MS, XRD, BET, $CO_2$-TPD, and pyridine-FTIR. The catalyst test was performed at 400 °C with LHSV 7 – 56 $h^{-1}$. The hydrocarbon products were quantitatively analyzed using a GC-FID (Agilent 7890 B equipped with an HP-5 column). The stability test was conducted at 400 °C with LHSV 21 $h^{-1}$ for 100 h.

**Results and discussion.** Various dual-bed systems (Al-Ba, Al+Ba (physical mixing), and Ba-Al) were examined for 1-octanol dehydration(not shown here). Among these, the Al-Ba system with $Ba/Al_2O_3$ positioned at the end of the catalyst bed exhibits the highest 1-octene purity [2]. The effect of the Al-Ba bed ratio on the activity of the Al-Ba catalyst system was investigated (Fig. 1). The Al-bed ratio affected 1-octanol conversion because the $Al_2O_3$ ratio incresed the concentration of acid sites in catalyst bed. Interestingly, 1-octene selectivity increased in propotion to Ba-bed ratio. Furthermore, the basicity of the catalyst hindered the side reaction by readsorption of 1-octene and supressed the formation of octenes isomer. Notably, the optimal Al-Ba ratio varied depending on the flow rate. The 10Al-90Ba system with a high Ba-bed ratio exhibited a high 1-octene yield (34.7 %) under high conversion at LHSV 7 $h^{-1}$. Meanwhile, at LHSV 56 $h^{-1}$, the 60Al-40Ba system showed the highest 1-octene yield (57.3 %). Based on these results, stability tests were conducted on the dual-bed (10Al-90Ba, 40Al-60Ba) and single-bed systems ($Al_2O_3$, $Ba/Al_2O_3$). Minimal changes were observed in the 1-octanol conversions of all the catalyst systems with respect to time on stream (not shown here). Notably, the dual-bed system maintained high durability compared to the Ba single-bed system. Moreover, the 10Al-90Ba system exhibited excellent stability and high 1-octene yield, making it the most efficient catalyst for alcohol dehydration and 1-octene production.

**Keywords:** Pre-carburization, Hybrid catalyst, Green Liquid Fuel.

**Introduction:** The global issues: global warming and a shortage of fossil fuels: gas, oil *etc.* making an uncertainty in sustainable development goal resulting the price-up of commodity: energy, fuels, foods *etc.* has called for the synthesis of green liquid fuels (GLF): gasoline, diesel and jet-fuel. CO hydrogenation called Fischer-Tropsch (FT) process is well known for efficient GLF production by using syngas synthesized from $H_2O$ and $CO_2$ accused for global-warming, but proficient process is still limited for low yield. On GLF production, many articles emphasized the $Co/Al_2O_3$-based systems in industrial application uniquely for low-price/stability of Co and $Al_2O_3$[1] focusing the role of Co-surface modification in change of acidity-basicity, reducibility, dispersion *etc.* by extra addition of inorganic oxides or organic moieties (OM) to increase activity with higher yield.[2,3,4] OM effect in surface modification of hybrid/nonhybrid Co-based catalyst for FT is still very limited, although their positive effects enhance the catalytic efficiency. Therefore, based on aiming to develop a proficient FT process for GLF production, our finding pointed out the OM effect in Co-based hybrid catalyst, and revealed very high stability and efficiency in gas to GLF production.

**Experimental:** $Co/Al_2O_3$ using Co-organic precursor was prepared in usual wet-impregnation method and finally, it was hybridized with zeolite, marked as xCo(O)-**Hcat** (x = wt%). For GLF synthesis, its activity after in-situ reduction was evaluated in a fixed-bed FT process at $H_2$:CO/2:1 in 13-26 ($g_{cat}$·h)/mol, 1.0 MPa, and 210-230°C and all species was quantified in online GC (TCD/FID), and offline GC-MS and offline FID-GC.

**Results and discussion.** At first, 20-40Co(O)-**Hcat** at the above FT conditions were tested and the results showed excellent stability with high activity, high yield (>65%) and selectivity (72-84%) to GLF: $C_5$-$C_{19}$ exploring significant decrease of $CH_4$ and $CO_2$ for 30Co(O)-**Hcat** compared to those for 20Co(O)-**Hcat** and 40Co(O)-**Hcat**, but OM free 30Co(N)-**Hcat** ($Co(NO_3)_2$ precursor used) resulted in low efficacy to GLF shown in Fig. 1. Furthermore, $Co/Al_2O_3$ hybridization enhanced the selectivity to gasoline-range GLF ($C_5$-$C_{11}$ in >70%) with suppressing $CH_4$ and $CO_2$ relative to those for nonhybrid $Co/Al_2O_3$. Here the study of HRTEM, $H_2$-TPR and TG confirmed the C-existence in **Co(O)-Hcat**, while the HRTEM disclosed C-coated cobalt species (**A**). Despite the higher **A** formed with the higher Co loading, 30Co(A)-**Hcat** afforded higher efficacy for a proper combination developed between **A** and zeolite. Besides, a long-time heat treatment of 30Co(O)-**Hcat** resulted in decarburized 30Co(12h)-**Hcat** that showed a notable drop of efficiency to GLF by $CO_2$ and $CH_4$ increase due to the active surface-structure change for absence of C-species. Here, we assume that such combination developed the active $Co^{\partial+}$—$C^{\partial-}$ phase and textural properties, which enhanced the chain-propagation for modification in CO and $H_2$ activation[4] without C-deposition, affording the higher efficiency and selectivity to GLF, while C-deposition was confirmed for Co(N)-**Hcat** and Co(12h)-**Hcat** for the FT stability. More investigation is still now progressing, and we think it would be open a new door to design the hybrid catalysts for $CO/CO_2$-hydrogenation in the future.

# Catalysts of Zr-based metal-organic framework applied in the direct oxidation of methane to methanol

Thielle N. V. S. Ferreira[1], Janaina F. Gomes[1] and Jose M. Assaf[1]
[1]*Federal University of São Carlos, São Carlos, Brazil*

**Keywords:** methane, methanol, metal organic framework, MOF-808.

**Introduction**

The direct conversion of methane into methanol is an important challenge to be overcome due to the strong C-H bond, high ionization energy of methane and excessive oxidation of methanol [1]. In the literature, metal organic frameworks (MOFs) present attractive characteristics for their application as catalysts and some of these structures have shown to be promising for the conversion of methane to methanol, especially those containing copper [2]. This work aims to study Cu-MOFs with varying Cu loading applied in the direct oxidation of methane to methanol at low temperature and atmospheric pressure, as well as the reuse of these materials. MOF-808, which is a Zr-based MOF, was synthesized using the solvothermal method. Subsequently, a post-synthesis step was performed to add an organic ligand, namely EDTA, and incorporate Cu II. The catalysts were characterized by X-ray fluorescence, X-ray diffraction and thermal analysis. The catalytic activity of Cu-MOF-808 was evaluated.

**Experimental/methodology**

MOF-808 and MOF-808-EDTA were synthesized following the procedure previously reported in the literature [2]. Copper incorporation was carried out with nominal Cu/Zr molar ratio of 1.8, 1.9, 2.0, 2.1. Catalytic experiments were carried out in three steps: (1) catalyst activation with oxygen at 150 °C, (2) methane oxidation at 150 °C and (3) product extraction in water.

**Results and discussion**

The diffractograms of the investigated samples presented in Figure 1a are in agreement with the simulated MOF-808, showing that the metallic organic structures were successfully synthesized [1]. From Figure 1b, three regions of loss of mass can be observed. Up to 100°C the loss of mass is associated with samples humidity, up to 250°C physically adsorbed trimesic acid (BTC) is released and, from 250°C onwards the loss of mass is related to the removal of modulator and solvent [3]. As shown in Figure 1c, the average methanol productivity ranged from 54 to 90 µmol $g^{-1}$cat, being higher for the MOF-EDTA-1.9Cu and MOF-EDTA-2.0Cu catalysts, indicating an effect of copper loading on the production of methanol. Results of the catalyst reuse (Figure 1d) show a decrease of the methanol productivity with increasing number of reuse cycles, although it is less pronounced from the 2nd to the 3rd cycle. The impact of the Cu loading on the methanol productivity and the cause of the samples deactivation are being further investigated.

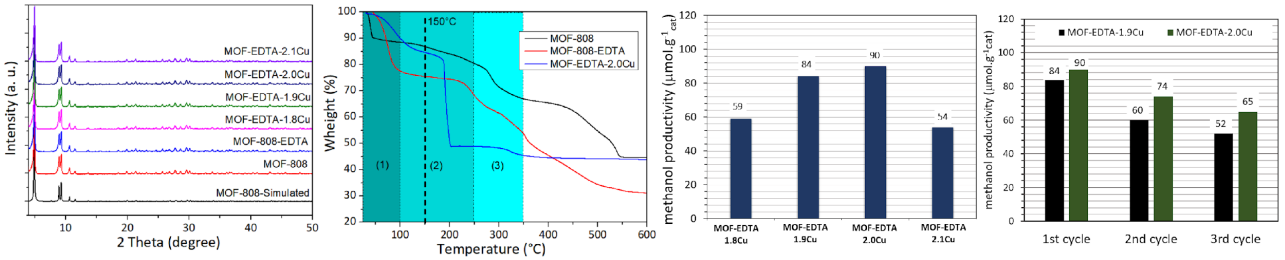

**Figure 1.** a) X-ray diffractograms of MOF-808 and post-synthesis modified materials, b) thermogravimetric analysis of MOF-808, MOF-808-EDTA, MOF-EDTA-2.0Cu samples, c) methanol productivity and d) reuse evaluation of MOF-EDTA-1.9Cu and MOF-EDTA-2.0Cu catalysts.

# Measurements of spatially-resolved concentration profiles on Fischer-Tropsch synthesis in a fixed-bed compact profile reactor

J. Mettke[1*], F. Wolke[1], S. Hilbig[1], E. Reichelt[1], M. Jahn[1]

[1]*Fraunhofer IKTS, Dresden, Germany*
[*]*judith.mettke@ikts.fraunhofer.de*

**Keywords:** Fischer-Tropsch synthesis, Reaction profiles, In-situ analysis

**Introduction.** Fischer-Tropsch synthesis (FTS) has recently experienced renewed interest, as hydrocarbon chains can be built up from hydrogen and carbon monoxide (syngas) via a heterogeneously catalysed chain growth reaction [1]. Therefore, FTS plays a major role in power-to-X concepts and is considered one of the key technologies for the energy transition process. Since syngas cannot only be obtained from fossil but also from renewable carbon feedstocks such as biogas and $CO_2$ [2], the sustainability of the production of fuels or other valuable products like higher alcohols can be notably increased using FTS. The Fischer-Tropsch synthesis is characterized by a large reaction network and a product mixture of hydrocarbons from different substance groups and chain lengths. The product spectrum is also strongly dependent on the reaction conditions. Although the first insights into this reaction were published in the 1920s [3], the underlying reaction mechanisms and kinetics are still poorly understood due to their complexity. This leads to difficulties in process optimization according to ecological and economic criteria.

**Experimental/methodology.** Conventional slurry or fixed-bed reactors allow only integral measurements of product selectivity and derived parameters like chain growth probabilities [4]. Hence innovative reactor designs are required to gain more insights than classical integral reactor setups. The application of the so-called compact profile reactor (CPR), developed by *Reacnostics GmbH* (Hamburg, Germany), can give access to previously inaccessible information. This setup allows for the local sampling of the gas phase at distinct positions in the catalyst bed so that using gas chromatographic methods spatially resolved profiles of the individual product species can be obtained [5]. Thus, the CPR offers the possibility to derive differential data within fixed beds at reaction conditions.

**Results and discussion.** In the first experiments on FTS on iron-based catalysts, spatially resolved concentration profiles could be obtained for short-chain components, leading to promising new insights into the influence of operating conditions as well as of secondary reactions on product selectivity [6]. To also obtain spatially resolved concentration profile data of long-chain hydrocarbons and to determine meaningful reaction kinetics, it is necessary to improve the existing experimental setup. For this purpose, advanced on-line analysis and the possibility of dosing both liquids and gases will be used, which will enable co-feed experiments. The current state of development and future improvement of spatially resolved profile measurements for Fischer-Tropsch synthesis will be presented.

# The conversion of methane to methanol with in situ generated $H_2O_2$

Fenglou Ni[1], Richard J. Lewis[1], Graham J. Hutchings [1*]

[1]*Cardiff Catalysis Institute, School of Chemistry, Cardiff University, Main Building, Park Place, Cardiff, CF10 3AT, UK.*

**Keywords:** Methane oxidation, $H_2O_2$, Methanol

**Introduction.**
As methane is the most abundant component in natural gas, it remains a great challenge to directly convert methane to valuable chemicals with both high activity and high selectivity under mild conditions.[1,2] Currently, hydrogen peroxide ($H_2O_2$)[3] and nitrous oxide[4], as the oxidants, are often used to directly activate methane. But both oxidants would limit the industrial application due to the high cost or environmental-related problems. Instead of using the above oxidants, researchers also used molecular oxygen ($O_2$) to promote the selective oxidation of methane to oxygenates.

To date, Pd-based catalysts are efficient for the direct synthesis of $H_2O_2$ from $O_2$ and hydrogen ($H_2$), which can further decompose into the active hydroperoxyl and hydroxyl species to oxidize methane.[5] However, due to the low activity of oxygen and the overoxidation of the oxygenates, the methane oxidation reaction with $O_2$ or $O_2/H_2$ suffers from low activity and poor oxygenates selectivity. Here, we synthesized zeolite-supported AuPd catalysts to activate methane with in situ formed $H_2O_2$ from $H_2$ and $O_2$.

**Experimental/methodology.**
The oxidation of methane was carried out using a Parr stainless steel autoclave with a nominal volume of 50 mL reactor and a maximum working pressure of 2000 psi. To evaluate catalytic activity towards the autoclave was charged with catalyst (0.027 g) and solvent (10 g $H_2O$, Fischer Scientific, HPLC grade). The reactor was purged with methane (100 psi) and then charged with pure $H_2$, $N_2$, $O_2$ and $CH_4$ such that the total pressure equalled 435 psi. The gas phase composition was 0.8% $H_2$/ 1.6% $O_2$/ 76.7% $CH_4$/ 20.8% $N_2$ to ensure the mixture was outside of the explosive limits. The autoclave was then heated to the desired reaction temperature (50 °C), once at the set temperature, the reaction solution was stirred at 1500 rpm for 0.5 h.

**Results and discussion.**
We prepared a series of AuPd catalysts with different ratios for the in situ methane oxidation. with the Au:Pd ratio approaching 1:1, the catalyst showed the highest methanol productivity and $H_2O_2$ productivity. Although the Pd-only catalyst showed greater $H_2O_2$ productivity, no methanol was observed during the reaction. Thus, the addition of Au could not only improve the formation of $H_2O_2$, but also favor the activation of methane. Such trends may indicate the key role of alternative reactive oxygen species (•OOH, •OH and $•O_2^-$) for methane oxidation which has been reported previously. Moreover, optimizing the total loading of Au and Pd and the preparation methods might further improve the performance.

# Heat transfer intensification in tubular reactors for the Fischer-Tropsch synthesis by adopting conductive cellular internals: a pilot-scale study

Martino Panzeri[1], Carlo Giorgio Visconti[1], Gianpiero Groppi[1] and Enrico Tronconi[1]*

[1]*Laboratory of Catalysis and Catalytic Processes, Politecnico di Milano, Milan (Italy)*

[*]*enrico.tronconi@polimi.it*

**Introduction**. The interest in the application of highly conductive internals for the intensification of processes controlled by heat-management has grown significantly [1]. Such an option becomes even more interesting if the catalyst is packed inside the cellular structure, rather than dispersing it by washcoating. We report the application of this concept to the Fischer-Tropsch synthesis (FTs) in a pilot-scale reactor. The choice of the FTs as a demo reaction originates from the high current industrial interest, but also from its high reaction enthalpy ($\Delta H°_r$=-165 kJ/mol) and high temperature sensitivity, which make this process the perfect case study to explore the impact of shifting from convective (packed beds) to conductive heat transfer. The experimental activity has been focused on the selection of geometry and design of the conductive cellular reactor internals for the maximization of the heat transfer rate. Different reactor configuration were tested and, adopting the packed bed as reference, we show the advantages of introducing conductive internals. Aluminium open cell foams (OCF) [2] and periodic open cellular structures (POCS) [3] with skin are the internals herein tested.

**Materials and methods.** Experiments were carried out on a semi-pilot FTs rig. The $Co/Al_2O_3$ catalyst particles (dp=300 μm) were packed inside an externally cooled, jacketed tubular reactor, 1 m long and 28.80 mm I.D.. The catalytic bed (20 cm in depth) was positioned at the central zone of the tube, in which one single internal (L = 20 cm), or two (L = 10 cm each) were introduced. The cooling fluid was diathermic oil flowing with high rates. The FTs tests were carried out at 25 barg, with a GHSV of 4 Nl/h/$g_{cat}$, feeding syngas with a $H_2$/CO ratio of 2.1. The thermal behavior of the structured reactor was studied at different heat duties, varying the coolant temperature and measuring the axial temperature profiles along the reactor centerline ($T_c$), as well as the skin temperature of the reactor ($T_w$).

**Results and discussion.** The introduction of highly conductive internals (Al OCF and POCS) (Figure 1) enabled up to 70% CO conversion per pass. For each tested configuration, an overall heat transfer coefficient was estimated from the slope of the linear fit of the data (Figure 1, left), where $Q_{sup}$ is the reaction heat divided by the heat exchange surface, $T_{c,avg}$ is the average catalyst temperature at the centerline and $T_{w,avg}$ is the average temperature of the reactor wall, confirming the advantages of OCF and POCS application. The adoption of Al open cell foams (dc= 2 mm, void fraction ε=0.88) incremented the heat transfer coefficient by one order of magnitude (400 W/m$^2$/K), allowing to operate at temperatures and CO conversions which are not accessible by the packed bed reactor (40 W/m2/K). An even better result was achieved when testing an engineered structure: POCS with skin (dc=3 mm, void fraction ε=0.80). For this kind of internals, the research was focused also on the benefits offered by the improved contact of the structure with the reactor wall, studying the effect of varying the "gap" (POCS – tube clearance) on the heat transfer performance. The last experiments involved the adoption of POCS with the skin (dc=3 mm, ε=0.69). The new internal design enabled CO conversions above 70% with an overall heat transfer coefficient exceeding the outstanding value of 1200 W/m$^2$/K.

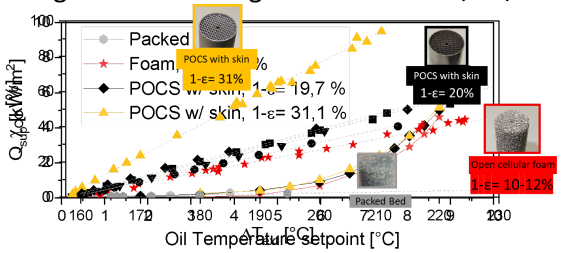

**Figure 1.** (left) Specific heat duty vs. $\Delta T_{ext}$ (= $T_{c,avg}$ - $T_{w,avg}$). (right) CO conversion vs. oil temperature setpoint.

**Acknwoledgment**: This project has received funding from the European Research Council (ERC) under the EU Horizon 2020 research and innovation programme (GA No. 694910 -'INTENT').

**Keywords:** Fischer-Tropsch synthesis, Bifunctional catalysts, Iron-based catalysts, Zeolites

**Introduction.**

Low-temperature Fischer-Tropsch synthesis (LT-FTS) is an attractive way to produce liquid fuels from syngas (CO + $H_2$). LT-FTS is considered a preferred method for selectively producing liquid fuels due to its ability to minimize gaseous hydrcarbon ($C_1$-$C_4$) generation [1]. The wide distribution of $C_{5+}$ hydrocarbons in LT-FTS can be the main drawback when used as liquid fuel, which requires an additional hydrocracking process to convert FTS waxes into liquid hydrocarbon range ($C_5$-$C_{20}$) [2]. The bifunctional catalysts consisting of iron-based catalysts and zeolites can be used to improve the selectivity and yield of liquid hydrocarbons in LT-FTS without required for additional hydrocracking processes. The acid sites of zeolites in bifunctional catalysts usually dictate the selectivity of the desired products. Therefore, it is essential to understand the precise relationship between acidity and hydrocarbon distribution in order to precisely design bifunctional catalysts. However, no study has reported a clear correlation between acidity and the distribution of hydrocarbons. In this study, we report a linear correlation between the acid sites and the cracking rate in the bifunctional process of LT-FTS and cracking for the first time, in which bifunctional catalysts were physically mixed with the precipitated iron-based catalysts and H-ZSM-5.

**Experimental/methodology.**

The bifunctional model catalysts by physically mixing industrially important precipitated iron-based LT-FTS catalysts and H-ZSM-5 to exclude any undesired chemical interactions between the two catalysts. The acidity of the model catalysts was controlled by adjusting the ratio Si/Al and the ratio of Precipitated iron-based catalysts to H-ZSM-5. The acidity of bifunctional model catalysts was quantitatively characterized by ammonia temperature-programmed desorption ($NH_3$-TPD) and pyridine-adsorbed Fourier transformation infrared spectroscopy (Py-FTIR). The FTS was performed using physically mixed bifunctional model catalysts which were diluted with glass beads to keep the length of the catalysts bed constant and then charged into the fixed-bed reactor composed of stainless steel. The catalysts were activated in situ with $CO_2$-containing syngas at 280 $^oC$ and ambient pressure for 5 h, and then the FTS was conducted at 275 $^oC$ and 1.5 MPa using syngas for 114 h.

**Results and discussion.**

The activity of precipitated iron-based catalysts was not affected by the addition of H-ZSM-5, while greatly influenced the hydrocarbon distribution. The higher the acidity of the bifunctional model catalysts, the higher the $C_5$-$C_{20}$ Selectivity in hydrocarbon, which is expected to be related to the linear correlation between the brønsted acid site and cracking rate. In this study, the highest hydrocarbon selectivity of $C_5$-$C_{20}$ was 72.2 wt%, which was about twice as high as that of the P-Fe Catalysts.

**Keywords:** methanol synthesis, $Cu/ZnO/Al_2O_3$, *in situ* poisoning, *ex situ* poisoning, sulphur poisoning

With the utilization of new $CO_2$ sources from highly polluted industrial exhaust gases, sulphur poisoning of $Cu/ZnO/Al_2O_3$ catalysts in methanol synthesis is of high interest.[1] To investigate the poisoning strengths of different S-containing impurities reported in literature,[2] long-term measurements with 6 g $Cu/ZnO/Al_2O_3$ tablet fragments and 10 ppm thiophene continuously added into the syngas feed were carried out and compared to deactivation only by thermal deactivation.

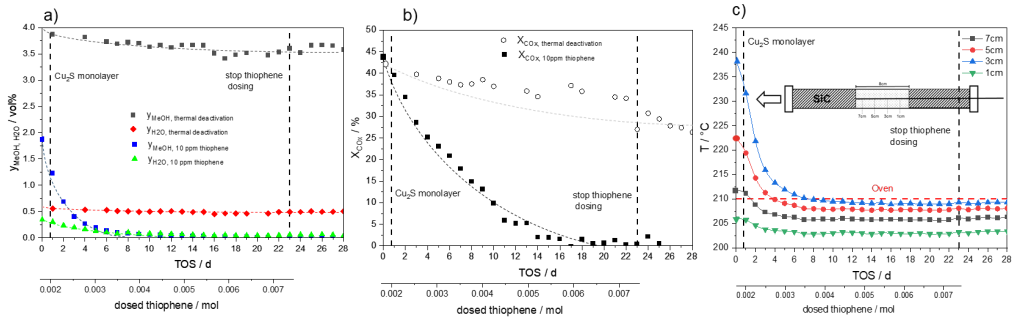

**Figure 1.** a) Recorded mole fractions of MeOH and $H_2O$ at kinetically controlled conversion at 210°C for the 10 ppm thiophene and the only thermal deactivation measurement and b) COx conversion as well as c) recorded temperatures at four positions in the catalyst bed at the same conditions. All measurements were performed at 60 bar with a synthesis gas containing 10.0 vol% CO, 2,0 vol% $CO_2$, 78.0 vol% $H_2$ and 11.0 vol% $N_2$.

Since *in situ* long-term experiments are always time-consuming and, in addition, the post-mortem analysis of the used catalyst only permits a certain degree of poisoning (usually complete irreversible poisoning of the surface), *ex situ* poisoning studies with 1 propanethiole were carried out to gain deeper insight.[3] The poisoned catalysts were characterized using XPS, XRD, TEM, $N_2O$ RFC, CHNS analysis as well as TEM/EDX and compared to the post-mortem characterization data obtained in the *in situ* poisoning study. By XPS in combination with XRD and CHNS analysis it was possible to identify axially decreasing sulphur content in form of $Cu_2S$ and ZnS phases for the *in situ* poisoned samples. In addition, we identified $CuSO_4$ and $ZnSO_4$ surface layers caused by passivation of the catalyst. The self-developed *ex situ* poisoning method was identified as only involving the surface of the catalyst. We envisage to calculate the specific sulphur poisoning threshold value for $Cu/ZnO/Al_2O_3$ catalysts allowing us to deduce hypotheses about the active sites.

**Keywords:** hydrogen production, formic acid, molybdenum sulfide, cluster

**Introduction:** The global energy crisis is driving the transition from fossil fuels to renewable energy sources. Converting wind, solar or hydropower into green hydrogen by water splitting has been proposed as a sustainable energy carrier.[1] Reconvention can be achieved by combustion or in fuel cells with water as the only by-product.[2] However, using hydrogen directly as an energy source raises several concerns related to safety and transportation issues, which necessitate the development of new hydrogen storage methods.[3] Liquid organic hydrogen carriers (LOHCs) have been considered one possible approach in safely storing hydrogen. Formic acid appears to be a good LOHC candidate considering its hydrogen content of 4.4 wt%. Moreover, FA is stable and low toxic at ambient conditions, easy to transport, handle and store.[4]

**Experimental:** The dehydrogenation of formic acid (FADH) enables the production of carbon monoxide-free hydrogen on demand, which is an important prerequisite for use in fuel cells. Our group has recently shown that Molybdenum PNP complexes are capable of converting FA by DH or disproportionation.[5] Furthermore, a cubane-type $Mo_3S_4$ cluster hydride has been shown to be active in FADH.[6] Motivated by the efficiency of Molybdenum, we have analyzed the catalytic activity of several $Mo_3S_4$ clusters, containing different bidentate ligands. These compounds can be easily prepared in a two-step synthesis starting from a $[Mo_3S_4Cl_4(PPh_3)_3(solv)_2]$ cluster. DH reactions were done in a double walled reactor which was equipped with a double burette manual set-up. The set-up was purged with argon several times, loaded with the catalysts and the solvent. Reactions were started by adding a mixture of FA and base.

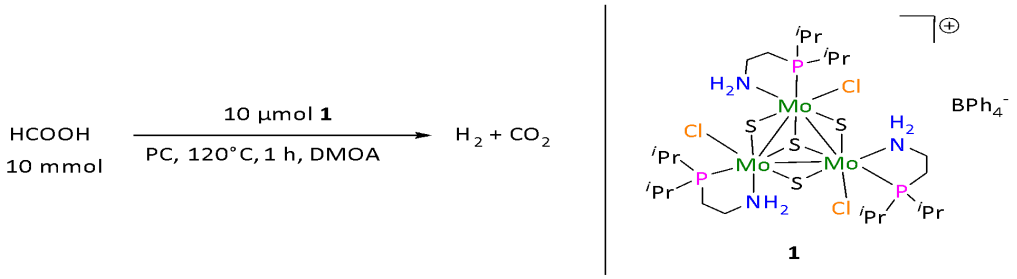

*Figure 1. Formic acid dehydrogenation catalyzed by a cubane-type $Mo_3S_4$ Molybdenum cluster.*

**Results and discussion:** In multiple experiments the best cluster as well as reaction conditions were identified (shown in Figure 1). Crucial for the reaction is the use of a base. All catalysts yielded carbon monoxide free hydrogen. The best results have been achieved using cluster **1.** In a solvent-free restart experiments a TON of 1900 and $TOF_{1h}$ of 950 $h^{-1}$ could be observed at 70°C. Complex **1** was studies further with in situ nuclear magnetic resonance spectroscopy, kinetic studies and density functional theory calculations to explain the reaction mechanism for FADH with clusters.

[*]*ben.sutens@vito.be*

**Introduction.** A shift from fossil fuel-based technologies towards renewable energy sources is becoming more and more important to meet the targets of the Paris Agreement in 2050. Especially in the aviation and shipping sectors which contributes significantly to the total anthropogenic $CO_2$ emissions worldwide, research towards alternative feedstocks has gained increased attention. One promising pathway includes the conversion of bio-based waste into syngas and subsequent Fischer-Tropsch synthesis into valuable liquid fuels. Conventional Fischer-Tropsch synthesis includes the use of cobalt as a catalyst in a fixed-bed reactor, typically in the shape of pellets/extrudates [1]. Although pellets and extrudates are widely commercially applied due to the simplicity and speed of the manufacturing process, a packed bed of these structures entails several drawbacks. Besides the large pressure drop that is created throughout the reactor column, mass-transfer limitations can occur due to slow diffusion to the particles core. A promising solution to overcome these drawbacks while offering a high loading per reactor volume includes the direct 3D-printing of catalyst material. Although several papers have been published involving the use of Robocasting or Direct Ink Writing (DIW) for direct 3D-printing of active species [2], limited work has been published describing the deposition of active metals on a 3D-printed support and the impact of the impregnation method.

**Experimental/methodology.** In this work, the impact of the Co impregnation method was studied. Cobalt on alumina catalyst structures were synthesized, characterized and tested in Fischer-Tropsch synthesis. Three different impregnation methods were evaluated, including (A) incipient wetness impregnation of the structure after printing (B) adding the metal salt precursor to the printing recipe and (C) impregnation of the alumina powder prior to 3D-printing.

**Results and discussion.** The physico-chemical properties of the materials were significantly influenced by the impregnation method, including the macropore volume, nanoparticle size and interaction between the cobalt and the support material. These different properties influenced the catalytic performance of the different materials, showing a clear correlation between the metal-support interaction and the activity of the catalyst. Impregnation after printing showed the highest activity whereas the activity was lowest when the cobalt salt was mixed in the print paste. A slight difference in selectivity could be attributed to the difference in cobalt nanoparticle size.

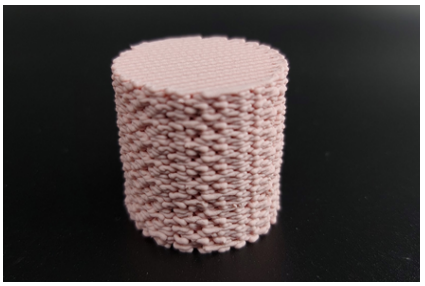

Figure 1. Picture of uncalcined 3D-printed catalyst with Co salt dispersed in the printing paste (method B).

# Plasma-catalytic $CO_2$ hydrogenation to methanol at room temperature and ambient pressure

Y. Wang[1], X. Tu[1*]

[1]*Department of Electrical Engineering and Electronics, University of Liverpool, Liverpool, UK*
[*]xin.tu@liverpool.ac.uk

**Keywords:** Non-thermal plasma, Plasma catalysis, $CO_2$ hydrogenation, Methanol synthesis

**Introduction.**
The chemical transformation of $CO_2$ into higher value chemicals and fuels has attracted significant interest and has been regarded as a key element of a future sustainable low carbon economy in the chemical and energy industries. However, the activation of $CO_2$ remains a great challenge as $CO_2$ is a thermodynamically stable molecule and requires a significant amount of energy for its activation. In conventional catalytic reactors, converting $CO_2$ to methanol requires high temperatures and pressures because of thermodynamic constraints. Non-thermal plasma (NTP) is an emerging and promising technology for $CO_2$ conversion under ambient conditions[1-3]. The combination of NTP with heterogeneous catalysis has great potential to generate a synergistic effect from interactions between the plasma and catalysts, which can activate catalysts at low temperatures and improve the activity and stability of the catalysts, resulting in a remarkable increase in conversion, selectivity, and yield of end-products, as well as the energy efficiency of the process. Moreover, plasma processes can be switched on and off instantly, allowing for great flexibility in decentralized chemical production using renewable energy sources, particularly intermittent renewable energy[4]. Here, plasma-catalytic $CO_2$ hydrogenation to methanol was investigated in a dielectric barrier discharge (DBD) reactor under ambient conditions using MgO, γ-$Al_2O_3$, and a series of $Co_xO_y$/MgO catalysts.

**Experimental/methodology.**
Plasma-catalytic $CO_2$ hydrogenation was conducted in a water-cooled DBD plasma reactor. A mixture of $H_2$ and $CO_2$ with an $H_2/CO_2$ ratio of 3:1 was used. The catalyst (0.5 g) was fully packed in the discharge gap. The reaction temperature was kept constant at 35 $^{o}$C. All the electrical signals were recorded using an oscilloscope (Tektronix DPO 3034).

**Results and discussion.**
In this study, we demonstrate the potential of plasma-enhanced catalysis for $CO_2$ hydrogenation to methanol under ambient conditions. Packing a catalyst in a DBD plasma enhanced the conversion and narrows the product distribution of $CO_2$ hydrogenation. We found that the basicity of the MgO support enhanced the conversion of $CO_2$ compared to more acidic supports (γ-$Al_2O_3$). Both types of support promote the production of CO as the main product. When testing the $Co_xO_y$/MgO catalysts, the quantity and dispersion of metal-support interface sites are important for activity enhancement and methanol selectivity. Although CO is the main product, catalysts with higher cobalt metal loadings and good cobalt oxide dispersion favor methanol production. The most active catalyst was 15 wt % $Co_xO_y$/MgO, which converted 33% $CO_2$ and 24% $H_2$ near room temperature and at atmospheric pressure. This catalyst gave a 10% methanol yield, the highest among the tested materials. A further increase in the metal loading leads to larger cobalt oxide particles that block the pores, giving lower $CO_2$ conversion and less methanol. This work might shed light on the rational design of efficient catalysts for plasma-enhanced catalysis chemical reactions.

**Keywords:** Direct $CO_2$ hydrogenation, Fischer-Tropsch synthesis, iron carbide, alkali-less

**Introduction.**

To achieve carbon neutrity, conversion of $CO_2$ into liquid hydrocarbons ($C_{5+}$) as e-fuel by using catalyst has attaracted great attention. A prospective approach for this is a successive catalytic reaction of reverse water gas shift (RWGS) reaction followed by Fischer–Tropsch synthesis (FTS). However, design of the system is not easy due to the large diremption of optimal reaction temperature between RWGS and FTS, leading energy loss. Therefore, direct $CO_2$ hydrogenation to aquire $C_{5+}$ via Fischer-Tropsch synthesis on one step ($CO_2$-FTS) is strongly desired. Iron-based catalysts is a promising candidate for $CO_2$-FTS, in which iron carbide is the key active species.[1] Main products of iron-catalyzed FTS are light olefins, and the addition of an alkali promoter such as K is considered essential for $C_{5+}$ production since alkali promoters are responsible for advancing catalytic carburization[2]. On the other hand, there are few studies for the $CO_2$-FTS referring to a growth of carbon chains over the alkali-less iron carbide catalysts. In this study, alkali-less iron carbide catalysts were prepared and their reactivity and product compositions were investigated.

**Experimental.**

Alkali-less iron carbide catalyst (FeCx) was prepared by heating commercial iron(II) oxalate dihydrate at 350°C for 4 h under 30%CO/$N_2$ gas flow atmosphere. Alkali-modified catalyst (K-FeCx) was also prepared in the same procedure by adding $KNO_3$ to the raw material (K/Fe = 10, molar ratio). The addition of $KNO_3$ was carried out by a wet impregnation method, and then the obtained sample was dried at 120°C overnight. The catalytic activity was evaluated with pressurized fixed bed flow reactor under a reaction condition of 0.8 MPa(a), 150–340 °C, $H_2/CO_2/N_2$ = 3/1/1, and GHSV = 7400 mL $h^{-1}$ $g_{cat}^{-1}$. The gaseous products and cold-trapped liquid products collected were analyzed by using a gas chromatograph (MCGC990, agilent) and a gas chromatograph mass spectrometer (GCMS-QP2010, shimadzu), respectively.

**Results and discussion.**

The obtained FeCx and K-FeCx catalysts were composed of mixed crystalline phases of $\theta$-$Fe_3C$ and $\chi$-$Fe_5C_2$. Fig. 1 shows the $CO_2$ conversion and product selectivity of $CO_2$-FTS over FeCx and K-FeCx catalysts at 320°C. The $CO_2$ conversion of FeCx was slightly higher than that of K-FeCx, suggesting that the alkali-less FeCx is more active for $CO_2$ hydrogenation. However, methane formation preferencially proceeded over FeCx than that over K-FeCx. On the other hands, GCMS analysis revealed that K-FeCx tends to afford oxygenated compounds such as carboxylic acids, while such the oxygenates were negligible in case of FeCx. These results propose that the alkali-less FeCx catalyst has an extraordinary potential to produce hydrocarbons without the formation of oxygenated compounds.

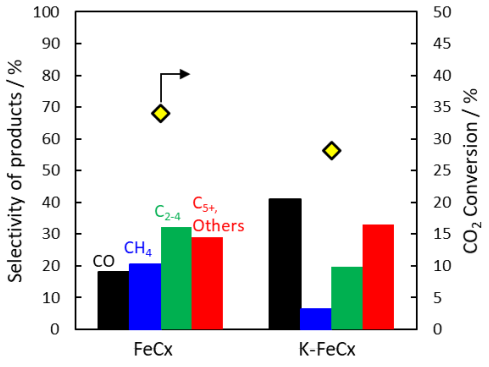

Fig. SEQ Fig. * ARABIC 1 $CO_2$-FTS results over FeCx and K-FeCx at 320°C. "$C_{5+}$, others" denotes liquid hydrocarbons and the other carbon compounds.

# Overcoming the fundamental limitation of electrochemical methane-to-alcohol conversion via outsourced atomic oxygen – A theoretical perspective

Sungwoo Lee[1], Jaehyun Lee[2], Jun Hyuk Moon[2], Jong Suk Yoo[1*]

[1]*Department of Chemical Engineering, University of Seoul, Seoul 02504, Republic of Korea*

**Keywords:** Methane-to-alcohol, conversion, atomic oxygen

**Introduction.** Exploiting electrocatalysis to convert methane to alcohols offers significant advantages because; (1) room temperature can be maintained throughout the process; (2) oxo-metallic sites can be continuously regenerated by forming oxygen species from the water solvent under the operating (oxidizing) condition; and (3) the water solvent is always present to extract alcohols from the catalyst surface via solvation.[1-2] Nevertheless, electrocatalytic conversion of methane to alcohols has not been very successful due to the fundamental limitation in terms of a compromise between activity and selectivity.

A good methane conversion catalyst needs to bind oxygen species extremely weakly in order to efficiently activate methane via the OH-/O-assisted mechanism. However, the consequence is that a rather high potential must be applied to form OH* and O* from water, and at this high potential, the oxygen species are prone to complete oxidation via the oxygen evolution reaction (OER) significantly decreasing the methane conversion faradaic efficiency.[3-4] In this study, we overcome the fundamental limitation using relatively abundant $Fe_2O_3$ as electrocatalyst for methane-to-alcohols conversion by generating active atomic oxygen (O*) on the catalyst surface via a non-electrochemical route, i.e., using carbonate ions from $Na_2CO_3$ as oxidant. This allows methane conversion to occur at low potential and thereby increasing the stability of the weakly bound atomic oxygen by circumventing full oxidation via OER.

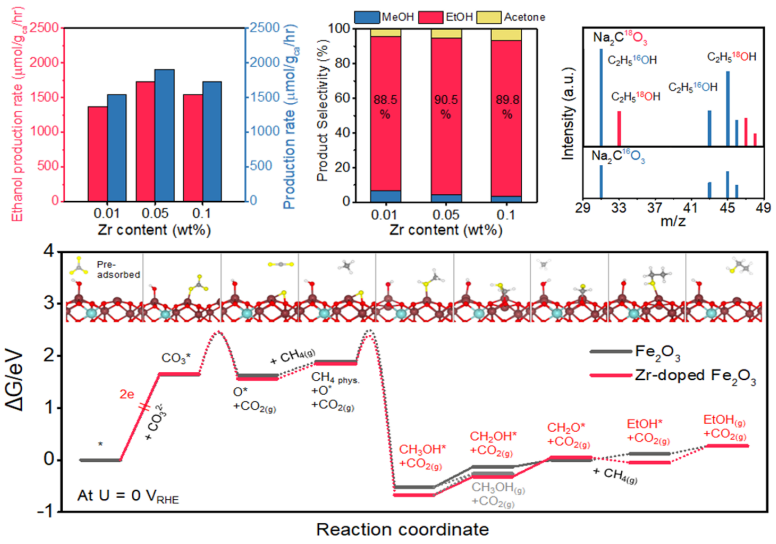

Figure SEQ Figure * ARABIC 1. Production rates of ethanol and total oxygenates for Zr-$Fe_2O_3$; Product selectivity for various Zr contents in Zr-$Fe_2O_3$; GC-MS spectrum for the ethanol product when isotope-labelled $Na_2C^{18}O_3$ is used; Calculated free energy diagrams for O* generation from $CO_3^{2-}$ and the subsequent methane-ethanol conversion on Zr-$Fe_2O_3$ [0001].

**Experimental/methodology.** Various electrochemical characterizations, isotope labeling experiments, and DFT calculations are conducted to examine the methane-to-alcohol conversion over the synthesized $Fe_2O_3$ catalyst.

**Results and discussion** Fig. 1 shows that, an alcohol productivity of 1200 μmol/gcat/hr with the alcohol selectivity of 97.5 % (63.9 % for ethanol (1.91 USD/gal) and 33.6 % for methanol (1.45 USD/gal)) are achieved. We also adopt a zirconium doping strategy to substantially increase the alcohol productivity as well as the ethanol selectivity, achieving ~1800 μmol/gcat/hr with the ethanol selectivity of 90.5 %, as shown in Fig 1.

**Keywords:** Low Energy Ion Scattering, surface analysis, elemental composition, outer layer
**Introduction:** The outer atomic layer of heterogeneous catalysts is obviously essential for the performance. Numerous analytical methods exist which look a the “surface” to analyse both the material as well as the chemical processes taking place. However, only high-resolution and high-sensitivity Low Energy Ion Scattering (LEIS) is able to quantitatively determine the elemental composition of the outer atomic layer, both for model as well as for industrial catalysts [1]. To demonstrate this unique possibiltity, we will show a range of examples of successful analysis.
**Experimental/methodology:** We used a Qtac 100 Low Energy Ion Scattering spectrometer, which is a specialised instrument for high-resolution and high-sensitivity quantitative elemental composition analysis of solids. The technique is insensitive to sample topography and works on insulators and conductors, making it well suited for catalyst research. Its high detection sensitivity also allows for analysis of industrial catalysts.
Using this tool and in-situ preparation techniques, catalyst materials were analysed. Ranging from single atom catalysts to automotive applications, we covered quite a range of different materials.
**Results and discussion.** This presentation will illustrate the possibilites arising from LEIS applications in heterogeneous catalysis. We will present the analysis results for the different materials and highlight the significance of the gained data for each of the examples. A special focus will be on explaining why LEIS could play an essential role in material characterisation in this field, as a complement to the existing surface analysis/surface science techniques.

**Keywords:** Operando spectroscopy, $CO_2$ Utilisation, Methanol, EXAFS, DRIFTS

**Introduction.** Recently $Pd/In_2O_3$ systems have emerged as promising candidates for $CO_2$ hydrogenation to methanol. Unlike traditional Cu-based systems, $Pd/In_2O_3$ can achieve near quantitative methanol selectivity and are highly stable.[1,2] We have developed a novel series of $Pd/In_2O_3$ catalysts deposited on alumina, which despite having a fraction of the metal content, have comparable activity to pure $Pd/In_2O_3$ species. The precise interactions between Pd and $In_2O_3$ are key to creating an optimal catalyst, with the literature divided on the role of PdIn alloys. Here we present the *first operando* spectroscopic study on $CO_2$ hydrogenation on the synergy between Pd and $In_2O_3$, towards a better understanding of catalyst design.

**Experimental/methodology.** Our ternary $Pd/In_2O_3/Al_2O_3$ catalyst was studied with *operando* X-ray Absorption Spectroscopy (XAS) and compared with analogous $Pd/Al_2O_3$ and $In_2O_3/Al_2O_3$ systems with *operando* Diffuse Reflectance Infrared Fourier Transform Spectroscopy (DRIFTS). Spectra were collected under 20 bar of pressure between 30 – 250 °C, under reaction conditions, whilst the products were measured using online mass-spectrometry. XAS data of Pd and In were measured simultaneously, first under reduction activation, and then under catalytic conditions, to correlate any changes in behaviour to alloy formation and catalytic activity.

**Results and discussion.** XAS data under *in situ* reduction and *operando* catalytic conditions shows Pd reducing from PdO to active Pd nanoparticles (Figure 1). In remained as $In_2O_3$, however analysis of coordination numbers confirmed oxygen vacancies were forming on the $In_2O_3$ surface. During the reaction, subtle differences were seen for Pd and In, although at no point was there any significant evidence of PdIn alloy formation, suggesting the two metals operate as distinct, though likely proximate, active sites. Comparing the *operando* DRIFTS data of the monometallic and bimetallic systems strongly suggests that Pd is indeed a strong hydrogen activator but cannot efficiently activate the $CO_2$, which led to poor overall activity. Conversely, $In_2O_3/Al_2O_3$ showed continual development of activated $CO_2$ species on the surface but was unable to effectively activate them. As such, we will discuss the benefits of combining Pd and $In_2O_3$ on our unique catalyst series, the mechanistic implications this has, and how this can guide future catalyst design for $CO_2$ utilisation.

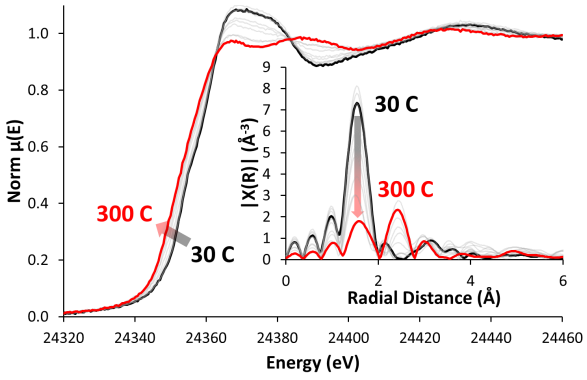

**Figure 1:** Showing the evolution of the Pd K-edge XAS spectra under reduction conditions.

**Introduction.** Hydrogen production from methanol decomposition to syngas ($H_2$ + CO) is a promising alternative route for the clean energy transition. One major challenge is related to the quest for stable, cost-effective, and selective catalysts operating below 400 °C [1]. Ni-based catalysts combine stability, catalytic activity, and low cost of raw materials, thus representing ideal candidates for industrial scaleup. One of the major challenges regards the optimization of the catalytic activity and selectivity of Ni-based alloys [2].

**Experimental/methodology.** In this work, we investigate the methanol decomposition mechanism of Ni−Sn intermetallic compounds with different Sn content ($Ni_3Sn_4$ and $Ni_3Sn_2$), at temperatures between 250 and 300 °C. Indeed, such a hitherto unexplored temperature range would be extremely advantageous for industrial methanol decomposition implementation. We unveiled the physicochemical mechanism ruling low-temperature methanol decomposition by combining *operando* ambient-pressure NEXAFS spectroscopy[3], synchrotron-based *in situ* X-ray photoemission spectroscopy (XPS) and high-resolution transmission electron microscopy (HR-TEM), complemented by density functional theory (DFT) calculations. The use of *operando* and *in situ* spectroscopic techniques using synchrotron radiation is particularly appropriate to monitor the status of the catalyst surface during the reaction while standard *ex-situ* investigations can only probe irreversible surface modifications, thus inevitably losing information on the various reaction steps.

**Results and discussion.** Our results show that a surface oxide skin imaged by HR-TEM, emerging from the natural interaction of the catalyst surface with the ambient atmosphere, plays a pivotal role in the catalytic mechanism. We also established that different amounts of Sn in the alloy strongly influence methanol decomposition selectivity, and we find an increased selectivity to $H_2$ with respect to secondary reaction products for $Ni_3Sn_4$, compared to $Ni_3Sn_2$. The role of surface oxide phases was also demonstrated through the analysis of pretreatment procedures of the Ni−Sn catalysts. Spectroscopic results were correlated with a semiquantitative analysis of the gas products, detected through online micro gas chromatography.

**Keywords:** Palladium, Platinum, nanoparticles, reconstruction, characterization, DFT, hydrides, carbonyls.

**Introduction.** Ductility of metal nanoparticles promoted by adsorbates is a crucial phenomenon in catalysis, currently brought back to the spotlight by the newest developments of experimental and theoretical methods for studying nanomaterials.[1] Here we focus on two highly dispersed 5 wt.% $Pd/Al_2O_3$ and $Pt/Al_2O_3$ industrial catalysts and their interaction with two probe molecules of catalytic relevance: CO and $H_2$. We gathered evidences of temperature- and pressure-dependent adsorbate-induced reconstructions by coupling various experimental techniques, mainly IR spectroscopy, Microcalorimetry and Inelastic Neutron Scattering (INS), with DFT calculations.

**Experimental/methodology.** In situ FTIR spectra were recorded either by dosing with gas pulses, or by tuning the desorption pressure and temperature. INS spectra were recorded on the IN1-Lagrange instrument at the ILL in Grenoble. Periodic DFT calculations were performed with the VASP code, with models of extended surfaces and of clusters of various sizes (13-55) supported on γ-$Al_2O_3$ surface models.

**Results and discussion.** IR spectra collected while dosing small incremental CO pulses on $Pd/Al_2O_3$ indicate that, at high coverage, bridged carbonyls on the Pd(100) facets decrease in favor of top ones (Fig. 1A). This phenomenon entails an unexpected increase in the heat of adsorption of CO, measured by Microcalorimetry. This suggest that CO is triggering a surface reconstruction entailing the corrugation of the Pd(100) facet into novel defective adsorption sites. We are performing DFT calculations to inspect the impact of CO adsorption on the stability of "low index" and corrugated "high index" Pd crystal facets.

The vibrational fingerprints (collected with FT-IR[2] and INS[3]) of the hydrogenous species generated at the surface of $Pt/Al_2O_3$ under $H_2$ atmosphere reveal a different distribution of surface Pt-H species at high and low $H_2$ coverage (Fig. 1B). The DFT simulation of vibrational and thermodynamic properties of this system led to a rationalization of the observed phenomenon,[3] with a massive reconstruction of Pt nanoparticles in the catalyst, modifying both their morphology and their degree of interaction with the support.[3]

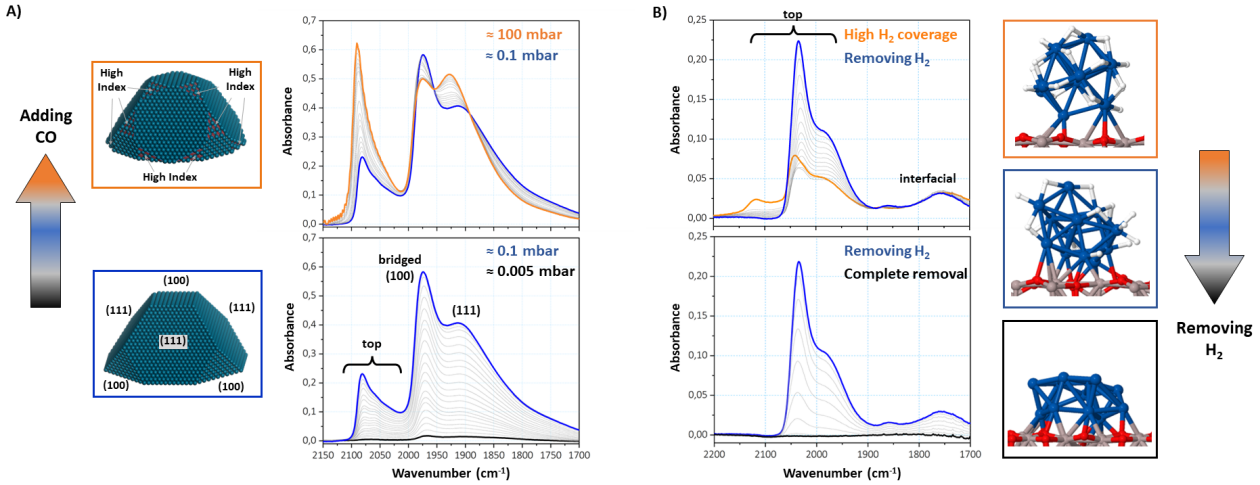

**Fig. 1.** FT-IR spectra collected while increasing CO coverage on the $Pd/Al_2O_3$ catalyst (A) and while decreasing $H_2$ coverage on the Pt/Al2O3 catalyst (B). The two reconstructions are visualized thanks to a few molecular models.

**Introduction.** The wasteful handling of natural gas in the oil and gas sector in combination with the strive for resource efficiency has animated research efforts to identify effective methods to convert retained $CH_4$ into high-value commodity chemicals such as $CH_3OH$. [1,2] Direct, low-temperature $CH_4$ oxidation by Cu exchanged zeolites via chemical looping has proven to be a particularly promising technology as a result of its scale flexibility and exceptional $CH_3OH$ selectivity. Among the different zeolite topologies, Cu exchanged chabazite (Cu-CHA) is of special interest due to its superior $CH_3OH$ yield. [3] However, attempts at industrial implementation are impaired by the lack of knowledge regarding the influence of the Si/Al ratio and the Cu-loading on the Cu active site speciation governing the redox behavior and $CH_3OH$ selectivity of the material. [4] This is further aggravated by the fact that information about the site-specific kinetic properties is missing. The present work aims at identifying the composition dependent Cu speciation by determining characteristic spectroscopic fingerprints and at elucidating their distinct kinetic behavior. Structure-activity relationships are established by correlating these results to the redox activity and $CH_3OH$ selectivity of the bulk material.

**Experimental/methodology.** Four Cu-CHA materials differing in Cu speciation were prepared by deliberately varying the Si/Al ratio and Cu-loading. The results of plug flow reactor (PFR) reactivity tests were correlated to *in situ* X-ray absorption near edge structure (XANES) and *in situ* Fourier-transform infrared (FTIR) spectroscopy experiments. The observed differences in redox behavior and $CH_3OH$ selectivity of the samples were linked to the variation in Cu speciation, which was established by means of *in situ* FTIR of adsorbed NO as well as *ex situ* Raman, *ex situ* photoluminescence (PL), *operando* ultraviolet-visible diffuse reflectance
(UV-Vis), and *operando* electron paramagnetic resonance (EPR) spectroscopy.

**Results and discussion.** Samples exhibiting a low Si/Al ratio and Cu content predominantly host isolated $Cu^{2+}$ ions, whereas oxygenated Cu centers are favored at high Si/Al ratio and/or Cu-loading. The latter includes monomeric $[CuOH]^+$ as well as dimeric $[Cu_2(\mu\text{-}O)]^{2+}$ and $[Cu(\mu\text{-}1,2\text{-}O_2)]^{2+}$ species. Compared to Cu-oxo compounds, bare $Cu^{2+}$ active sites are characterized by a slower reaction rate, which is reflected in a shift of the redox activity profile to higher reaction temperatures. Simultaneously, these active centers feature a higher $CH_3OH$-based Cu efficiency and $CH_3OH$ selectivity than their oxygenated counterparts do. This indicates that the high activity of $[Cu_2(\mu\text{-}O)]^{2+}$ and $[Cu(\mu\text{-}1,2\text{-}O_2)]^{2+}$ moieties comes at the expense of material selectivity. The findings (summarized in Figure 1) highlight the influence of the composition on Cu active site speciation, which ultimately determines the material properties in $CH_4$ oxidation.

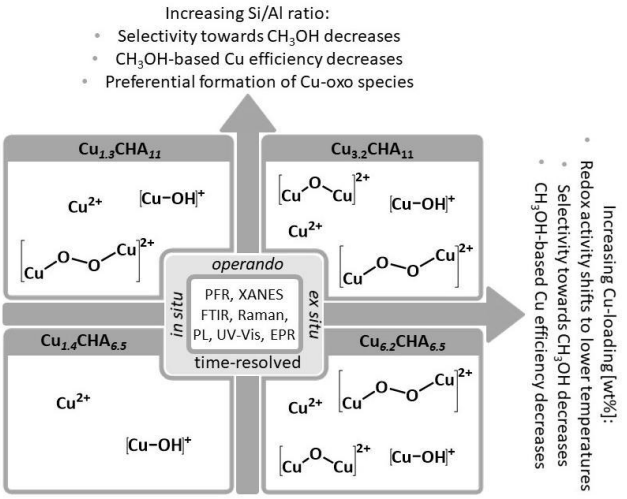

**Figure 1. Cu speciation of different samples as well as the influence of the Si/Al ratio and the Cu-loading on the material behavior in $CH_4$ oxidation.**

**Introduction** The nature of the active site of the industrial $Cu/ZnO/Al_2O_3$ catalysts is still under debate despite 50 years after the discovery. The structures of active Cu-ZnO synergy under working conditions were prevalently reported [1]; however, their roles in the mechanistic aspects are still ambiguous. Moreover, interfacial metal sites such as Ga and In at the periphery of Cu nanoparticles also play a similar role in boosting methanol selectivity over Cu-based catalysts [2].
**Experimental** The copper-based catalysts with single-site promoters ($Cu\text{-}M/SiO_2$, M = Zn, Ga, and In, **Fig 1a**) were prepared precisely via surface organometallic chemistry (SOMC) [3]. *Operando* transient DRIFTS and isotopic transient experiment (SSITKA) have shed light on the roles of surface intermediates and M sites.
**Results and discussion**. All the $Cu\text{-}M/SiO_2$ catalysts proceeed through the same reaction pathways and common formate intermediate on Cu. The M sites at the periphery of Cu particle stabilize formate species spillovering from Cu for faster hydrogenation (weakened C–O bond and strengthened C–H bond). Moreover, the transfered formate from Cu to M sites suppresses its decomposition to CO over Cu, and improves methanol selectivity. Based on significant kinetic isotope effects (KIE), the methanol activation towards formation/desorption to methanol is the rate-limiting step, and there were slight KIE for formate hydrogenation and negligible KIE for $H_2$ dissociation and formate formation.

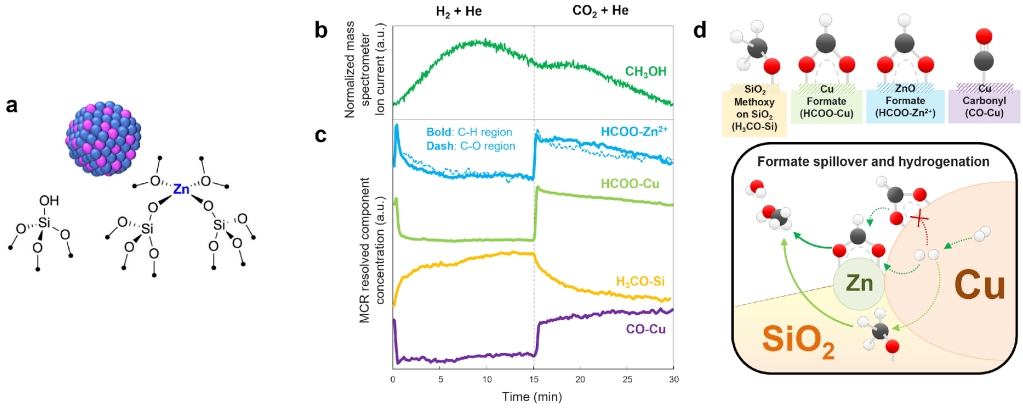

**Fig. 1 a** Structure of $Cu\text{-}Zn/SiO_2$ prepared via SOMC reported elsewhere [3]. Transient responses of surface species and gas products during switching from He + $CO_2$ to $H_2$ + He over $Cu\text{-}Zn/SiO_2$ catalysts at T = 230°C, P = 20 bar, $F_{total}$ = 10 NmL $min^{-1}$: **b** $CH_3OH$ signal from MS. **c** Surface species concentration profiles obtained from multivariate curve resolution (MCR). **d** The proposed reaction pathway for formate hydrogenation via spillover to Zn sites.

The mechanisms proposed for the $Cu\text{-}Zn/SiO_2$ is shown in **Fig 1d**. Overall, formate over Zn is more reactive (higher methanol formation rate), while the formate spillover toward Ga is more facile (higher methanol selectivity). The mechanistic insights from the model $Cu\text{-}Zn/SiO_2$ catalyst unveiled the nature of highly debated Cu-ZnO synergy that plays a crucial role in defining the catalytic activity of the industrial $Cu/ZnO/Al_2O_3$ catalysts. This also highlights the essence of Cu-M interfacial sites in determining selectivity, which is important for the rational design of nano-structured catalysts for selective $CO_2$-to-methanol.

**Keywords:** $CO_2$RR, Ni-based Single atom catalysts, X-ray Absorption Spectroscopy, Machine Learning.

**Introduction.**
In the last decade, Ni and nitrogen co-doped carbons have attracted attention as promising catalysts for the $CO_2$ electroreduction reaction ($CO_2$RR) exhibiting high $CO_2$-to-CO conversion activities, comparable with those of noble metal catalysts [1]. In these systems, N atoms are incorporated in the carbon support forming a binding site for the singly-dispersed Ni species [2]. However, it is worth noting that a large number of different structural motifs can coexist in these systems and evolve during the $CO_2$RR process, making the identification of actual active sites and interpretation of the $CO_2$RR reaction steps difficult to realize experimentally. We addressed this issue by combining *operando* X-ray absorption spectroscopy with advanced data analysis. In particular we show how the combination of unsupervised and supervised machine learning approaches is able to decipher Ni K-edge XANES spectra of these systems, disentangling the contributions of different Ni sites coexisting in the working catalyst. Moreover, thorugh this approach, we obtained quantitative structural information about the local environment of the active Ni species, including their interaction with adsorbates, allowing us to shed more light on the complex dynamic mechanism of the $CO_2$ electroreduction.

**Experimental/methodology.**
*Operando* time-resolved XANES data were used to unveil the local structure around Ni sites in their *as prepared* states, but also under realistic working conditions during $CO_2$RR. A multi-step approach has been used for the interpretation of the collected XANES data. First, we identified the number of different coexisting Ni species, their corresponding kinetic profiles and XANES spectra using unsupervised machine learning methodologies, such as the principal component analysis combined with a multivariate curve resolution technique [3]. In the second step, we deduced the atomistic structures for each of the identified species through a XANES fitting procedure, realized exploiting a supervised machine learning approach [4]. Finally, we validate the predicted structures processing the corresponding EXAFS spectra *via* Reverse Monte Carlo simulations [5], taking into account the structural disorder in the local environment around the identified Ni species.

**Results and discussion.**
Our results confirm that the single Ni sites are the active species for the $CO_2$RR, but also reveal their dynamic, heterogeneous nature and adaptation to the reaction conditions. In particular, our data suggest that the local environment around Ni is directly affected by the interactions between the Ni site and CO adsorbates. We found that the initial state of our catalysts (before the $CO_2$RR), can be represented by a six coordinated model with four planar Ni-N bonds and two axial O atoms. The $CO_2$RR induces a local structural distortion of the Ni site in the N doped carbon matrix, with the progressive substitution of both the O atoms with a CO adsorbate. Overall, these results demonstrate the potential of XAS spectroscopy in combination with advanced data modelling to access an unprecedented level of understanding of a complex multi-component catalytic system, yielding novel insights into the birth of Ni-active sites for the $CO_2$RR reaction.

**Keywords:** Metal Oxide Cluster, Base Catalysts, HERFD-XAS

**Introduction.** Metal oxide clusters consisting of group-V transition metals such as $[M^{V}_{6}O_{19}]^{8-}$ ($M^{V}$=Nb, Ta) have a unique strong base catalyst that is comparable to MgO. They catalyze Knoevenagel condensation reactions and $CO_2$ fixation reactions without being deactivated by molecular adsorption[1]. In this study, we investigated unique molecular adsorption states on $[M^{V}_{6}O_{19}]^{8-}$ by high-energy-resolved fluorescence detection X-ray absorption spectroscopy (HERFD-XAS) which enables direct observation of the crystal field of Nb and Ta correlated with local structural change[2]. We have acquiredHERFD-XANES spectra of Nb K- and Ta $L_3$-edges and successfully observed changes in the crystal field attributed to molecular adsorption for the first time.

**Experimental/methodology.** Tetrabutylammonium salts of $[M^{V}_{6}O_{19}]^{8-}$ were synthesized by a microwave-assisted hydrothermal method in reference to the literature[3] and characterized by infrared spectra and electrospray ionization mass spectra. HERFD-XANES spectra at Nb K-edge was measured with Laue-type X-ray emission spectrometer at SPring-8 BL12XU and Those at Ta $L_3$-edge with Rowland-type X-ray emission spectrometer at SPring-8 BL39XU.

**Results and discussion.** Molecular adsorption states of $[Nb_6O_{19}]^{8-}$ (Nb6) were studied by pre-edge peaks in Nb K-edge HERFD-XANES spectra (Fig.a). When 1% $CO_2$ gas with $N_2$ balance and acid-base indicators as adsorbents were added to Nb6 DMF solution, the intensity of pre-edge peaks in both XANES spectra decreased compared to the pristine Nb6. These results indicate that $CO_2$ and protons adsorbed to the same base sites with an increase in their octahedral symmetry. Ta $L_3$-edge HERFD-XANES spectra (Fig.b) also reflected d-orbital splitting affected by molecular adsorption to $[Ta_6O_{19}]^{8-}$ (Ta6), and the increasement of splitting width of the white line by $CO_2$ adsorption was observed. From comparison with reference samples combined with theoretical calculations, we conclude that Ta6 activated $CO_2$ accompanied with the increase of the octahedral symmetry near the active site of Ta6 (Fig.c).

**Figure (a) HERFD-XANES spectra at Nb K-edge and (b) those at Ta $L_3$-edge. (c) Expected molecular adsorption states.**

**Introduction.** Polypropylene and polyethylene find numerous applications in the household and industry. Currently, only 1% of waste is chemically reprocessed to recover the olefinic building blocks, thus meeting the criteria for a true circular economy. In this context, the process of catalytic decomposition of polymers into value-added products is an important element in meeting the societal challenge of plastic disposal.

Zeolites are some of the most important heterogeneous catalysts in oil refining and petrochemistry. They offer nonpareil properties such as high surface areas, high thermal and chemical stability and finally well-defined topology with uniform micropores hosting numerous and strong acid sites. The confined adsoption of reactants in micropores provides exceptional selectivities in catalytic processes. Uniqe shape selectivity property is often untouched when bulky reactants are involved. The presence of severe diffusion limitations dramatically reduces the catalytic potential of zeolites. Several different approaches concerning their synthesis and modifications have been developed to zeolites with additional meso- and macroporous feature. The synthesis methods are gathered around two main routes: top-down approaches concerning the preferential extraction of silica or alumina from the zeolite structure and bottom-up methods employing templates to synthesize so-called nano-zeolites or embryonic zeolites (EZ). The latter are X-ray amorphous materials, collected in the early stages of zeolite synthesis, but their active sites are more accessible, allowing the conversion of large reactants. Similarly to zeolites wide pores zeolites and the mesoporous counterparts currently employed as the catalysts in oil refining and petrochemistry, the EZ extend the range of applications to the processing of heavy oil fractions and related feedstocks such as polyolefins.

**Methodology.** The catalytic cracking of polypropylene over EZs and purely crystalline counterparts was monitored by *operando* FT-IR coupled with CG-MS to simultaneously measure catalytic activity, product selectivity and deactivation process.

**Results and discussion.** On the EZ, polypropylene produces the lowest $C_3$-$C_4$ (gaseous) and $C_5$-$C_6$ (liquid) fractions but more of the $C_{7+}$ than native H-ZSM-5 catalyst as the lower confinement in micropores inhibites recracking reactions. The textural properties of EZ are responsible for advanced hydrogen-transfer processes resulting in a much higher paraffin (70 %) selectivity. In a sense, EZ-ZSM-5 behaves more like a FAU than an MFI structure. 2D COS IR spectroscopy monitoring of coke formation and combustion highlight the role of silanols in the coke retention. The unique microporosity qualifying EZ as wide pore material allows the efficient contact between reactants (coke and oxygen) due to not restricted the diffusion of oxygen.

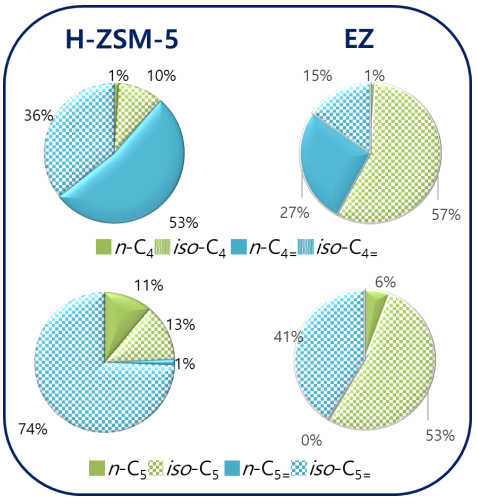

**Fig. 1. Product distribution in $C_4$ and $C_5$ fractions.**

**Keywords:** Metal-organic framework catalyst, metal-ion DNP, solid-state NMR

**Introduction.** Metal-organic frameworks (MOFs) are crystalline porous materials featuring a unique combination of properties, including ultrahigh surface area, structural diversity and adjustability. This renders MOFs a perfect platform for the fundamental understanding of the catalysts and for the rational design of new catalytic solids [1]. The catalytic studies on MOFs rely on a broad spectrum of characterization techniques, and solid-state Nuclear Magnetic Resonance (ssNMR) is of great importance: it provides information on the MOF structure and on the interactions of MOF, as a host, with adsorbed reagents, as guests [2]. Despite considerable success, NMR application is limited by its inherently low sensitivity. It hinders characterization of nuclei present in small quantities (in active sites or in adsorbed reagents), having low natural abundance ($^{13}C$, $^{17}O$, $^{15}N$ etc.) or exhibiting extremely broadened NMR signals (metal nuclei). Significant improvement in NMR sensitivity has been achieved in the last two decades by the introduction of Dynamic Nuclear Polarization (DNP). In DNP we introduce unpaired electrons that possess a 3-4 orders of magnitude higher polarization than nuclei and apply microwave irradiation to transfer this polarization to nuclei of interest and enhance their NMR signal. In standard DNP experiment, the catalyst is impregnated with a solution of organic radicals – *exogenous polarizing agents* (*PA*). Despite its effectiveness, this approach may be destructive for highly reactive active sites and not suitable for studying host-guest interactions, since the pores are filled with the PA solution. An alternative approach developed in our group for energy storage materials characterization is *endogenous metal-ion DNP* (MIDNP), in which paramagnetic metal ions doped into materials structure play the role of PAs [3]. Here, we extend this approach to MOFs with an ultimate goal of facilitating NMR application to MOF-based catalysts and providing new insights on their catalytic properties.

**Experimental/methodology.** To demonstrate the applicability of *endogenous MIDNP* to MOFs, we synthesized a series of samples with the MOF structure and various amount of paramagnetic dopant. The electron spin properties of paramagnetic dopant were characterized by EPR spectroscopy and their efficiency was investigated using commercially available Bruker 400 MHz DNP-NMR system.

**Results and discussion.** Endogenous MIDNP was applied to MOFs for the first time to our knowledge, leading to 30-fold enhancement of NMR signals of MOF linkers, while the pores stay empty for reagents adsorption and the sites present on the pore surface remain intact. Furthermore, we discuss the parameters that affect MIDNP efficiency in MOFs, such as concentration of the PA, the presence of $O_2$ in the pores, the mobility in MOFs, and suggest the optimal conditions for the DNP-enhanced NMR experiments. Overall, our results demonstrate that MIDNP approach is a promising tool for studying catalytically active MOF-based systems and it can potentially be extended to other porous catalytic systems.

**Introduction**

The speciation of a molecular catalyst during turnover contains a wealth of information, including the effectiveness of precursor activation, amount of inactive or dormant states, and population of in-cycle reaction intermediates. Access to this information requires a non-invasive, quantitative *operando* technique that is compatible with the reaction conditions. We have developed a multi-nuclear, high-resolution FlowNMR spectroscopy setup[1] that may analyse air-sensitive homogeneous catalytic systems during turnover under high temperature and pressure conditions in real time to combine reaction progress monitoring (rates & selectivities) with quantitative catalyst tracing in a single experiment.[2]

**Results and discussion**

We will briefly discuss the technique and point out some critical considerations for its effective use,[3] including hardware aspects as well as the importance of flow effects on continuous NMR acquisition.[4] As an example of application, we will present some of our recent work on using this setup to interrogate the industrially relevant hydroformylation reaction of terminal alkenes catalysed by $Rh/PR_3$ catalysts.[5] In addition to demonstrating the difference between *in situ* and true *operando* analysis, we show how the many different catalyst intermediates formed in this dynamic system may not only be observed but even quantified across different reaction conditions to provide catalyst speciation maps[6] that explain the mechanistic origin of ligand effects in this widely used reaction.[7]

# Using NAP-XPS to elucidate when the surface of cobalt and promoted cobalt Fischer-Tropsch catalysts can become oxidised by water

K. L. MacIntosh[1], N. Novruzova[1], A. Zachariou[1], M. Almashnowi[1], E. Olivas[1], A. Marsh[1], S. K. Beaumont[1]*

**Keywords:** Fischer-Tropsch Synthesis; water deactivation; oxidation; cobalt; promoters

**Introduction.** Fischer-Tropsch (FT) chemistry, while originally focussed on producing synthetic fuel, is now rapidly finding itself an attractive prospect for non-fossil derived chemical production from other sources of syngas (waste plastic pyrolysis gas, electrocatalysis with renewables, gasified biomass). One still poorly understood aspect of this important transformation is the extent to which water can cause deactivation.

While bulk oxidation (except in the presence of alumina) doesn't happen thermodynamically [1], and diligent XAFS measurements have shown water doesn't cause bulk oxidation in $Co/SiO_2$ [2], the idea of surface oxidation is still prevalent in the literature, and may play an important role in the design of processes if it is a deactivation pathway [3,4]. The process is also hard to separate in rate measurements from sintering effects that may also be induced by water [5], and further complicated by the well-known different susceptibility of different sized metal particles to oxidation [6,7].

To address this, we have prepared size-controlled nanoparticles of Co (a widely used FT catalyst), tested them for FT activity and investigated their surface oxidation state with NAP-XPS (near ambient pressure X-ray photoelectron spectroscopy) using Diamond Light Source's capabilities to go to high mbar pressures of water. Being a surface sensitive technique (in contrast to bulk techniques employed in other studies) allows us to elucidate the impact of water on the reoxidation of FT catalysts' surfaces.

**Experimental/methodology.** Small (3 nm) and large (9 nm) colloidal nanoparticles were prepared by decomposition of $Co_2(CO)_8$ as reported elsewhere [9]. Some samples were modified by the addition of a precious metal promotor. These were tested in a fixed-bed reactor after deposition on $SiO_2$ or used for NAP-XPS after deposition at sub particle-monolayer coverages on a Si wafer. Samples were oxidised and reduced *in situ* at the B07 endstation, then exposed to increasing pressures of water.

**Results and discussion.** Typical cobalt samples prepared are shown in Figure 1. Catlaytic tests confirmed the expected results from literature that large particles were more active than small particles (only the larger particles show conversion of CO (7.9 ± 1.1 %) at 200 °C, and the addition of precious metal promotor increases conversion. After *in situ* reduction in the NAP-XPS system both pure cobalt samples could not be oxidised by 5mbar water, however oxidation did occur in the presence of water for the precious metal promoted sample (Figure 2). This is a striking result as precious metals are typically added to promote reduction, but here also appear to promote oxidation by water.

**Keywords:** Raman spectroscopy, Operando, Layered materials, Liquid phase characterization.

**Introduction.**

The development of new catalysts for biomass conversions induces new demands on the materials as reactions are often carried out in the liquid phase, catalysts should be water tolerant and allow sufficient access of the reagents to the active sites because derivatives from biomass often involve the transformation of large substrates such as saccharides or diols [1]. These constraints on the catalysts imply that they should also be characterized in similar conditions. However, unlike reactions in the gas phase, the operando characterization of catalysts is rarely undertaken in the liquid phase and adequate methodologies for such characterization still need to be developed.

**Experimental/methodology.**

Operando Raman spectroscopy has thus been used here to evaluate layered catalysts for the conversion of diols. Diols can be used as a representative model reactant, and we showed recently that acidic layered materials $HNbMoO_6$ and $HNbWO_6$ were efficient catalysts for 2,5-hexanediol cyclodehydration to 2,5-dimethyltetrahydrofuran in liquid phase [2,3]. Niobate layered materials will be compared here with their tantalate equivalents $HTaMoO_6$ and $HTaWO_6$, working at different temperatures in a batch autoclave adapted for simultaneous Raman measurements.

**Results and discussion.**

In a first stage, Raman spectroscopy was used to evaluate and compare the acidity of the solids by adsorption of a liquid probe molecule. Then, operando Raman was specifically carried out in liquid medium to monitor both the reactant intercalation and its effective reaction on the layered materials. Raman spectroscopy then allows to determine the conversion and reaction parameters, through the use of the reactants and products specific bands, but also to follow the evolution of the solid catalysts in the course of the reaction. For each of these Raman characterization stages, adequate spectroscopic analysis methodologies were developed.

The layered materials proved to be efficient catalysts for the transformation of the 2,5-hexanediol polyoxygenate without any preliminary thermal activation step. The tantalates appear less active than the niobates while molybdates are more active than tungstates. Differences in acidity do not account for these different activities. Nevertheless, the chemical changes in the materials composition are also accompanied by changes of the interlayer spacing affecting at the same time the intercalation of the diol. Our results point out the importance of the ability of the material to accommodate the reactant between its layers and its large influence on their reactivity.

# Nanoscale Chemical Diversity of Coke Deposits on Metal Nanocatalysts Visualized by Tip-Enhanced Raman Spectroscopy

M. Filez,[1,2] C. Detavernier,[2] H. Uji-I,[3] M. B. J. Roeffaers[1,*]

[1] *cMACS group, KU Leuven, Leuven, Belgium*
[2] *Conformal Coating of Nanomaterials group, Ghent University, Ghent, Belgium*
[3] *Division of Molecular Imaging and Photonics, KU Leuven, Leuven, Belgium*
**maarten.roeffaers@kuleuven.be*

**Introduction.** Coke formation is a prime cause of catalyst deactivation.[1] During hydrocarbon conversion, non-selective side reactions occur which lead to the formation of undesired carbonaceous products. These species eventually anchor on the catalyst surface as carbon deposits, i.e. 'coke', which block the active sites and inhibit further reaction.[2] To regenerate coked catalysts, high-temperature $O_2$ calcination treatments are applied to burn coke deposits[3,4] into $CO_2$ and $H_2O$, thus further accelerating climate disruption.

To increase process efficiencies and remediate our environment, next generation catalysts need to be designed which prevent coke formation. Yet, foundational knowledge gaps still exist on the origins of coke formation, thus not offering rationally-guided concepts to redesign today's catalysts.[5] The missing key for knowledge build up is the lack of nanoscale characterization tools which can chemically identify coke very locally at the catalyst surface, to elucidate their origin and link their nature to the catalyst structure.

**Methodology.** Here, we apply tip-enhanced Raman spectroscopy (TERS) as a nanoscale chemical probe to identify and localize the coke species on a post-mortem model metal catalyst (Fig. 1a). Therefore, axially-aligned Pt nanorods ($l$ x $w$ x $h$ = 200 x 10 x 10 nm$^3$, Fig. 1b) supported on $SiO_2$ are exposed to a 15 min $C_3H_8$ flow to perform propane dehydrogenation reaction ($C_3H_8$ = $C_3H_6$ + $H_2$ + coke), leading to coke deposition.

Applying conventional TERS on such relevant metal-oxide supported catalysts is very challenging – if not unfeasible – since no sufficient Raman enhancement is obtained in the gap between the plasmonic tip and the insulating support.[6] Here, this issue is overcome by using specialized Ag nanowire tips: by cutting the tips, a spherical apex is generated which contains nanoscale defects that inherently boost plasmonic enhancement, independent of the nature of the support. This approach enables first-of-its-kind nanoscale metrology of coke deposits on relevant model metal catalysts, with 20 nm spatial resolution.

**Results and discussion.** An exemplary TERS spectrum collected at one surface location of the coked Pt/$SiO_2$ catalyst shows a diversity of Raman peaks, directly proving the rich chemical diversity of coke deposits at the nanoscale (Fig. 1c). The local TERS enhancement yields very sharp peaks, enabling unparalleled coke characterization compared to conventional bulk Raman spectra. Three classes of carbon-based materials can be distinguished: (I-orange) nanocrystalline graphite built-up of ordered, 2D-stacked graphene layers, (II-red) amorphous sp$^2$-bound carbon, and (III-green) C-rich polymeric carbons, all having different origins.

Clustering analysis allows to sort the hyperspectral TERS map into three zone with different averaged spectral features (Fig. 1d): (A-blue) Pt lines with high coke concentration of high disorder, (B-yellow) an off-Pt zone with intermediate coke concentration and medium disorder, and (C-green) a support with low coke concentration and relatively ordered graphite. This analysis suggests that disordered coke species formed on Pt spill over to the support where they react and grow into more ordered, graphitic coke. This approach paves the way to fundamental knowledge build up on deactivation by coke and smart catalyst redesign.

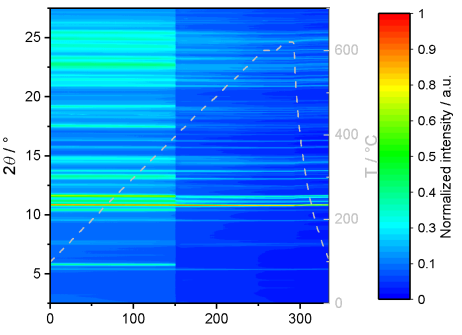
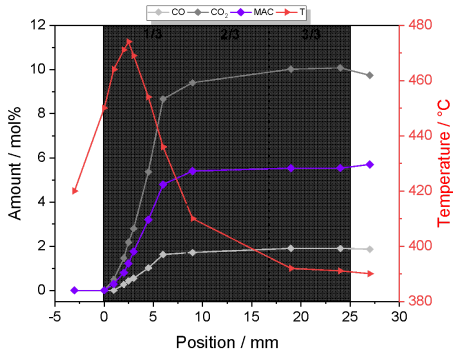
# Monitoring the structural evolution of multicomponent catalysts for selective olefin oxidation by complementary *operando* techniques



Linda Klag[1], Thomas L. Sheppard[1,2], Jan-Dierk Grunwaldt[1,2*]



[1]*Institute for Chemical Technology and Polymer Chemistry (ITCP), Karlsruhe Institute of Technology, 76131 Karlsruhe, Germany* [2]*Institute of Catalysis Research and Technology (IKFT), Karlsruhe Institute of Technology, 76344 Eggenstein-Leopoldshafen, Germany* [*]*grunwaldt@kit.edu*

**Introduction.** Selective oxidation of olefins is a key reaction in chemical industry, leading to important intermediates and various products.[1] These include selective propylene and isobutene oxidation to acrolein and methacrolein, respectively, both typically catalysed by bismuth molybdate based multicomponent systems.[2] Such catalysts exhibit a complex phase ensemble, forming composites of selective, active, promoting and inert phases.[3] However, the role of individual (mixed) metal oxide phases and their interaction is still in its infacy and strongly discussed.[4,5] To close the knowledge gap between functionality of model systems (*e.g.*, Bi-Mo-O) and industrially-applied catalysts (*e.g.*, Bi-Mo-Fe-Co-W-K-Si-O), studying Bi-Mo-Co-Fe-O as a 4-component system is very promising, as it provides a suitable representation of complex metal oxide phase mixtures and superior catalytic performance.[6] Since catalyst performance is highly sensitive towards *e.g.* synthesis conditions, we investigate the influence of preparation method and elemental composition on catalyst activity and selectivity. Advanced synchrotron *operando* techniques are crucial to monitor the dynamic and synergistic interplay of the various phases of the catalyst in its working state. As this affects several time and length scales, we present both integral and spatially-resolved insights into structure and activity of such 4-component Bi-Mo-Co-Fe-O catalysts.

**Experimental/methodology.** Bi-Mo-Co-Fe-O catalysts differing in promotor content were prepared by flame spray pyrolysis (FSP) and hydrothermal synthesis (HTS). Catalysts were tested for several days on stream at different oven temperatures and WHSVs (70/14/8/8 % $He/O_2/C_nH_{2n+2}/H_2O$ ; n = 3, 4). Catalyst characterization was performed by complementary synchrotron-based *operando* XRD (BM01, ESRF, Grenoble, FR), XAS (ROCK, Soleil, Saint-Aubin, FR), and Raman spectroscopy to cover both crystalline and amorphous phases. Moreover, we performed spatially-resolved characterization with (simultaneous) acquisition of spatially-resolved activity and temperature profiles.

**Results and discussion.** Both preparation methods and elemental catalyst composition of Bi-Mo-Co-Fe-O directly influenced catalytic performance. This could be explained by the formation of various metal oxide phases regarding the inital catalyst state, leading to different phase (trans-) formations upon catalyst activation as seen by *e.g.* synchrotron XRD (Fig. 1). For the FSP catalysts, an Mo content of ≥ 50 mol% resulted in high, controllable activity and high selectivity to acrolein or methacrolein. Conversely, lower Mo content led to extremely active catalysts and strong hot-spots in the catalyst bed (Fig. 2). Finally, direct comparison of phase evolution during selective propylene and isobutene oxidation allowed to gain general conclusions on structure-activity relations and thus a more profound understanding of the working principles of such complex catalyst systems.

# Critical Role of Water in Preferential Carbon Monoxide Oxidation over Pt-Fe Catalysts: Operando XAS/DRIFTS Approach

Ilia I. Sadykov[1,2], Frank Krumeich[2], Dennis Palagin[3], Davide Ferri[1], Igor V. Plokhikh[1], Jeroen A. van Bokhoven[2,1], Maarten Nachtegaal[1], and Olga V. Safonova[1]*.

**olga.safonova@psi.ch*

**Introduction.** Water accompanies hydrogen production and purification via the main industrial routes, such as the reforming of hydrocarbons and the water-gas shift reactions.[1] Highly efficient preferential carbon monoxide oxidation (PROX) is vital for the purification of hydrogen from the traces of poisonous carbon monoxide. Water strongly affects PROX Pt-Fe catalysts but the nature of its action remains unclear.

**Experimental/methodology.** In this work, we were able to decipher the water effect on the reactivity of supported Pt-Fe PROX catalysts using operando X-ray absorption spectroscopy and operando diffuse reflectance infrared Fourier transform spectroscopy (DRIFTS) coupled with in-line mass spectrometry following catalytic state, conversion, and selectivity of active sites in real-time.[2]

**Results and discussion.** Our work shows that the addition of water both during the reduction pretreatment of the catalysts at high temperatures and during the catalysis is beneficial and can lead to a significant increase in carbon monoxide conversion preserving high selectivity. We found that pretreatment of Pt-Fe catalysts under the 98 vol.% $H_2$ – 2 vol.% $H_2O$ (hydrogen-steam) gas mixture up to 473 K and the direct addition of water into the reaction mixture enables to achieve the highest activity among reported Pt-Fe catalysts.

The kinetic experiments, including those with $^{18}O$-labeled water, in combination with operando DRIFTS (**Figure 1**), show that water hydroxylates the redox-active iron phases during high-temperature pretreatment in the hydrogen-steam mixture. This pretreatment creates active iron-associated hydroxyl groups with enhanced reactivity towards carbon monoxide chemisorbed on platinum nanoparticles.

A quantitative correlation between the catalytic activity of Pt-Fe/γ-$Al_2O_3$ catalysts and $Fe^{2+}$ concentration, obtained using operando X-ray absorption spectroscopy,[2] shows that the number of carbon monoxide molecules converted per each individual active $Fe^{2+}$ site increases after the reduction pretreatment in the hydrogen-steam mixture. Density functional theory (**Figure 1**) provides a model demonstrating that hydroxylation of oxidic iron species stabilizes the $FeO_x(OH)_y$/Pt interface. Hydroxyl groups bound to redox-active iron constitute active sites (**Figure 1**), allowing ambient temperature selective catalytic oxidation.

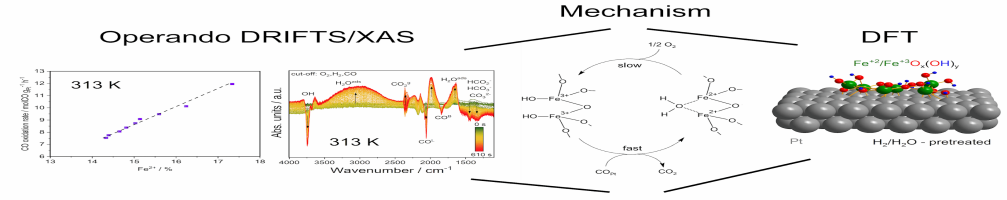

Figure 1. The results of operando XAS/DRIFTS experiments with steam-activated Pt-Fe/γ-$Al_2O_3$ catalyst, the proposed mechanism of PROX reaction, and the DFT model of the active $FeO_x(OH)_y$/Pt interface.

# Tracking catalyst structures from synthesis to reaction via pair distribution function on a Ag@H-BEA zeolite

F. Müller*, N. Simitsis[2], R. Palkovits[2], M. Zobel[1]

[1]RWTH Aachen University, *Institute of Crystallography, Aachen, Germany*

**Keywords:** PDF, Beta Zeolite

**Introduction.**
For sustainable catalysis and in light of changing feedstocks to renewable sources, novel catalytic systems are required. We have designed an Ag@H-BEA bifunctional catalyst system for the selective synthesis of dimethoxymethane by non-oxidative dehydrogenation of methanol, based on the synthesis of Cu@H-BEA [1]. To tackle the structure-activity-correlation of Ag loading of 1 to 20 wt% and catalyst pretreatments (calcination, reduction) with catalytic activity, structural insight into the nature of the active sites, the structure of the support and its relation to the activity of the overall catalytic system are vital. The pair distribution function (PDF) is able to provide this access into both the short-range order and local structure of the zeolite and the supported Ag nanoparticles.

**Experimental/methodology.**
The atomic PDF is a histogram of all interatomic distances in the sample, calculated from high energy X-ray scattering data. The PDF is well suited to structurally characterize non-crystalline, disordered and nanostructured materials beyond common crystallographic approaches. Further, occupancies or thermal motion, as well as local coordination environments and nanoparticle diameter can be refined in the PDF [2]. Having pushed the quality of laboratory PDF data in recent years on diffractometers [3], we can now achieve detailed insight into supports and active species of heterogeneous catalysts in our laboratory. [4] Here, we employ a STOE STADI P powder diffractometer in transmission geometry, using monochromatic Ag $K\alpha_1$ radiation and a MYTHEN2 4K detector.

**Results and discussion.**
Our XRD and PDF results show that the H-Bea zeolite structure is affected by Ag loading and treatment conditions, such as reducing atmosphere. The active species can be described as Ag fcc nanoparticles. The zeolite features rather low crystallinity and undergoes increasing restructuring, the higher the Ag loading, reflected in splitting of few Bragg peaks. Structural refinements of the zeolite show an increase of the average domain size from about 3 nm for the unloaded zeolite to about 4 – 5 nm for the reduced and spent catalysts. Further we correlate pore sizes in PDF and $N_2$-physisorption analysis.
Hereby, we show that a rational design of future catalysts crucially depends on characterizing the evolution of catalyst structures from synthesis via reaction to spent state with advanced scattering techniques.

**Keywords:** methanation reaction, SSITKA, transient CO hydrogenation-DRIFTS, Co/γ-$Al_2O_3$.

**Introduction**

Fischer-Tropsch synthesis (FTS) is regarded as one of the most effective and key technologies to assist in future decarbonization of various industries by utilizing syngas derived from renewable feedstocks. SSITKA is established as one of the most advanced kinetic techniques to quantify the composition of adsorbed phase (surface coverage, θ) of active reaction intermediates, and to estimate rate constants of individual elementary reaction steps on a working catalyst surface via microkinetic modeling of rival mechanisms [1]. Also, SSITKA-DRIFTS determines the chemical structure of active and inactive reaction intermediates [1]. The present work established a powerful protocol based on SSITKA-Mass Spectrometry, SSITKA-DRIFTS, and transient CO-DRIFTS hydrogenation coupled with kinetic modelling to further promote fundamental understanding of the $H_2$ pressure effect on important kinetic parameters of mainly the methanation reaction at 230 °C and 1 atm on a commercially relevant Co/γ-$Al_2O_3$, and in particular that of $\theta_H$, for the first time [1].

**Experimental/methodology**

The step-gas concentration switch 5 vol% $^{12}CO$/x vol% $H_2$/Ar (5 h, 230 °C) ⟶ 5 vol% $^{13}CO$/x vol% $H_2$/1 vol% Kr/Ar (t) (x = 10-50) at the entrance of a microreactor was applied ($X_{CO}$ < 20%), followed by 3-min Ar purge, transient isothermal hydrogenation (TIH, 50% $H_2$/Ar, 7 min), and temperature-programmed hydrogenation (TPH). Transient CO hydrogenation - DRIFTS with kinetic modelling, and SSITKA-MS were used to esimate the dependence on $P_{H2}$ of the $\theta_H$ and site hydrogenation activity ($k_{eff}$) of the two linear-types adsorbed CO-s [1].

**Results and discussion**

The surface coverages (θ) of reversibly adsorbed CO-s and active -$CH_x$ ($C_\alpha$) were found to be influenced slightly only by $P_{H2}$, as opposed to the θ of inactive carbonaceous species, hydrogenated at 230 °C to $CH_4$ (under TIH), named $C_\beta$ (-$C_xH_y$) - "soft carbon", and those hydrogenated at T > 230 °C (TPH), named $C_\gamma$ ($C_{\gamma1}$-$C_{\gamma3}$) - "hard carbon" (**Fig. 1A**). A large influence of $P_{H2}$ was also observed on: (i) $TOF_{CO}$ and $TOF_{CH4}$ ($s^{-1}$); (ii) the effective rate constant of $CH_x$-s hydrogenation ($k_{eff}$=k$\theta_H$), and (iii) the mean lifetime of adsorbed CO ($\tau_{CO,}$ s) and $CH_x$ ($\tau_{CHx}$). Transient exchange rate profiles (μmol $g^{-1}$ $s^{-1}$) of active $^{12}CH_x$-s for $^{13}CH_x$-s were estimated for the first time (**Fig. 1B**), as an additional descriptor parameter of SSITKA, aiming to provide fundamental understanding of the mechanism of methanation reaction without kinetic modelling. A shoulder becomes evident when $P_{H2}$ increases, result that supports the existence of more than one kind of $CH_x$-s hydrogenated to $CH_4$, and linked to chain-growth [1]. SSITKA-DRIFTS followed by TIH (**Fig. 1C**) and coupled with kinetic modelling, highlighted the $k_{eff}$ dependence on $P_{H2}$ for each of the two linear-types adsorbed CO-s identified (after IR band deconvolution). The influence of $P_{H2}$ on $\theta_H$ was establish for the first time (**Fig. 1D**). The increase of $\theta_H$ ($P_{H2}$=600 mbar) by a factor of ~ 4.5 relative to that at the lowest $P_{H2}$ (120 mbar) was used to explain the variation of $TOF_{CH4}$ and $k_{eff}$ with $P_{H2}$ [1].

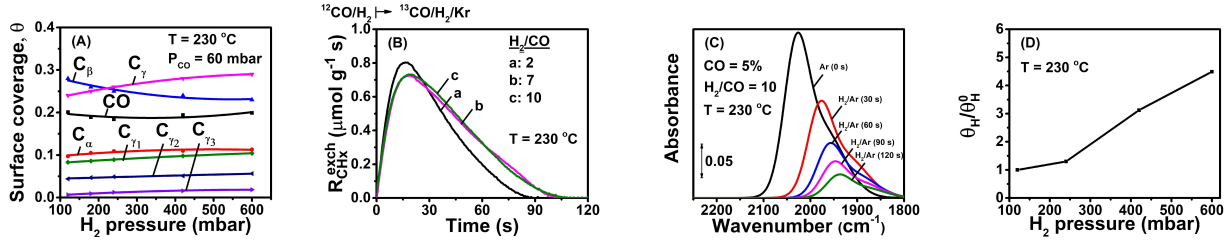

**Fig. 1: (A) Surface coverages of *active* CO-s and $CH_x$-s ($C_\alpha$), and of *inactive* $C_\beta$ and $C_\gamma$ (sum of $C_{\gamma1}$, $C_{\gamma2}$, $C_{\gamma3}$); (B) Dynamic evolution of the transient rate (μmol $g^{-1}$ $s^{-1}$) of $^{12}CH_x$-s exchange; (C) CO-DRIFTS spectra recorded in Ar and 50% $H_2$/Ar gas flow; (D) Dependence of $\theta_H$ (at $P_{H2}$) with respect to the reference $\theta^0_H$ (at $P_{H2}$=0.12 bar) on $P_{H2}$.**

**Keywords:** Photocatalysis, APXPS, Photo-ALD, solar simulator.

**Introduction.** Processes driven by solar radiation play a crucial role in life on Earth. Nowadays, replacing fossil fuels with clean and renewable energy sources is one of the most important challenges for modern human civilization. Natural photoassisted solar reactions can convert solar energy into usable chemical energy by driving reduction and oxidation processes via generation of electrons and holes, respectively, upon irradiation of the photocatalyst. Photo-assisted atomic layer deposition (Photo-ALD) is a less studied approach to facilitating selective area ALD. ALD is an extremely versatile thin film deposition process that is currently used in many steps within the microelectronics process flow and is also attracting increasing interest in other industrial areas.

**Experimental/methodology.** The APXPS endstation at SPECIES beamline at MAX IV is designed to perform in-situ and operando XPS experiments in a controlled atmosphere at pressures up to 20 mbar [1]. Research areas of interest include catalysis, material and surface sciences, environmental chemistry, and atomic layer deposition. However, there is a lack of APXPS studies that pair synchrotron light with external light sources. Here we will introduce and discuss the use of solar irradiance with APXPS cells and provide a series of scientific case studies that serve to illustrate the usefulness of the concept.

**Results and discussion.** One such scientific case is hydrogen production via water splitting sunlight is used to induce a photocatalytic reaction at a photoactive surface. We study pristine Ni@NiO/$NiCO_3$ core-shell nanostructures as photocatalysts and characterize their post-annealing variants. During illumination, it was observed that the metallic Ni peak vanishes, and the new peak appeared that we've assigned to NiOOH. However, no changes were observed in the Ni 2p peaks from NiO and/or $NiCO_3$.

Another example lies in an under-utilized technique called photo-ALD which allows spatially selective ALD to be carried out. Herein, we tested the photo-ALD set-up using a hafnium tert-butoxide ($Hf(OtBu)_4$) precursor and UV light to produce $HfO_2$ on a Si (100) wafer. Throughout the deposition, XPS was recorded with time-resolved snapshot mode tracking a series of pertinent core-levels every 15 s. Results show HfOx is being formed during the UV pulse.

In summary, the APXPS endstation at SPECIES beamline has two ambient pressure cells, a standard cell for catalysis, redox chemistry, etc. and an ALD cell for ALD research. Solar simulator and UV-lamp can be used with both cells, as we've demonstrated. These combinations provide a unique platform to conduct experiments to study the electronic structure of matter under IR/visible/UV radiation and at different pressure ranges and gas mixtures.

**Keywords:** copper zeolites, partial methane oxidation to methanol, site-selective & operando spectroscopy

**Introduction.**

Cu-exchanged zeolites are promising candidates for a mild, selective oxidation of methane to methanol, which is a major goal of modern chemistry [1]. Three zeolite topologies are particularly promising and have dominated literature since 2005: MFI, MOR and CHA. In the past, our group managed to identify and characterize a mono-(μ-oxo) dicopper(II) species ($[Cu\text{-}O\text{-}Cu]^{2+}$) in MFI [2] and two slightly different $[Cu\text{-}O\text{-}Cu]^{2+}$ species in MOR [3] as active sites at temperatures around 423-473 K. Recently, we added two new active sites to this catalogue of fully characterized active sites.

**Experimental/methodology.**

After ion exchange with copper(II) acetate and calcination, the copper-zeolites were autoreduced in helium at elevated temperatures, activated with $N_2O$ or $O_2$ and reacted with methane at 473 K. Active site characterization occurred via a combination of DR-UV-Vis, in-situ resonance Raman (rR) , EPR, MCD and XAS spectroscopies. Kinetic parameters of the active site for methane oxidation were obtained by operando UV-Vis. DFT models (B3LYP) were constructed in agreement with the spectroscopic and kinetic results.

**Results and discussion.**

First, in Cu-CHA zeolites, we fully characterized a $[Cu\text{-}O\text{-}Cu]^{2+}$ that is present after activation with $N_2O$ or $O_2$ [4]. This species exhibits a clear absorption band around 22400 $cm^{-1}$ in the DR-UV-Vis spectra, which decays upon methane reaction. An analysis of resonance Raman vibrations and their $^{18}O$ isotope shifts obtained after activation with $^{18}O_2$ was key in revealing the $[Cu\text{-}O\text{-}Cu]^{2+}$ structure.

Second, in Cu-MOR zeolites, we elucidated a $[CuOH]^{+}$ active site that is characterized by a broad $OH^{-}$ to Cu(II) charge transfer band at 20700 $cm^{-1}$, a $g_{\|}$ = 2.27 feature in EPR and a Cu-O stretch of 750 $cm^{-1}$ in resonance Raman ($\Delta^{18}O$ = 35 $cm^{-1}$) [5].

This catalogue of active sites in Cu-MFI, Cu-MOR and Cu-CHA allowed us to compare their reactivity in methane oxidation by monitoring the decay of the characteristic absorption bands of $[CuOH]^{+}$ and $[Cu\text{-}O\text{-}Cu]^{2+}$ during reaction with methane. This revealed three key elements that determine reactivity: zeolite confinement influencing methane adsorption [6], lattice-imposed geometrical constraints reminiscent of the entatic state concept in metalloprotein chemistry [4] and higher metal nuclearity leading to delocalization of the electron gained in the hydrogen atom abstraction step and increasing reactivity.

These principles could open up new applications that require lower reaction temperatures, such as the ambient capturing of $CH_4$ as a negative emission technology. Additionally, these structure-reactivity relationships are more generally applicable to redox catalysis over transition metal ion exchanged zeolites.

**Keywords:** copper zeolites, methane oxidation, methanol, methane coupling, in situ MAS NMR, MTH, MTO.

**Introduction.** The transformation of methane to valuable chemicals at small-scale levels is an attractive strategy for valorization of abundant, yet currently underutilized natural gas resources. Direct methane oxidation to methanol via chemical looping over copper-containing zeolites is considered as a promising process [1-2]. Previously, we demonstrated that apart from methane partial oxidation to methanol, C-C coupling takes place in the course of methane conversion over copper-containing zeolites at elevated temperature leading to formation of $C_2$+ hydrocarbons [3]. In the current work, we applied *in situ* MAS NMR spectroscopy to identify the mechanism of the formation of higher hydrocarbons.

**Experimental/methodology.** Different reaction pathways may lead to the C-C bond formation: i) the direct coupling of methane over copper (I) sites ii) the methanol-to-hydrocarbon (MTH) pathway, in which methanol formed by methane oxidation over copper(II)-oxo sites subsequently transforms into hydrocarbons and iii) the Koch carbonylation of the methanol or methoxy species with carbon monoxide into methyl acetate and its further conversion [3-5]. To differentiate the various possible mechanisms, we investigated the conversion of different mixtures containing $^{13}$C-labelled and nonlabelled reactants over copper-containing mordenite and traced $^{13}$C isotope label in products.

**Results and discussion.** Figure 1 summarizes the reaction network observed for transformation of methane and its partial oxidation products over copper-containing mordenite. Methane reaction with copper(II)-oxo sites yields partial oxidation products, namely methanol, methoxy species, and dimethyl ether. At elevated reaction temperature the partial oxidation products may undergo further transformations. Thus, the MTH process can take place, where conversion of methoxy species over acid sites leads to the formation of methylsubstituted cyclopentenyl cations, which form the hydrocarbon pool working as co-catalyst in methanol transformation to hydrocarbons. In the presence of carbon monoxide, methoxy species are transformed into surface acetates via the Koch carbonyation reaction. The acetates themselves are converted into methylsubstituted benzenes at elevated temperature, forming another type of hydrocarbon pool as compared to the pure methanol conversion. Specific adsorption of methane over copper (I) takes place, however, no further transformation of this complex to $C_{2+}$ hydrocarbons was observed up to 773 K.

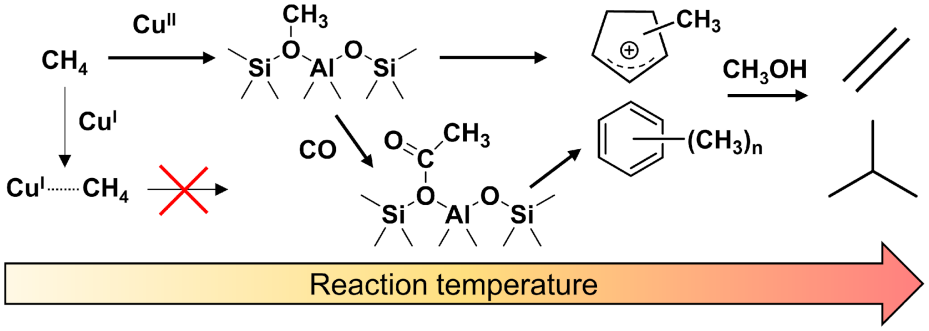

**Figure 1. Chemical transformation observed in the course of methane conversion over oxygen-activated copper-containing mordenite**

The study provides the mechanism of methane partial oxidation and MTH reactions at the molecular level and demonstrates a possibility to combine the mentioned processes over multifunctional copper-containing zeolitic materials, thereby offering attractive eventual route for methane valorization.

**Keywords:** Methanol-to-olefins, zeolites, operando spectroscopy

**Introduction.** The methanol-to-olefins (MTO) process will be a green alternative for the olefins and fuel industry of the future. Notoriously the reaction pathway involves the formation of hydrocarbon species that operate as active sites in the so-called hydrocarbon pool (HCP) mechanism.[1] Olefins and aromatic hydrocarbons represent the main two classes of molecules that can convert methanol within the respective catalytic cycle through consecutive methylation and cracking/dealkylation steps upon mediation of Brønsted acid sites of zeolites.[2] Quantitative correlations between olefins and active centers in the HCP are often drawn through $^{13}C$ labelling and laborious extraction of retained species post-reaction. Here we have developed an operando IR spectroscopy approach with transient MeOH flow that allows identification of active carbenium ions which correlate linearly with olefins for three representative zeolite topologies.

**Experimental/methodology.** We have employed diffuse reflectance IR spectroscopy (DRIFTS) and a custom-built flow reactor cell that ensures isothermal operation by design and probing of the catalyst along the vertical cross section of the bed.[3] Methanol was modulated asymmetrically through an automatic switching valve system synchronized with micro-GC sampling: this was done by alternating a short section of methanol flow with a longer period in which the catalyst was exposed solely to an inert Ar flow, in a cyclic manner. Within the second step of the cycle weakly adsorbed molecules are removed leading to IR spectra free of non-desirable absorption peaks which can hinder their interpretation. ZSM-5 (MFI), SSZ-13 (CHA) and Ferrierite zeolites with similar Si/Al ratio (~11) were employed.

**Results and discussion.** We identified different carbenium species by their features in the ν(C=C) region of the IR spectrum in the three zeolites. In Ferrierite we report a limited formation of bulky aromatics in favor of acyclic alkyl cations along with the production of higher olefins ($C_{4+}$; GC), while methylated benzenium ions and alkylated cyclopentenyl species are identified in the three dimensional 10-membered ring channels system of ZSM-5 and in SSZ-13, featuring small 8-membered ring pores and large cages. In the last two cases only the former species, which grows following the S-shaped kinetics typical of MTO, quantitatively correlates with short olefins formation. The presented method applied to the MTO process provides a desirable perspective on the evolution of hydrocarbon species residing in zeolite micropores and those produced during the first stage of the reaction. It also clarifies the topology-dependent relationship between nature of active sites and selectivity that could help to control product selectivity.

# The role of $MnO_x$ and alkali metals in $MnO_x$-M(Na, K, Rb, or Cs)$_2WO_4/SiO_2$ for product formation in oxidative coupling of methane

A. Zanina[1], V. A. Kondratenko[1], H. Lund[1], E.V. Kondratenko[1*]

**Keywords:** oxidative coupling of methane, in situ characterization, active sites, alkali metals

**Introduction.** $MnO_x$-$Na_2WO_4/SiO_2$ is one of the best-performing catalysts in the oxidative coupling of methane (OCM) to $C_2H_6/C_2H_4$ ($C_2$-HC). Despite numerous studies with this system, many fundamental aspects (mechanism, active sites, oxygen species, etc.) remain poorly understood. Against this background, we combined in situ catalyst characterization with sophisticated kinetic analysis including surface intermediates to clarify the roles of alkali metal (AM) (M=Na, K, Rb, or Cs) and $MnO_x$ in bimetallic ($M_2WO_4/SiO_2$) and trimetallic ($MnO_x$-$M_2WO_4/SiO_2$) catalysts and to determine the kind of oxygen species involved in selective and unselective pathways.

**Experimental/methodology.** ($MnO_x$)-$M_2WO_4/SiO_2$ catalysts were prepared via an incipient impregnation method and characterized by various techniques including in situ XRD analysis and in situ UV-vis spectroscopy. Steady-state catalytic tests were performed at different degrees of $CH_4$ conversion. They were complemented by steady-state isotopic transient kinetic analysis (SSITKA), temperature-programmed oxygen isotopic exchange, and temporal analysis of products.

**Results and discussion.** The catalytic tests with M(Na, K, Rb, or Cs)$_2WO_4/SiO_2$ with or without $MnO_x$ showed that high selectivity to the desired ($C_2H_6/C_2H_4$) products can be achieved over any catalyst, regardless of the kind of alkali metal and the presence of $MnO_x$. The Mn-containing catalysts revealed higher rates of $CH_4$ conversion than the Mn-free catalysts. The activity of the former did not obviously depend on the kind of AM, while an effect was established for $M_2WO_4/SiO_2$. $CH_4$ pulse experiments with and without oxygen demonstrated that lattice oxygen of $M_2WO_4/SiO_2$ is not capable of $CH_4$ conversion into $C_2$-HC. In contrast, these products were formed over $MnO_x$-$M_2WO_4/SiO_2$. For both systems, the activity is enhanced in the presence of adsorbed oxygen species formed from gas-phase $O_2$. Importantly, monoatomic and diatomic adsorbed oxygen species were concluded to contribute to the formation of $C_2$-HC and $CO_2$, respectively. The ability of $M_2WO_4/SiO_2$ to generate adsorbed species is affected by the electronic properties of AM [1].

Figure SEQ Figure * ARABIC 1. Transient responses of $H_2{}^{18}O$ (a) and $C^{16}O^{18}O+C^{18}O_2$ (b) over $MnO_x$-(Na, K)$_2WO_4/SiO_2$.

SSITKA experiments were instrumental to understand the origin of the enhancing effect of $MnO_x$ on the overall catalyst activity (Figure 1). The presence of $MnO_x$ does not result in higher number of active sites/species but increases their reactivity in comparison with $MnO_x$-free catalysts. Moreover, it was shown that the formation of water is slower than the formation of carbon dioxide. This result suggests that the rate-limiting step can be not the abstraction of C-H bond but the regeneration of catalytically active sites through water formation.

In conclusion, involvement of adsorbed oxygen species in $C_2$ formation was found to be essential for $M_2WO_4/SiO_2$. Efficiency of oxygen activation depends on electronic properties of alkali metals. While the participation of both lattice and adsorbed oxygen (Langmuir-Hinshelwood and Mars-van Krevelen mechanisms) was determined for $MnO_x$-$M_2WO_4/SiO_2$. According to the SSITKA results, $MnO_x$ has the role of a promoter. No substantial effect of an alkali metal in the trimetallic composition could be confirmed.

**Introduction.** Molybdenum supported in zeolite H-ZSM-5 (Mo/HZSM-5) is one of the most effective catalysts for direct conversion of methane to aromatics through methane dehydroaromatization (MDA). The initial steps of the MDA reaction take a Mo-oxo species and form carbidic- and oxycarbidic-Mo in the presence of methane. While it is agreed that the Mo starts as an oxide, there is debate in the literature as to what is the nature or structure of the Mo-oxo species prior to exposure to methane.[1-2] In this work we used temperature programmed oxidation (TPO) and *operando* X-ray absorption spectroscopy (XAS) combined with DFT and advanced modeling to characterize how synthesis methods lead to different Mo-oxo species.

**Experimental/methodology.** Mo/HZSM-5 samples were synthesized with varying Mo loadings through physical mixing of $MoO_3$ and H-ZSM-5 or through incipient wetness impregnation of H-ZSM-5 with ammonium heptamolybdate tetrahydrate. Operando XAS spectra at the Mo K-edge (20,000.0 eV) were recorded at the Stanford Synchrotron Radiation Lightsource as samples were treated under flowing air up to 700°C with effluent gas measured by mass spectrometry. XAS correlation and deconvolution methods and DFT combined with XAS modeling were used to identify the evolution of Mo species.

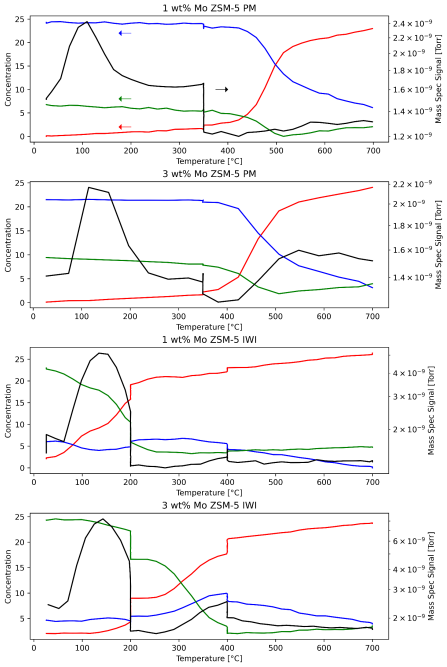

**Figure 1. Water (m/z = 18) signal in the mass spectrometer and the concentration of each XAS MCR-ALS score as a function of temperature during TPO.**

**Results and discussion.** *Operando* XAS was used to track the Mo speciation during the TPO. Principal component analysis (PCA) and multivariate curve resolution-alternating least squares (MCR-ALS) analysis on the XAS spectra during the TPO were used to identify the evolution of species. When correlated[3] to the water signal in the mass spectrometer and sample temperature it was shown that the formation of the anchored Mo-oxo species predominantly occurs during dehydration of the IWI samples while formation of the Mo-oxo species occurs at much higher temperatures for the physically mixed samples. DFT simulations combined with QuantEXAFS[4] analyzing the extended X-ray absorption fine structure (EXAFS) spectra of the activated Mo species post-TPO show that mono- and dimeric Mo-oxo species are formed during the TPO. Moreover, these species are dependent and tunable based upon the choice of Mo precursor, synthesis method, Mo loading, and zeolite acidity.

**Keywords:** hydrogen production, syngas, NAP-XPS, methane dry reforming, bimetallic catalysts

**Introduction.** Dry reforming of methane (DRM) is a key method for hydrogen production and a preferred first step in the Fischer-Tropsch synthesis. Despite intensive investigation, limitations and drawbacks still exist, which have to be solved: deactivation due to carbon deposition, low $CO_2$ activation, and compatibility with a green feedstock as biomethane [1]. When creating an active and stable catalyst, the activation of the reactants ($CH_4$ and $CO_2$) is a major consideration. The incorporation of ruthenium in a $Co/CeO_2$ catalyst [2] by a mechanochemical synthesis is investigated to enhance the performance of the monometallic catalyst.

**Experimental/methodology.** Mono- and bimetallic samples are synthesized by conventional impregnation method (IWI) and ball milling (BM). All catalysts were tested from 550 to 950 ⏭C. Operando synchrotron X-ray diffraction (SXRD) and Near-Ambient Pressure X-ray Photoelectron Spectroscopy (NAP-XPS) techniques were used to comprehend the interaction between the two metals and with the support.

**Results and discussion.** Higher $CH_4$ and $CO_2$ conversion were obtained by the mechanochemically-prepared samples (mono- and bimetallic), outperforming their conventionally synthesized counterparts. SXRD results suggest the inclusion of cobalt in the structure of the $RuO_2$ due to a shift in the peaks of the bimetallic as-prepared samples, as well as the stabilization of smaller metal nanoparticles in the bimetallic IWI sample. NAP-XPS results show that Ru addition alters the metal-support interaction with higher $Ce^{3+}$/Ce ratios for the bimetallic samples and modifies the oxidation state of Ru. In addition, the synthesis method revealed an impact on the species' reducibility and rearrangement during the DRM reaction, as shown in Fig. 1. Cobalt species under DRM conditions at 550 ⏭C exhibited different oxidation states, with the BM catalysts being more oxidized at lower temperatures due to a stronger ability to activate $CO_2$. In the high-temperature regime (700 ⏭C), the BM catalysts had a greater reduction degree than their IWI counterparts, most likely as a result of a higher methane conversion rate. These findings demonstrated that the surface of the milled catalyst is more reactive and dynamic than their conventionally-impregnated equivalents.

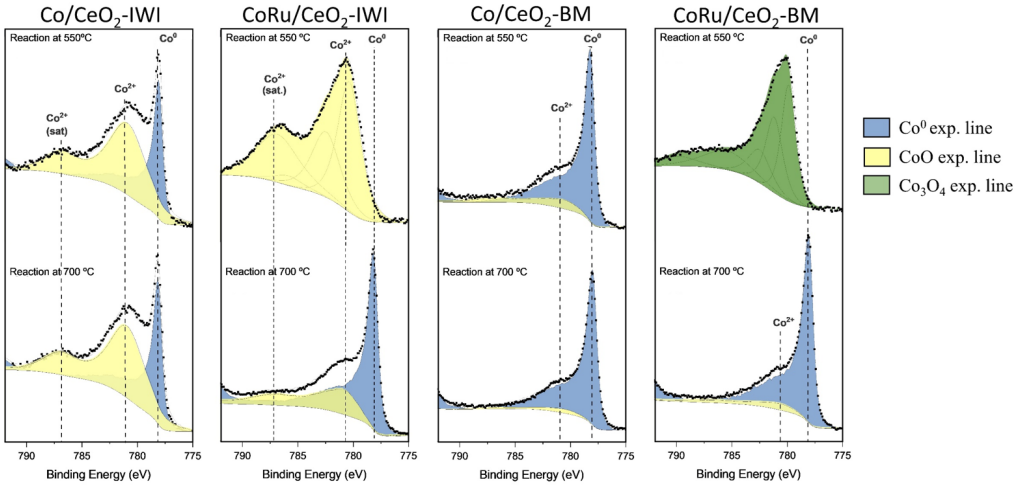

**Fig. 1. NAP-XPS spectra of the Co 2p region of $Co/CeO_2$ and $CoRu/CeO_2$ catalysts, IWI and BM under $CH_4$+$CO_2$ at 1 mbar at 550 and 700 °C, scans obtained with a KE of 215 eV.**

# Ru-REO/$Al_2O_3$ as dual-functional materials for combined $CO_2$ capture and methanation: An operando DRIFTS study

Lizbeth Moreno Bravo[1], Frederic Meunier[2], and Jan Kopyscinski[1*]

[1]*Department of Chemical Engineering, McGill University, Montreal, Canada*
[2]*Université Claude Bernard Lyon, CNRS, IRCELYON, Villeurbanne, France*
**jan.kopyscinski@mcgill.ca*

**Introduction.** In recent years, some studies have focused on combining $CO_2$ capture and subsequent methanation in the same reactor by using Dual-Functional Materials (DFMs) [1-2]. DFMs contain sorbent (mostly alkali metal oxides) and catalyst (Ni, Ru) components. This combination enables selective $CO_2$ capture from a gas stream to later hydrogenate the adsorbed $CO_2$ to $CH_4$ via isothermal cyclic operations. We propose rare-earth metal oxides (REO) as sorbents due to their higher surface basicity, yielding additional $CO_2$ adsorption sites [3] and the highly active Ru as hydrogenation site. To gain a better understanding of the reaction mechanism ($CO_2$ uptake, hydrogenation), the involved surface intermediates, and the structure-reactivity/selectivity relationship of the catalysts, we conducted operando diffuse reflectance infrared spectroscopy (DRIFTS) analyses to determine the $CO_2$ storage capacity and $CH_4$ yield.

**Experimental/Methodology.** A series of Ru-REO/$Al_2O_3$ catalysts were synthesized via incipient wetness impregnation on commercial alumina. First, REO (10 wt% of $Gd_2O_3$, $Sm_2O_3$, $Nd_2O_3$, $Ce_2O_3$) was impregnated on the alumina support and calcined at 700 °C. Then, ruthenium (5 wt%) was added and calcined at 350 °C. Prior to activity testing, catalysts were reduced under 20% vol $H_2$/Ar. $CO_2$ uptake and methanation experiments were conducted in a fixed-bed reactor, TGA, and DRIFTS reactor at 200-500 °C and 1 $bar_{abs}$ at various flow rates and partial pressures. Product gas was analyzed via mass-spectrometry (MS) and/or IR spectroscopy. The morphology, crystallinity, and textural properties of the catalysts were investigated by means of $N_2$ adsorption/desorption, $H_2$ chemisorption, XRD, SEM-EDS, TEM. Long-term cycling experiments were also performed using TGA-MS to test material stability.

**Results and discussion.** Under methanation conditions, all Ru-REO/Al catalysts exhibited high $CH_4$ selectivity (>97 %), specially at low temperatures (200-250 °C) where almost no CO formation was observed. The addition of different REOs improved catalytic activity and increased $CH_4$ production up to 30%, with RuSm/Al performing best. In all cases, the hydrogenation pathway only existed on Ru, as proved by DRIFTS. Upon $CO_2$ exposure during the cycled experiments, higher formation of hydrogen-carbonates, mono- and bidentate carbonates occured on the surface of Ru-REO/Al catalyst in comparison to Ru/Al. These species contribute to additional promoter-related pathways in parallel to the Ru-based pathway. Fig. 1 presents the DRIFT results for one cycle of $CO_2$ capture (red spectra) and subsequent hydrogenation (blue spectra) with He flush steps (green spectra) in between. In this sample, after $CO_2$ saturation, the Ru-CO (2019 $cm^{-1}$) bond remains stable under He, but is rapidly hydrogenated upon $H_2$ introduction. Formates and carbonates (1321-1643 $cm^{-1}$) show a mix of fast and slow reaction rates, hinting at the presence of both weakly and strongly bound species, as well as spectator species. After the hydrogenation step (under He atmosphere), a carbonate's spillover to Ru active sites is observed (~2000 $cm^{-1}$, top green spectra), which can be hydro-genated to $CH_4$. This process is slow and does not significantly contribute to overall conversion. Preliminary characterization results indicate that REO addition: (1) increases $CO_2$ uptake, while lowering $H_2$ uptake; (2) $N_2$ physisorption shows no significant surface area loss; (3) $CO_2$-TPD highlights that the overall basicity of the material was increased, creating favorable metal–support interactions that yield higher catalytic activity for $CO_2$ capture and hydrogenation.

# Detecting Surface Intermediates Beyond Carbon Monoxide in the Copper-Catalyzed Electroreduction of Carbon Dioxide

**Introduction**

The electrochemical reduction of $CO_2$ (eCO2RR) on copper has gained increasing attention as it has the potential to store intermittent renewable energy in chemical bonds. Copper has the unique ability to catalyze the formation of C-C bonds (*e.g.*, ethylene) in eCO2RR, but the behavior of reaction intermediates at the copper surface remains debated. [1,2] Experimentally it has been observed that residual oxides boost the C-C coupling efficiency. In order to understand the beneficial influence of oxygen on the surface, *in situ* Raman spectroscopy has proven to be a great tool to probe the copper surface during the eCO2RR process.[3] Although *in situ* Raman spectroscopy measurements have shown that linear adsorbed CO is one of the main intermediates on oxide-derived copper surfaces, many other observed Raman signals are still not confidently assigned to specific surface species.[3]

**Results and discussion**

Here, we present a systematic approach to gain more insights in the different surface species on oxide-derived copper electrocatalysts. These surface species are characterized by strong vibrational features in the low wavenumber region (around 500 $cm^{-1}$), indicating metal-adsorbate vibrations. By studying the behavior of these intermediates as function of both potential and time, it was observed that initially after the reduction of $Cu_2O$, linear CO vibrations dominate the copper surface ($\delta_{Cu\text{-}CO}$ 280 $cm^{-1}$, $\nu_{Cu\text{-}C}$ 360 $cm^{-1}$, and $\nu_{CO}$ 2090 $cm^{-1}$). However, after 15 min these linear CO vibrations fade out, whereas the vibrational features around 500 $cm^{-1}$ grow in intensity, as shown in Figure 1a below. These surface intermediates are related to Cu-C intermediates, as evidenced by isotope labeling, and more strongly bound to the copper surface, as indicated by the increased vibrational energy ($\nu_{Cu\text{-}C}$ 500 $cm^{-1}$ vs. $\nu_{CuC}$ 360 $cm^{-1}$). It is observed that the surface (composition and coverage) can be tuned by the introduction of anodic pulses, which regenerate the copper oxide catalyst and reintroduce Cu-CO at the surface, as observed in Figure 1b. This observation suggests that the 500 $cm^{-1}$ bands correspond to intermediates beyond CO.

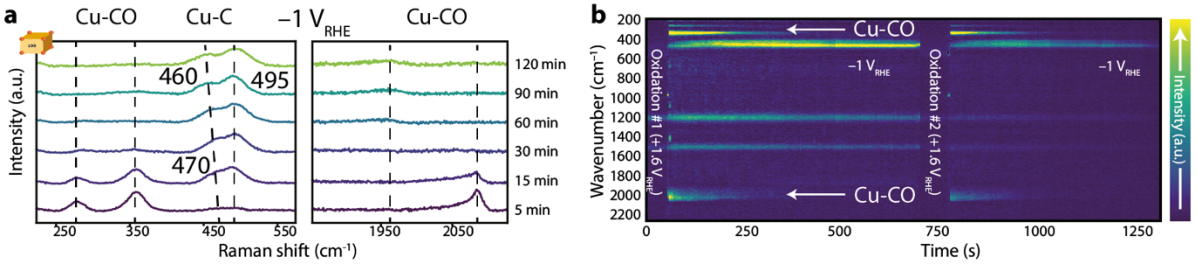

**Figure 1 – a) Time dependent Raman spectra during eCO2RR on $Cu_2O$ cubes at –1 $V_{RHE}$. b) Heatmap of Raman spectra before and after anodization, showing a rich CO coverage directly after surface oxidation.**

**Keywords:** $CO_2$ activation, Gold nanoparticles, RWGS, Surface Plasmon Resonance, UV-Vis spectroscopy

**Introduction.** A key-challenge in reaction engineering is the constant demand for more efficient catalysts and sustainable processes, which requires a deep knowledge of the catalyst functionality at atomistic level.[1] In this scenario, we focused on studying gold nanoparticles that, when highly dispersed on a support, are active for $CO_2$ hydrogenation by means of renewable $H_2$ *via* reverse water gas shift (*r*WGS) reaction ($CO_2 + H_2 \rightleftarrows CO + H_2O$).[2] To study their changes in size and shape as a function of the reaction feed, we exploited the surface plasmon resonance (SPR) phenomenon,[2c,d] which intrinsically depends on the nanoparticle structure, as a fingerprint for the *operando* characterization of the active nanoparticles.

**Experimental/methodology.** A 4%Au/α-$Al_2O_3$ catalysts was tested in an *ad-hoc* optimized *operando* UV-Vis setup, with a quartz reactor connected to a microGC. The *operando* UV−Vis experiments were performed during the reduction pretreatment (from RT to 200°C, 2°C/min, 50 Ncc/min−5% $H_2/N_2$ balanced) and during the *r*WGS catalytic testing (50 Ncc/min, $CO_2/H_2$=1, GHSV=15000 $h^{-1}$). The reaction was monitored over time, until steady state was reached both in the spectra and in $CO_2$ conversion. Measurements were carried out from RT to 600 °C with a heating ramp of 5°C/min, flowing the desired gases ($H_2/N_2$ or $CO_2/H_2/N_2$) with an *ad hoc* built gas flow setup. *Operando* XAS and PXRD data were collected at BM31 beamline [3] of the European Synchrotron Radiation Facility.

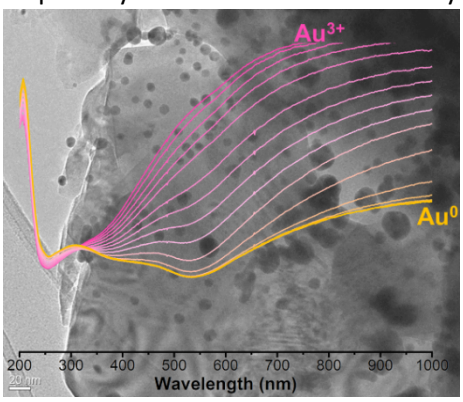

**Figure 1.** *Operando* diffuse reflectance UV-Vis spectra of Au/α-$Al_2O_3$ reduction in 5% $H_2/N_2$ flow, from RT to 200°C (pink to gold curves) and HRTEM image of gold NPs formed during the reduction ramp.

**Results and discussion.** In this contribution surface plasmon resonance (SPR) is proposed for the first time to monitor metal nanoparticles morphology in condition relevant for the catalysis. UV-Vis *operando* spectroscopy allowed us following the dynamics of nanoparticles formation and their subsequent reactivity during reverse water gas shift reaction. We monitored the progressive change in coordination of $Au^{3+}$ ions, and the behaviour of the formed gold nanoparticles in reaction conditions, through the the SPR peak. Namely, the SPR peak position of supported gold nanoparticles was found to be affected both by the nanoparticle dimensions and the presence of agglomerates. The catalytic results measured during the *operando* UV-Vis experiment evidenced a good activity for *r*WGS of the Au catalyst, with a 100% CO selectivity. *Operando* XAS and PXRD data confirmed the experimental evidences from UV-Vis spectroscopy, showing that Au nanoparticles are formed with very small size and are stable in reacting feed. The results obtained proved the potential application of the SPR to the study of catalysts morphology. To our knowledge this approach represents a novelty with respect to literature, allowing for obtaining direct information on the structure-activity relation in the field of metal-based supported catalysts.

**Keywords:** Cu-complexes, hydrocarbon oxidation, *in situ* spectroscopy, UV-Vis, EPR, DFT, modeling

**Introduction.** The selective oxidation of hydrocarbons is an important class of reactions for environmentally conscious resource management in chemistry. Oxygenated analogues often improve transport and stocking options, and many of these relatively simple molecules are in high demand as base or platform chemicals. The current way of performing these reactions on a large scale often involves the use of precious metals and/or harsh conditions, and much focus is being put in the development of milder alternatives. In this context, Cu-based catalysts are studied as simple redox systems that can carry out this reactivity in both heterogeneous (zeolites, MOFs) and homogeneous (complexes, enzymes) phases. Understanding the reaction mechanism, structure-activity relationships and catalyst deactivation pathways is crucial for rational catalyst design, and a wide variety of spectroscopic techniques and theoretical tools are available for this task. In this work, we propose $[Cu(6,6'\text{-dimethyl-}2,2'\text{-bipyridyl})_2]PF_6$ as a catalyst in solution for the oxidation of cyclohexene into 2-cyclohexen-1-one and 2-cyclohexen-1-ol using *tert*-butyl hydroperoxide (tBuOOH). The Cu(I)/Cu(II) redox cycle involved in this reaction is studied via time-resolved *in situ* UV-Vis and EPR spectroscopies, aided by multivariate curve resolution (MCR) modeling and density functional theory (DFT) calculations. The results indicate the formation of an oxygenated species on the complex as fifth ligand and the involvement of this adduct as the key intermediate for this reaction.

**Experimental/methodology.** UV-Vis-NIR spectra have been recorded on an Agilent 8454 spectrophotometer on a 0.2 cm cuvette and on a 1.0 cm cuvette with a 40 ml reservoir and septum stopper. Sample aliquotes were extracted with a syringe after each UV-Vis spectrum and frozen for EPR analysis on a Bruker X-band Elexsys spectrophotometer. All DFT calculations were carried out using the ORCA software (version 5.0.3).

**Results and discussion.** As suggested by previous results [1], the conversion of the substrate towards the products is mediated by an oxidized form of the complex that presents an additional O-containing ligand. Time-resolved *in situ* UV-Vis and EPR spectra (**Figure 1**) confirm the presence of at least two interconverting Cu(II) species that start forming after the addition of tBuOOH. DFT simulation of UV-Vis spectra for possible candidates, as well as g- and A-values extracted from EPR fitting, are consistent with a 5-coordinated species with a strained geometry for the final state. Additionally, the MCR extraction of pure spectra and concentration profiles allows to disentangle the UV-Vis spectra of the two Cu(II) species and to trace a kinetic profile of the reaction that agrees well with the catalytic tests. The combination of these spectroscopic and modeling tools is able to extract crucial information on the intermediates, and will be applied to study the second half of the catalytic cycle (i.e., the oxygenation of cyclohexene) to shed light on the key mechanistic aspects of this reaction.

**Keywords:** $CO_2$ conversion, catalysis, spectroscopy, X-rays

**Introduction.** Converting $CO_2$ into value-added products has seen renewed interest due to the considerable increment in emissions into the atmosphere. Utilising it to synthesise liquid fuels like methanol would reduce the dependence on fossil fuels as the primary energy feedstock. Although methanol is already produced on a global scale using copper-based catalysts (i.e., $Cu/ZnO/Al_2O_3$) operating at high pressure (> 50 bar gas), recent focus is on novel processes able to use more (hydrothermally) stable catalysts capable of producing methanol at lower pressures and temperatures (and thus with lower energy costs). One of the most promising catalyst design concerns supported PdZn nanoparticles, e.g., $PdZn/TiO_2$ catalysts [1]. Combined *operando* XAFS-XRD studies were conducted to gain insights into how structural changes affect the activity of these catalysts under reaction conditions while varying the Zn concentration and to study the salient properties and formation of the β-PdZn 1:1 alloy.

**Experimental/methodology.** $PdZn/TiO_2$ catalysts with varying Pd:Zn ratios and 5 wt% Pd fixed loading were prepared by chemical vapour impregnation. Combined XAFS-XRD studies at Pd and Zn K-edge were conducted at the B18 beamline at Diamond Light Source. Before testing, the catalysts were reduced *in situ* in a flow of 4 % $H_2$/Ar gas at 400 °C for 1h. Catalytic tests were performed at 250-270 °C and 20 bar under a gas flow of 1:3 $CO_2$:$H_2$ molar ratio. The effluent gases of the reactor were analysed by mass spectrometry.

**Results and discussion.** Catalytic testing prior to beamtime experiments showed that tailoring the Pd:Zn allowed us to control the methanol yield. However, the underpinning reason(s) why were unknown. In all cases, the β-PdZn 1:1 alloy was observed to form in the XRD data after reduction and appeared to be necessary for optimal activity. However, at high Pd:Zn ratios, there was some evidence of metallic Pd presence, possibly as part of a core-shell structure of the otherwise PdZn particles, influencing catalytic activity. However, at this point, the exact nature and structure of the active nanoparticles in these formulations are unclear [2, 3].

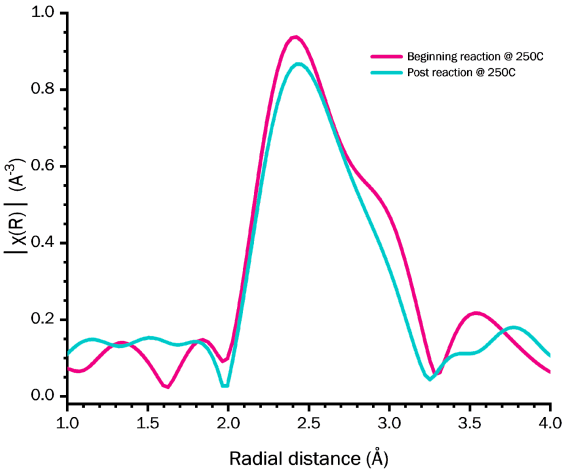

Figure 1. Changes in the Phase-corrected Fourier transform representation of Pd K-edge k$^2$-weighted EXAFS spectra observed during reaction conditions on PdZn/TiO$_2$.

When subjecting the same samples to the reaction gas mixture, a change was observed in the Pd-edge k-space of $PdZn(1:20)/TiO_2$, where the intensity of the oscillations diminished, corresponding to the disappearance of a shoulder ca. 2.8 Å in the Fourier transform representation (Figure 1), implying that the PdZn alloy phase, and/or its surrounding neighbours had evolved under reaction conditions. These results, together with changes seen in the MS signal simultaneously, demonstrate that small differences in the structure and composition of supported nanoparticles play a key role in the catalytic properties, and testing under more realistic conditions is very valuable, as has already been shown for Cu/ZnO-based catalysts [4].

[*]*alexandra.iacoban@infim.ro*

**Introduction.** Layered ternary carbides structures, such as in MAX phases (3D) are remarkable materials that combine the properties of metals and ceramics. They have the general formula $M_{n+1}AX_n$, where M is an early transition metal, A is a group A element, X= C and/or N, with n=1-4 [1]. These materials have important properties such as high thermal and electrical conductivity, mechanical strength, low density, and also resistance to high temperatures and oxidation [2,3]. By selectively etching, 2D MXene are obtained that exhibit quite different electronic, magnetic, optical, and electrochemical properties. Moreover, they present abundance of hydrophilic functional groups on the surface (-OH, –O and –F) formed during wet-etching synthesis of MXenes from MAX phases, implying promising (photo)catalytic properties [4]. However, little is understood about the dynamics of the structural and surface changes that these systems go through during catalysis that result in efficient catalyst function.

**Experimental/methodology.** Several materials, including MAX phase ($Ti_3SiC_2$) and MXene ($Ti_3C_2T_x$) were studied at the X07DB-In Situ Spectroscopy beamline at the Swiss Light Source Synchrotron. The dynamics of the surface and subsurface rearrangements were investigated under steady state Ar, $O_2$, $CH_4$ and/ or $H_2O$ environment at different temperatures (between room temperature and 350 ˚C) and ambiental pressure. Thus, the effects of reduction and oxidation conditions were evaluated. Sensitive surface and subsurface in situ XPS spectra were obtained at different kinetic photoelectron energies (300 and 600 eV). Furthermore, materials were characterized before and after the reaction with the help of different experimental techniques, such as XRD, TEM, UV-Vis and Raman spectroscopies.

**Results and discussion.** The dynamics of the structural and surface changes were studied at 1 mbar, under Ar, $CH_4$+ $O_2$ and $CH_4$+ $O_2$+ $H_2O$. The most significant result of this work was the presence of OH surface species on the MXene surface when $CH_4$ was present, which might be due to the activation of $CH_4$ on the metal species, then one C–H bond is broken and the resulting H is immediately attached to the O species on the surface. In addition, a good stability of the of MAX phase and MXene throughout the AP-XPS experiments was confirmed. The obtained results are of great interest in undertanding the behaviour of MAX phase and MXene in catalytic processes.

**Keywords:** Selective hydrogenation, Butadiene, Pd-based catalysts, Bimetallic, Promoter, Synergy

**Introduction.** The catalytic performance of bimetallic nanoparticles critically depends on the atomic distribution of the metals within the particles.[1,2] Monometallic Pd and Cu have excellent activity and selectivity in (selective) hydrogenation reactions, respectively.[2,3] Interestingly, synergistic catalytic performance can be achieved in bimetallic CuPd systems, due to both geometric and electronic effects.[4,5]

**Experimental/methodology.** Bimetallic CuPd nanoparticles with molar Cu:Pd ratios varying from 7:1 to 167:1 were prepared by colloidal approach. In short, Cu(I)- and Pd(II)acetate was heated in trioctylamine and tetradecylphosponic acid which resulted in particles of 7±1 nm in size. Heterogeneous CuPd/C catalysts were prepared by a wet impregnation of the colloidal suspension onto carbon support, followed by drying and calcination. After reduction, their catalytic performance was tested in the selective hydrogenation of 0.3% 1,3-butadiene from a 30% propylene feedstock in 20% hydrogen (He as balance).

**Results and discussion.** Extensive characterization comprising XRD, STEM-EDX and TPR indicated the co-existence of both metals within individual nanoparticles in all as-synthesized catalysts. EXAFS showed that after reduction (250 °C, $H_2$), Pd was coordinated mainly to Cu, and to a lesser extent to Pd for the 7:1, 13:1 and 31:1 ratios. The catalysts were active in selective hydrogenation, especially at lower Cu-fraction, with a maximum activity around 31:1 Cu:Pd ratio (Figure 1). Interestingly, limited alkane formation resulted in an optimum in selectivity at similar Cu:Pd ratio. Insight into the origin of the fraction-dependent performance with respect to electronic or geometric effects, and to atomic redistribution during catalysis is under investigation and will be discussed during the conference.

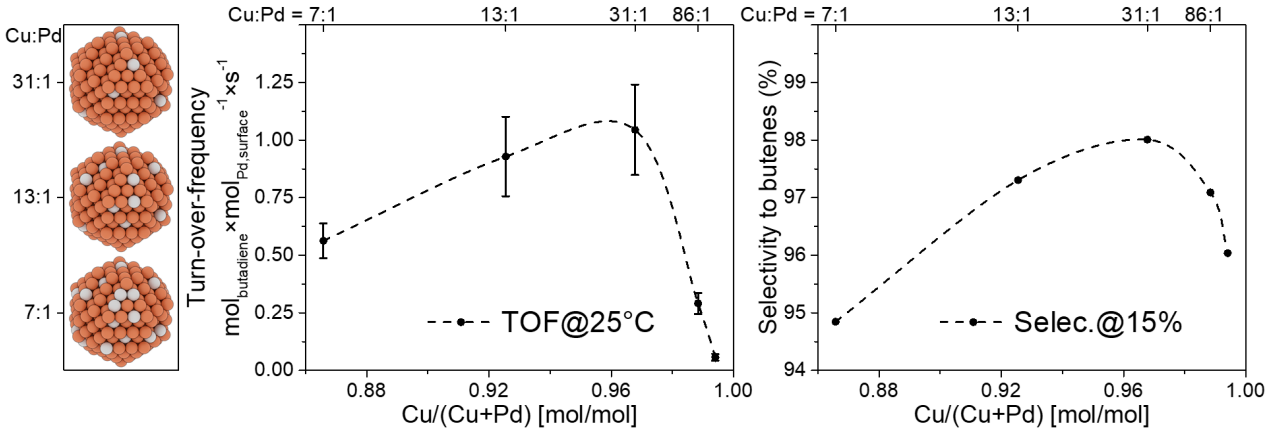

**Figure 1. (Left) Schematic representation of bimetallic nanoparticles with varying Cu:Pd ratio. (Middle) Butadiene activity and (right) butene selectivity during selective hydrogenation of butadiene as function of Cu-fraction.**

**Introduction.** Wet-kneaded silica–magnesia is a benchmark catalyst for the one–step ethanol-to-butadiene Lebedev process [1-3]. Magnesium silicates, formed during wet-kneading, have been proposed as active sites responsible for butadiene formation, and their catalytic performance has been mainly explained by the variations in the ratio of acid and base sites. While the Lebedev process was developed in the 1930s, a detailed insight into how the peculiar, yet essential wet-kneading synthesis leads to the generation, location, and catalytic role of magnesium silicates has not been fully established [3].

**Experimental/methodology.** Typically, we prepared the conventional wet-kneaded silica-magnesia catalysts using Stöber silica and platelet shaped $Mg(OH)_2$ [1,2]. For the modified wet-kneading, the pH of the aqueous wet-kneading medium was adjusted, yielding two model catalysts [1]. The prepared catalysts were characterized by ICP-OES, SEM, TGA, PXRD, $N_2$ and Ar physisorption, $NH_3$- and $CO_2$-TPD, DRIFTS-MS, solid-state $^{29}Si$ and $^{25}Mg$ NMR. The catalytic activity of the samples were tested using high-throughput reactor system (Avantium) at 425 °C and ambient pressure (LHSV 1.0 $h^{-1}$).

**Results and discussion.** Here, we demonstrate that magnesium silicates formation occurs via dissolution of Si and Mg subunits from $SiO_2$ and $Mg(OH)_2$ precursors, initiated by the alkaline pH of the aqueous wet-kneading medium, followed by cross-deposition of the dissolved species on the precursor surfaces (Fig. 1a,b). The model catalysts prepared selective dissolution/cross-deposition (Fig. 1c) showed different catalytic roles in the Lebedev process: Si/MgO and $Mg/SiO_2$ for butadiene and ethylene, respectively (Fig. 1d). The close proximity of acidic and basic sites in Si–OH–Mg species in Si/MgO is thought to be key to efficient conversion [2,3]. To proof that, we have developed a spectroscopic titration approach revealing that the Si modification on MgO (Si/MgO) creates additional acid sites and these sites are indeed in close to basic sites in 5 Å range (Fig. 1e). We also show that the adsorption affinity of acetaldehyde on the catalyst surface has been reduced by surface modification with Si on MgO (Fig.1f).

**Keywords:** Three-phase liquid-liquid-gas reactions, polyoxometalates, density-functional calculations, spectroscopic investigations, catalyst activation/deactivation

**Introduction.** Three-phase liquid-liquid-gas reactions are often applied to make valuable chemicals from biomass or to efficiently remove contaminants from fuels. Hereby, molecular oxygen is used as a cheap, abundant and eco-friendly oxidant. Typically, the latter is activated by metal catalysts, whereby polyoxometalates (POMs), especially in their heteropolyacid form (HPA), are very efficient due to their combined Bronsted acidity and redox activity. Mostly used in homogeneously catalysed oxidations are HPAs from the so-called Keggin-type $H_{3+n}[XV_nM_{12-n}O_{40}]$ (HPA-x). Hereby, the catalytic activity is mostly introduced by substituting some of the framework metals (tungsten, molybdenum) with easily reducible heterometals like vanadium that results in shifting their reactivity from acidic to redox-dominance. [1]

**Experimental/methodology.** HPA-5 and HPA-2 were synthesized according to literature-known procedures. [2] All calculations were performed with the Turbomole program package. [3] ATR-FT-IR spectra were measured on a Shimadzu IRSpirit instrument with ATR accessory unit. Raman spectra were recorded in aqueous solution, using a Kaiser Raman Rxn1-785 instrument, equipped with an immersion probe. The excitation laser used a wavelength of 785 nm. NMR spectra were measured by the central NMR service facilities of the Universität Hamburg, using a 600 MHz instrument (242.94 MHz for 31P, 157.77 MHz for $^{51}$V). UV-Vis spectra were recorded using a Cary 60 UV-Vis spectrometer (Agilent Technologies) in a 3 mL Quartz cuvette (QS).

**Results and discussion.** Three-phase liquid-liquid gas reactions are promising strategies to combine highly active and selective homogeneous-catalysed oxidation reactions with in-situ product isolation. Hereby, an aqueous POM catalyst solution in combination with molecular oxygen as oxidant is used. However, contrary effects on the oxidation performance of the POM-catalyst were observed for different carboxylic acids as reaction products or intermediates. By using model calculations employing Density-Functional Theory (DFT) in combination with magnetic and optical spectroscopy, we could explain the experimental observations that oxalic acid activates the POM catalyst and therefore promotes its oxidation performance while acetic and especially formic acid form stable complexes with the active centres and therefore inhibit the oxidation activity. These findings greatly improve the understanding of POM-acid complexes and their effect on the catalytic performance. [4]

**Keywords:** Fe-ZSM-5, SCR, XAS

**Introduction.** Fe containing zeolites are active for $N_2O$ decomposition and selective catalytic reduction of NO by $NH_3$ [1,2]. In the last decades, much effort has been focused on identifying the structure of the most active Fe species, to optimize the method of Fe introduction into zeolites and to clarify the reaction mechanism[3]. The synthesis of Fe/zeolites containing monomeric Fe species, which are suggested to make up the active low temperature species, is challenging as Fe tends to cluster readily. In the current study an Fe-EDTA complex was used as the Fe precursor to ensure separation of iron ions in the ZSM-5 zeolite pores. Such a procedure resulted in synthesis of a Fe catalyst with monomeric Fe, which showed very high activity in the low temperature $NH_3$-SCR process[4].

**Experimental/methodology.** A $NH_4$-ZSM-5 zeolite with MFI structure ($SiO_2/Al_2O_3$ = 23; 400 $m^2/g$; Alfa Aesar) was dealuminated using an aqueous solution of $HNO_3$ (2 M; 100 ml/g of zeolite) at 80°C for 24 h. Subsequently, the material was filtered, washed with distilled water (2 L) and dried at 80°C overnight. The Fe-EDTA was added dropwise to an aqueous suspension of dealuminated ZSM-5 preheated to 65°C under $N_2$ atmosphere[4]. *Operando* Fe K-edge XAS studies were carried out at the SuperXAS beamline (SLS, Switzerland) under various reaction condition such as $NO/NH_3$ or $NO/O_2$ gas stream at temperatures ranging from 200-350°C d in fluorescence mode with a 5 s time resolution. The resulting large XAS dataset was analyzed with multivariate curve resolution analysis and subsequent *ab initio* modelling.

**Results and discussion.** *In-situ* XAS studies carried out in presence of $NO/NH_3$ or $NO/O_2$ at 350°C demonstrated the involvement of all iron atoms in the redox cycle and with that suggest that Fe species in the studied Fe/ZSM-5 catalyst are monomers, which was furthermore confirmed by EXAFS and UV-VIS spectroscopy. Ab initio simulation of the experimental X-ray absorption data, carried out using FDMNES, revealed that the single site Fe species in the sample obtained by this approach adopt a square planar geometry, which changes into five-fold coordination at low temperature by strongly binding to either NO or $NH_3$. This catalyst showed high activity in low temperature SCR compared to conventionally prepared Fe/ZSM-5. The presence of monomeric Fe species in this Fe/ZSM-5 convey molecular level insights into the temperature dependent $NH_3$-SCR activity and might prove useful in the study of other reactions over monomeric Fe species, such as methane partial oxidation or dehydroaromatization reactions.

**Introduction.** Ammonia, according to its high hydrogen content and energy density, convenient infrastructure for transportation and storage, is becoming a promising energy carrier. Hydrogen could be stored by synthesizing ammonia, afterwards released by ammonia decomposition. However, there is still a challenge in the design of a highly efficient catalyst for ammonia decomposition at mild conditions.[1] Recent studies revealed nitrogen desorption as being the rate-determining step on many transition metal catalysts, and explain the superiority of Ru catalyst by its moderate nitrogen binding energy.[2] Herein we present a synthesis route for Fe-based catalysts inspired by the highly-loaded Haber-Bosch catalyst, identify nitridation as the reason for its moderate activity and demonstrate how nitridation can be suppressed and a nitrogen binding energy similar to Ru can be reached by alloying with Co.

**Experimental.** All FeCo/MgO catalysts were prepared by co-precipitation of LDHs / hydroxides in an automated reactor system at various Fe:Co ratios. The precursors were calcined and further isothermally reduced in $H_2$. Activity tests were carried out in a flow reactor in a diluted gas (3% $NH_3$/He). Structural analyses of $Fe_{1-x}Co_x$/MgO catalysts were performed during the reduction process by *in situ* XRD and afterwards by *ex situ* STEM-EDX. *Operando* XAS measurements both at the Fe and Co K-edge were carried out at the CAT-ACT beamline at the KIT light source in Karlsruhe, Germany.

**Results and discussion.** High-loaded $Fe_{1-x}Co_x$/MgO samples were obtained from the reduction of spinel $Mg(Fe_{1x}Co_x)_2O_4$. XRD and STEM-EDX-mapping confirmed the formation of metallic Fe or FeCo alloy (loading ~60%) while the unreduced support material was identified as magnesium wuestite-like oxide. *In situ* XRD and XAS were performed to understand the reduction process. Considering the dispersions of mono-/bi-metallic NPs, $Fe_{0.75}Co_{0.25}$/MgO showed a similar TOF as $Fe_{0.5}Co_{0.5}$/MgO (~0.26 $s^{-1}$), which is higher than Fe/MgO (0.15 $s^{-1}$) and Co/MgO (0.13 $s^{-1}$) (Figure 1a). Hence, the bimetallic catalysts were more active than Fe or Co only, but higher Co content did not lead to a further improvement. *Operando* XAS measurements were performed on Fe/MgO and $Fe_{0.5}Co_{0.5}$/MgO catalysts. During the reaction, Fe/MgO showed 69% $Fe_3N$ and 31% Magnesium wuestite without α-Fe while $Fe_{0.5}Co_{0.5}$/MgO showed 82% FeCo alloy and 18% Magnesium wuestite. $Fe_3N$ on Fe/MgO was also identified in XRD after reaction, which was not observed on $Fe_{0.5}Co_{0.5}$/MgO. This indicates that iron is readily nitridated and the resulting nitrides have a negative effect, while the Fe-Co alloy was stable against nitridation. DFT calculations supported the nitridation of Fe and revealed that $Fe_3N$ surfaces exhibit too weak binding energies and are thus less active. By alloying Fe with Co, this nitridation could be suppressed and the nitrogen binding energy is additionally influenced to shift to a moderate value, leading to a highly active and stable catalytic performance (Figure 1b).

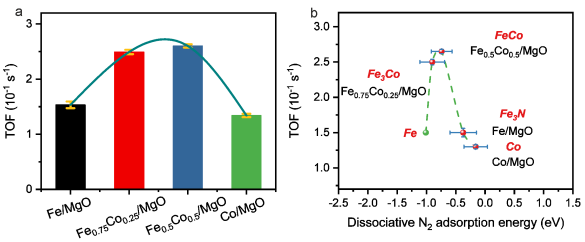

**Figure 1. TOF of the four $Fe_xCo_{1-x}$/MgO catalysts for ammonia decomposition at 500C (a) and TOFs of the four $Fe_xCo_{1-x}$/MgO catalysts as a function of the corresponding dissociative $N_2$ adsorption energy (b), green dashed volcano curve considering the $N_2$ adsorption energy of pure Fe site and of $Fe_3N$.**

**Introduction.**

The decomposition of ammonia has been brought into the focus of forefront research in recent years because ammonia has shown great potential as a potential energy storage molecule with high energy density and high hydrogen capacity. Currently, the ideal catalyst for ammonia decomposition is Ru-based due to the optimal $N_2$ adsorption energy, while the high cost of Ru limits its application at the industrial scale. One of the most promising candidates is Fe-based catalysts, but the activity and durability are still not comparable to the Ru-based catalysts. A speculative explanation is that Fe has much stronger chemical adsorption of $N_2$, which leads to the irreversible formation of iron nitride by dissociation of the triple bond of the produced $N_2$ on the surface. Therefore, the access of active Fe sites by $NH_3$ is inhibited in ammonia decomposition, leading to poorer catalytic performance. To prove this hypothesis, we studied two model catalysts, reduced $MgFe_2O_4$ and reduced $MgFeCoO_4$, and performed combined in situ AP-XPS and AP-NEXAFS characterizations to understand the electronic structure of catalysts surface upon redox/nitridation during catalysis.

**Experimental/methodology.**

In situ AP-XPS and AP-NEXAFS experiments were accomplished at the B07C beamline of Diamond Light Source. Catalysts sample powder was drop-casted on Au-coated Si wafers and mounted on a 'teapot' sample holder which has a built-in heater and thermocouple. The temperature of the sample was regulated between 298 and 873 K and the gas pressure was controlled between UHV and 1 mbar. The exhaust gas was analyzed continuously by a mass spectrometer. Fe/Co 2p XPS and N/O 1s XPS spectra were collected using excitation energy of 1025 eV and 1300 eV respectively to avoid interference from the Auger peaks. The Fe $L_{3,2}$-edge and Co $L_{3,2}$-edge NEXAFS spectra were measured in both total electron yield (TEY) mode using analyzer cone current and Auger electron yield (AEY). The Fe $L_2M_{23}M_{23}$ Auger emission at 592 eV and Co $L_3M_{23}M_{23}$ Auger emission at 648 eV were integrated for Fe $L_{3,2}$-edge and Co $L_{3,2}$-edge NEXAFS AEY-NEXAFS, respectively. Typical in situ conditions for XPS & NEXAFS include 1mbar H2 at 873K, 1mbar NH3 at 673K, 773K and 873K.

**Results and discussion.**

The reduction of surface Fe species, adsorption of $NH_3$ and $N_2$, as well as the formation of nitride, are observed in Fe 2p XPS, Fe $L_3$-edge NEXAFS and N 1s XPS respectively (Figure 1). Parallel studies on the more active and durable $MgFeCoO_4$ catalyst were also performed. With half of Fe but additional Co (which has weaker adsorption of $N_2$), the $MgFeCoO_4$ catalyst showed a much less significant reduction of Fe and the formation of nitride. Such a good correlation between the surface electronic structure and the catalytic activity provides solid evidence to support our hypothesis above and is inspirational to further mechanism studies for ammonia decomposition.

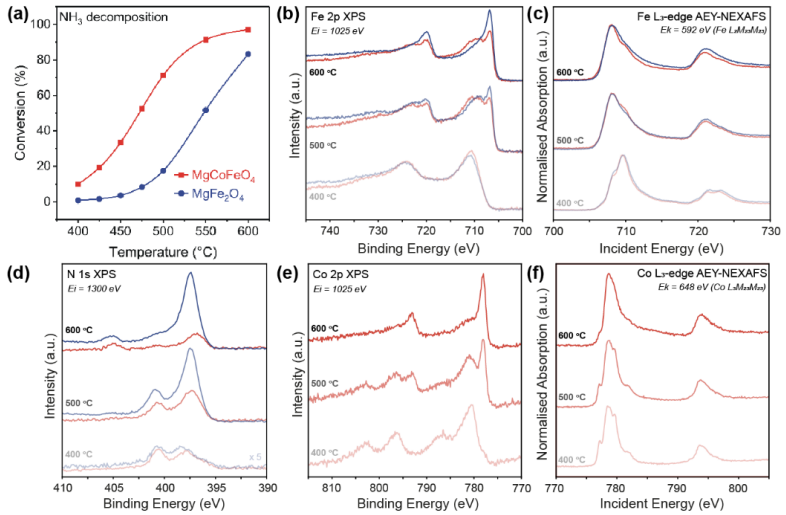

**Figure 1.** (a) Catalysis performance of Mg-Co-Fe catalyst (red curve) and Mg-Fe catalyst (blue) for $NH_3$ decomposition. *In situ* (b) Fe 2p XPS, (c) Fe $L_3$-edge AEY-NEXAFS and (d) N 1s XPS spectra of both catalysts during $NH_3$ decomposition at 673K, 773K and 873K respectively. In situ (e) Co 2p XPS and (f) Co $L_3$-edge AEY-NEXAFS spectra of Mg-Fe-Co catalyst during $NH_3$ decomposition at 673K, 773K and 873K respectively.

**Keywords:** single-atom catalysis, atomic distributions, transmission electron microscopy, machine learning.

**Introduction.** Single-atom catalysts (SACs) have unique properties that can affect their reactivity and efficiency.[1] Aberration-corrected scanning transmission electron microscopy (AC-STEM) is the main technique used to study the spatial arrangement of atoms in SACs, which is crucial to confirm the atomic dispersion and can provide insight into the density and proximity of atoms. However, the process of analyzing these images is time-consuming and the results are often not statistically robust.

**Methodology.** Our study aims to improve understanding of atomic distributions in SACs by using machine-learning techniques to analyze AC-STEM images of materials with specific properties, and complementing the analysis with insights gained from atomistic models.

**Results and discussion.** We developed a convolutional neural network (SAC-CNN) that can rapidly and accurately detect atoms in AC-STEM images of SACs based on non-crystalline supports (**Fig. 1a**).[2] This presentation explores the general applicability of the model and highlights the advanced insights it can provide for the design of SACs (**Fig. 1b**), considering the relationship between the observed atomic distributions and the underlying features of the support and metal species.

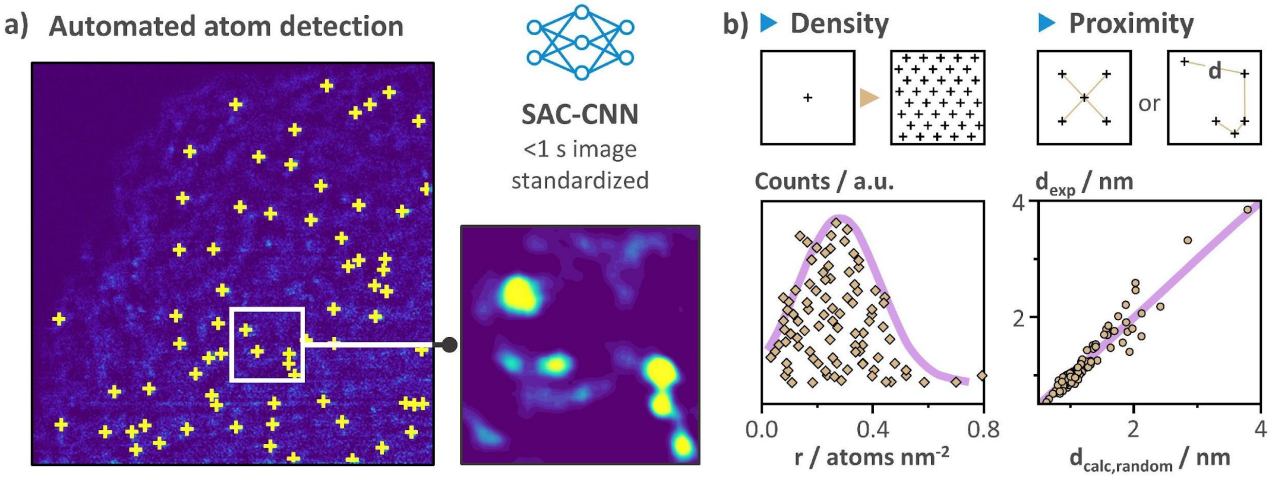

**Figure 1. (a) AC-STEM image of a $Pt_1$/NC SAC indicating the metal atoms detected by the SAC-CNN model (yellow crosses). The model generates a probability map, shown for the white boxed area, to standardize the analysis of single-atom dispersions. (b) The possibility to rapidly assess large image sets can provide statistically relevant insights into previously inaccessible properties of SACs.**

# Limits of Detection for EXAFS Characterization of Single Atom Catalysts

Jordan Finzel[1], Phillip Christopher[1]*, Simon R. Bare[2]*

[1]*Department of Chemical Engineering, University of California Santa Barbara*
[2]*Stanford Synchrotron Radiation Light Source, SLAC National Accelerator Laboratory*
*srbare@slac.stanford.edu; *pchristopher@ucsb.edu

**Introduction.** Single atom catalysts (SACs) attract attention due to their unique reactivity and precise chemical tunability. Authors often use – and reviewers often require – extended X-ray absorption fine structure (EXAFS) data to prove the absence of clustered metal (or metal-oxide, MO) structures under *in-situ* or *operando* conditions. However, there has been no critical assessment of the ability of EXAFS to substantiate such conclusive statements. Here we assess the ability of EXAFS to identify metal (oxide) clusters in catalysts containing predominantly SAs by modelling data for mixtures of atomically dispersed metals and metal or MO clusters. We quantify the fraction of metal species that can coexist with SA sites as either metal or MO clusters while eluding detection with any statistical significance. Additionally, through a descriptor-based screening approach we identify certain oxide structures for which differentiating atomically dispersed metal species and MO clusters would be infeasible by EXAFS.
**Experimental/methodology.** EXAFS were modelled using FEFF6 for a $Pt/CeO_2$ single atom site, a 0.6nm $Pt_{13}$ metallic cluster, and a 1nm $Pt_{14}O_{37}$ oxidized. Datasets consisting of linear combinations of spectra from various species were fit using a robust model for the $Pt/CeO_2$ SAC structure described by 5 dominant scattering paths. The $\chi(k)$ was calculated for various bulk oxides using experimental crystal structures. Spectra were analyzed using a continuous Cauchy wavelet transform (CCWT), and the maximum of the modulus of the CCWT beyond 2Å was identified as a descriptor for detection of oxide clusters.
**Results and discussion.** To identify the limits of detection of clustered species that coexist with SAs using EXAFS, it is important to distinguish the scattering features of different types of sites. SAs on oxide supports typically contain metal-oxygen (M-O) and metal-oxygen-support (M-O-S) interactions, metallic clusters predominantly display metal-metal (M-M) interactions, and metal oxide clusters exhibit both M-O and M-O-M scattering (Figure 1a). As an example, we modelled EXAFS of $Pt/CeO_2$ SACs. Linear combinations (LCs) of $Pt/CeO_2$ SAC with metallic $Pt_{13}$ clusters show clear changes as expected; (Figure 1b).

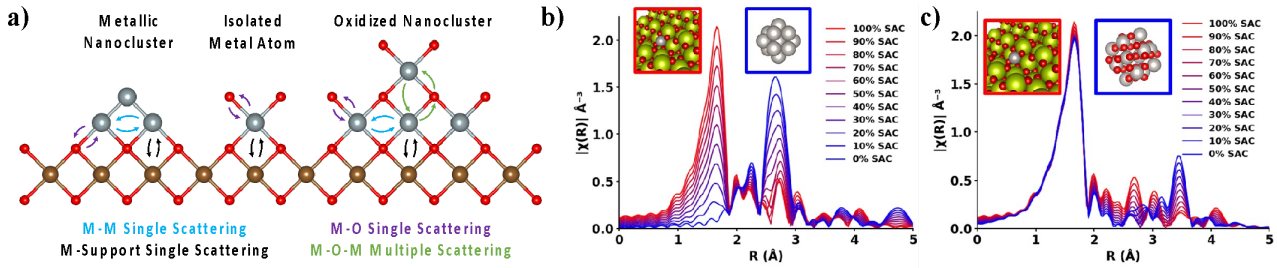

**Figure 1. (a) Scattering paths for isolated metal sites (middle), and metallic (left) or oxidized (right) nanoclusters. Modelled FT EXAFS data for mixtures of $Pt/CeO_2$ SAC and (b) metallic $Pt_{13}$ or (c) oxidized $Pt_{14}O_{37}$ clusters.**

Conversely, LCs from the SAC structure and a 1nm $Pt_{14}O_{37}$ cluster do not show pronounced differences. Similar Pt-O bonding necessitates analysis beyond the first shell, which shows Pt-Ce scattering paths at ~2.75 Å when the SAC is the majority species (red), while scattering associated with Pt-O-Pt interactions on the oxidized Pt cluster (blue) become more apparent at ~3.4 Å (Figure 1c). Fitting these datasets with a model of the SAC site, the quality of the fit (the R-factor) quickly deteriorates when the metallic $Pt_{13}$ cluster contributes as a minority species but is far less sensitive to the coexistence of the oxidized $Pt_{14}O_{37}$ cluster. Our results indicate that up to 40% of Pt may exist as oxidized clusters before being identified with any statistical significance. We also identified a descriptor based on a wavelet transform analysis – the CCWT modulus maximum – that trends well with the observed experimental prevalence of higher order scattering [1] and is necessary to differentiate SAC sites from metal oxide particles.

# Using Light to Sense the Local Temperature during Catalytic Reactions

T.S. Jacobs[1,*], F.T. Rabouw[1], B.M. Weckhuysen[1], W. van der Stam[1]

[1]*Inorganic Chemistry and Catalysis group, Debye Institute for Nanomaterials Science & Institute for Sustainable and Circular Chemistry, Utrecht University, Utrecht, the Netherlands*

[*]*t.s.jacobs@uu.nl*

**Introduction.** Catalysis operates on a broad range of pressures and temperatures, from ambient conditions to temperatures above 1000 K, depending on the catalyst and reaction of interest. Small variations in the overall reactor temperature are known to affect the catalytic performance. While local variations in temperature likely play an equally important role, these are rarely studied in detail.[1] To study local heat effects in catalytic reactions, temperature measurements over a broad temperature range and with a high spatial resolution are necessary.

**Experimental/methodology.** In this work, we use "luminescence thermometry" to study local temperatures during catalytic reactions.[2] Microcrystalline 1-$\mu$m-diameter $Y_2O_3$ particles doped with $Nd^{3+}$ are mixed into the reactor bed. $Nd^{3+}$ emits near-IR light with a temperature-dependent spectrum. We can thus determine local temperature variations by mapping the $Nd^{3+}$ emission spectrum. By tuning the $Nd^{3+}$ doping concentration for optimal signal strength, we achieve precise temperature readouts (error of <1 K) at temperatures relevant for various catalytic processes, including $CO_2$ hydrogenation performed at 673 K.

**Results and discussion.** We characterized spatial temperature heterogeneities with $\mu$m resolution during two catalytic processes. The exothermic $CO_2$ methanation reaction (Figure 1a, using a Ni/$TiO_2$ catalyst, $\Delta H_r$ = –165 kJ/mol) was studied at 673 K. Pulsing the reactant gasses (*e.g.,* $CO_2$) causes a temperature jump of +9 K on average, with a wide variations over a region as small as 35×35 $\mu m^2$ (Figure 1b). The formation of products (*e.g.*, $CH_4$) in the thermocatalytic reactions was detected with on-line mass spectrometry (MS) and correlated to the observed heat profile. Next to the thermocatalytic conversion of $CO_2$, these thermometers were also applied to $CO_2$ electroreduction at room temperature. An applied current density of –50 mA/$cm^2$ resulted in a temperature increase of +10 K. These applications of the luminescence thermometry sensor shine light on the temperature heterogeneity during catalysis.

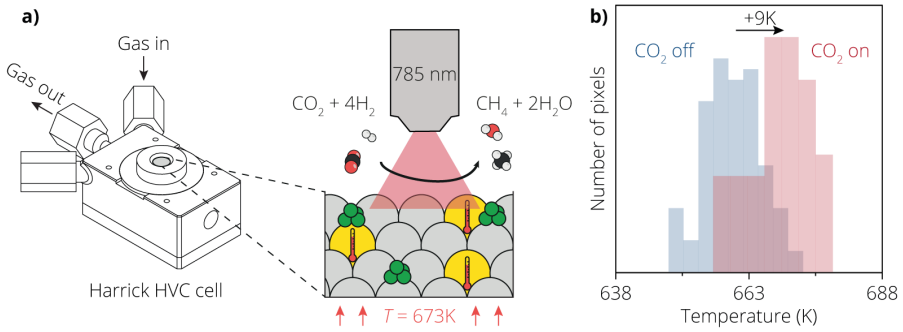

**Figure 1. a) Reactor setup with the Ni/$TiO_2$ catalyst (green and grey, respectively), mixed with the thermometers (yellow). b) Measured temperature distributions over an area of 35×35 $\mu m^2$ with pixel size of 3.5×3.5 $\mu m^2$, before and during the introduction of reactant gasses, showing the exothermicity of the $CO_2$ methanation reaction with an average temperature increase of +9 K.**

**arnaud.travert@unicaen.fr*

**Introduction.** Classical quantitative analytical methods for the characterization of adsorbents such as gravimetric analysis or calorimetry yield values averaged over the various adsorption sites[1]. Here, In situ IR spectroscopy combined with multivariate analysis has been used to identify and characterize quantitatively alcohol adsorption on zeolites.

**Experimental/methodology.** Spectroscopic isotherms (IR spectra vs pressure, fig.1a) at various temperatures were recorded and analyzed by using multivariate curve resolution analysis (MCR-ALS)[2] implemented in SpectroChemPy[3].

**Results and discussion.** Hybrid hard soft MCR-ALS, used for the first time in the field of adsoption, allowed us to recover pure response profiles: spectral profiles (fig.1b), allowing identification of distinct species on the basis of their spectra, and adsorption isotherms (fig.1c), allowing to assess sorption parameters by curve fitting a local isotherm such as the Langmuir isotherm or implementation of the isotherm as a hard constaint.

As shown in Figure 1, in the case of the adsorption of isobutanol on MFI zeolites, three species could be identified, in particular by analysis of the ν(OH) range: adsorption on bridged OH groups (#1), on extra-framework Al-OH (#2) and on silanol groups (#3). Analysis of the adsorption isotherms at various temperatures allowed recovering the corresponding adsorption enthalpies; $\Delta_{ads}H$ $\Delta_{ads}H$ (#1) ~ -110 kJ/mol; $\Delta_{ads}H$ $\Delta_{ads}H$ (#2) ~ -90 kJ/mol; $\Delta_{ads}H$ $\Delta_{ads}H$ (#3) ~ -30 kJ/mol.

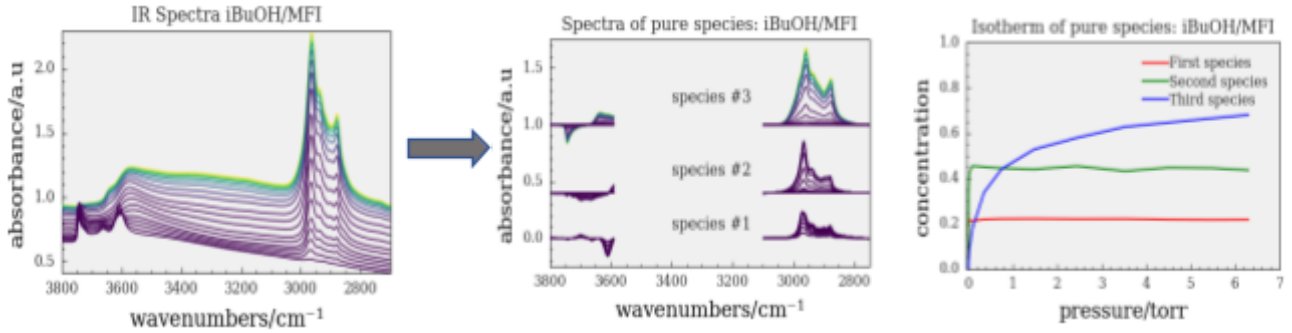

Figure SEQ Figure * ARABIC 1: MCR-ALS output -Spectra and concentration of pure species (iBuOH/MFI)

In conclusion, the present methodology has the potential to provide unique insights into the assessment of adsorption properties of complex zeolite-based catalysts. Its limits, advantages and drawbacks with respect to conventional methods will be discussed.

**Keywords:** characterization, X-ray tomography, deactivation, coking, dehydrogenation

**Introduction.** Understanding the deactivation of industrial catalysts is highly important for rational design of more stable catalysts. During light alkane dehydrogenation, coke formation is considered as major deactivation pathway requiring frequent regeneration cycles.[1] As industrially applied catalysts usually exhibit a complex 3D structure, e.g., involving binder materials to formulate macroscopically shaped catalysts, bulk analysis methods may only provide limited or unrepresentative information.[2] Recently, spatially-resolved hard X-ray tomography studies could identify coked regions of single catalyst grains, although the resolution was not high enough to probe accessibility of different regions in the catalyst particles.[3,4] Here we outline a study with complementary tomography methods to address this problem.

**Experimental/methodology.** An industrial propane dehydrogenation catalyst consisting of zeolite and amorphous silica binder was studied at different aging stages (Figure 1). Ptychographic X-ray computed tomography (PXCT) was performed for each catalyst at PSI – cSAXS beamline. Additionally, the fresh and harsh aged sample were impregnated with Cu solution serving as a fluorescent marker. These impregnated samples were studied by X-ray fluorescence tomography (XRF-CT) at MAX IV – NanoMax beamline.

**Results and discussion.** The combination of PXCT and XRF-CT enables to locate regions of coking and reveal pore accessibility in 3D space. PXCT provides quantitative information about electron density of the studied samples. This can be used to distinguish between binder and zeolite phases within the catalyst particles. Coke species formed in the pores lead to an increasing electron density. PXCT revealed that coke is predominantly formed within the pores of the binder and not the zeolite, but the resolution is not sufficient to probe the accessibility of pores. Complementary XRF-CT shows that the overall uptake of Cu ions used as fluorescent markers is reduced by more than 90 % comparing the harsh aged to the fresh sample. This reveals an important distinction that mainly coking of the binder phase leads to deactivation of the catalyst, not coking of the active zeolite component, even though the results of coking on the fate of the catalyst performance may be similar. The findings allow a future rational tailoring of the catalyst towards higher stability by increasing the coking resistance of the binder, highlighting the unique information available to hard X-ray tomography which cannot be obtained with contemporary characterization methods.

**Keywords:** operando ellipsometry, water splitting, electrocatalysis

**Introduction**

The reduction-oxidation transformations in the nm-thick diffusion layer near the electrode surface can be characterized by the Faraday current, or, by *in situ* probing methods. We used for the first time *in situ* ellipsometry [1] to study the sub-nanometer thick film formation of an anode catalyst in a quantitative and time-resolved way.

**Experimental/methodology**

Novel catalytic systems for water splitting use 1st row transition metals – including molecular catalysts – instead of noble metals. Several of our oxygen-producing anode catalysts alter during use, demonstrated *via* electrochemical characteristics, low-resolution solution spectroscopy, or *ex situ* surface analysis. The rapid initial processes, *e.g.*, molecular precursor decomposition and formation of a stable, catalytically active film on the electrode, are difficult to study and therefore they remained less explored so far [2,3]. The present study explored the initial stage of film formation from a molecular Cu-peptide pre-catalyst [3], and the dependence of the film properties on the applied potential.

**Results and discussion**

*In situ* ellipsometry established a correlation between the identified redox transformations and the film formation. The electrochemical-ellipsometric cell accommodated our indium tin oxide (ITO) or fluorine-doped indium oxide (FTO)-coated working electrodes used for the catalysis and an electrolyte with a composition optimized in our earlier study [3]. Electrochemical processes were controlled with a potentiostat-galvanostat. The solution layer at the working electrode was probed by ellipsometry, giving the thickness, depth-inhomogeneity with 0.5 nm resolution, and quantitative spectral properties of the resulting film; this has been corroborated by SEM and XPS measurements.

**Keywords:** Manganese; cobalt; catalyst deactivation; steady-state rate; deoxygenation

**Introduction:** Deoxygenation is a highly significant means of generating oxygen-free hydrocarbon fuels from liquid biomass. This study will deoxygenate sludge palm oil (FFA % = 42.35%) in an $H_2$-free atmosphere through a series of Mn-Co supported AC catalysts ($MnO_{0.5}CoO_{0.5}$/AC, $Mn_{0.5}Co_{0.5}S$/AC and $Mn_{0.5}Co_{0.5}P$/AC). The XAS in-situ results confirm that the preparation method of formation the catalyst structure was successful.

**Results and disscusion:** The catalytic results show that by oligomerizing unsaturated fatty acids produced during Diels-Alder reactions or radical additions, the $MnO_{0.5)}CoO_{0.5}$/AC can largely enhance the production of heavy products. It is a straightforward process to transform these heavy products into coke species, which enables the rapid deactivation of the catalyst. This study additionally showed that AC-supported sulphide and phosphide Mn-Co catalysts are hugely beneficial for steadily and reliably acquiring an above-average yield of diesel-range hydrocarbons at substantially reduced temperatures whilst simultaneously effectively impeding catalyst deactivation during deoxygenation. The deactivation kinetic study conform that the deactivation happens by the coke formation and flow the second order deactivation In this work, the effects that different catalyst structures have on deactivation and yield have been thoroughly investigated by deoxygenating several catalysts, including $Mn_{0.5}Co_{0.5}P$/AC, $Mn_{0.5}Co_{0.5}S$/AC, and $MnO_{0.5}$ $CoO_{0.5}$ /AC. In this study, the reactant feedstock was sludge palm oil with a high acid value and FFA content in excess of 95%. The feedstock oil was comprised of fatty acid units (both saturated and unsaturated). The results indicate that each of the three catalyst types successfully deoxygenated the feedstock by removing the oxygen in the forms of carbon monoxides, carbon dioxides, and water. What's more, the results show that the formation of heavy products during the oligomerisation of unsaturated fatty units when Diels-Alder reactions or radical additions are carried out is substantial. However, the application of metal oxide and metal sulphide catalysts can improve this by converting hydrogen into coke species. This is a relatively simple process. In this context, this study demonstrated that metal phosphide supported catalyst for deoxygenation has two significant advantages. First of all, it plays an important role in producing higher yields of diesel range n-hydrocarbon. Secondly, it can be effective in slowing down catalyst deactivation caused by the build-up of coke.

**Keywords:** copper-nickel catalysts, specific surface area, metal surface area, reducibility

**Introduction.** Copper-nickel catalysts represents a catalytic system suitable for converting of biomass-derived feedstocks into sustainable chemicals or biofuels. The advantage of the transitional metals is, besides their affordable price, the ease of the preparation, possibility to prepare different bimetallic compositions having diverse interactions with the support and, thus, different reducibility and metal dispersion resulting in tunability of their catalytic properties.

**Experimental/methodology.** $Ni/Al_2O_3$, $Cu/Al_2O_3$ and bimetallic $Ni\text{-}Cu/Al_2O_3$ catalysts varying in Cu and Ni content were prepared using wet impregnation. Metal oxides reducibility was studied by temperature programmed reduction by hydrogen ($TPR\text{-}H_2$). The number of surface nickel sites was determined by hydrogen pulse chemisorption and copper surface area was obtained by reactive frontal chromatography ($N_2O$ chemisorption). Specific surface area was evaluated by $N_2$ physisortion.

**Results and discussion.** Both metal sites, nickel as well as copper are accessible at the catalyst surface after a reductive treatment. The number of accesible surface sites depends on the reduction temperature and the respective metal content in the sample. However, the reducibility is strongly influenced by metal support interactions as well as by interactions between the individual metals in the bimetalic catalysts (Fig. 1).

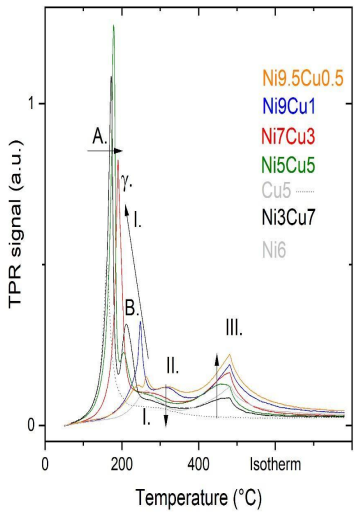

**Fig. 1**: $TPR\text{-}H_2$ of $Cu\text{-}Ni/Al_2O_3$ catalysts (ambient to 480 °C + 1 h isotherm). Peak A, B: Cu species, Peak γ: Cu+Ni species, Peak I - III: Ni species.

**Keywords:** electron transfer, metal support interaction, XFEL, pump-probe XAS

**Introduction.** A turnover in catalysis happens between the ms to s scale. However, an elementary step within a turnover can be as short as ps to fs second scale. It is therefore important to shoot a complete molecular movie of a catalytic process. Such understanding will improve the catalyst design towards better activity and selectivity. Here we report the dynamics of metal (Cu) – support ($CeO_2$) electron transfer during a catalytic process with an X-ray free electron laser (XFEL). The electron transfer from $Ce^{3+}$ to $Cu^{2+}$ takes **2 ps**[1-2] This result indicates the electron donation from $CeO_2$ support is almost instantaneous and explains the role of widely used $Ce^{3+}/Ce^{4+}$ redox pair in catalysis, such as the three-way catalyst and solid oxide fuel cell.

**Experimental/methodology.** 2wt% CuO-$CeO_2$ catalysts are prepared *via* a hydrothermal method.[3] The catalysts are pumped with a 267 nm laser (150 fs width) and probed with an X-ray pulse (150 fs width) with energy between Ce $M_5$ and Cu $L_3$ edges (850 to 940 eV). The delay time is set between the X-ray pulse and the laser pulse. Auger electrons emitted from the sample are collected (AEY mode) to measure the ground and excited states of Ce $M_5$ and Cu $L_3$ edge X-ray absorption spectroscopy (XAS).

**Results and discussion.** Upon excitation of 267 nm laser, two reactions proceed:

$$h\nu + Ce^{4+} + O^{2-} \longrightarrow Ce^{3+} + O^{-} \qquad \text{eq.1}$$

$$Ce^{3+} + Cu^{2+} \longrightarrow Ce^{4+} + Cu^{+} \qquad \text{eq.2}$$

The first reaction is a photochemical reaction whereas the second reaction is a typical support-metal redox reaction. To determine the dynamics of both reactions, First, the difference in Ce $M_5$ edge XAS between the ground and excited state is studied at Ce M5 edge (Fig. 1a). At 0.2 ps delay time, a decrease of $Ce^{4+}$ intensity and an increase of $Ce^{3+}$ intensity is observed, confirming the presence of eq. 1. Second, the difference in XAS intensity between excited and ground states at $Ce^{3+}$ and $Ce^{4+}$ features are studied by varying the pump-probe delay time (Fig. 1b,c). The $Ce^{3+}$ excited state arrives within 200 fs, indicating the dynamics eq.1 is below 200 fs. The excited $Ce^{3+}$ decays via electron transfer to $Cu^{2+}$ (eq.2) with an overall process within 2 ps (Fig. 2b). Third, the $Cu^{2+}$ dynamics is studied at Cu $L_3$ edge, also showing the reduction of $Cu^{2+}$ within 2 ps. Combining both the dynamics of $Ce^{3+}$ and $Cu^{2+}$, we confirm that eq.2 requires 2 ps only.

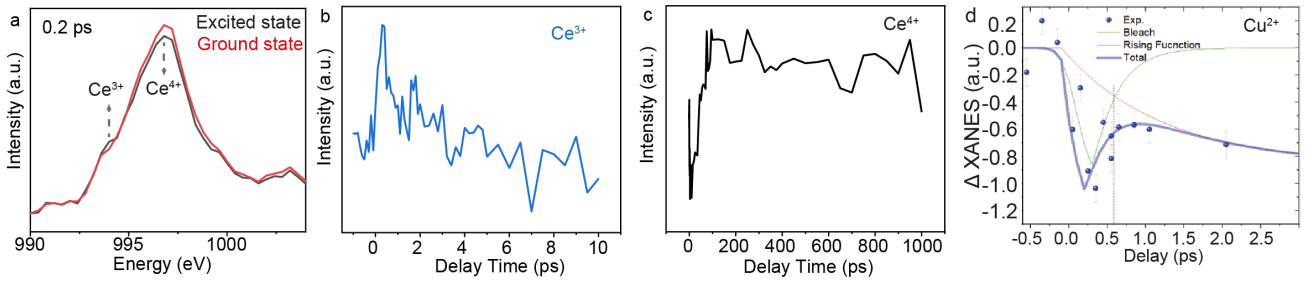

**Figure 1. a** Ground and excited state Ce $M_5$ edge XAS at 0.2 delay time. **b-d,** The difference between excited and ground state intensity of **b**, $Ce^{3+}$, **c**, $Ce^{4+}$ and **d**, $Cu^{2+}$ in the Ce $M_5$ and Cu $L_3$ XAS as a function of pump-probe delay time.

Our study is the very first step to shooting the molecular movie of a complete catalytic process. With more XFEL facilities and beamtimes available, the understanding of catalysis fundamentals will be significantly improved.

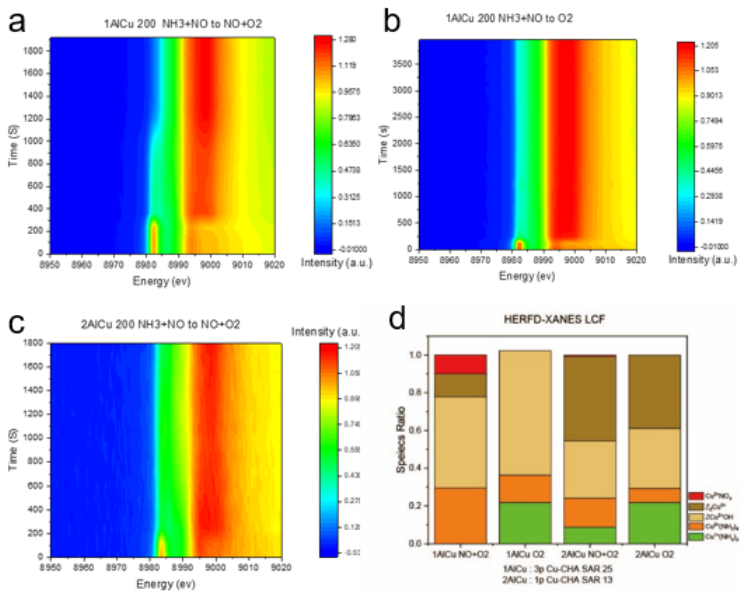
# *In situ* XAS and XES studies of Cu-CHA catalysts for Selective Catalytic Reduction (SCR) Reaction



Zhipeng Wang, Prof. Ryan Wang

**Keywords:** Cu-CHA, SCR, Nitrate, X-ray Absorption Spectroscopy, X-ray Emission Spectroscopy

**Introduction.** NH3-selective catalytic reduction (SCR) of NO is an effective method to meet the EU07 standards in 2027. The commercial Cu-CHA system still face challenges at low temperature, in particular the oxidation half cycle (OHC). Two different Cu active species were analyzed by *in situ* X-ray Absorption spectroscopy (XAS), High energy resolution detection fluorescence- X-ray absorption near edge spectroscopy (HERFD-XANES) and valence to core-X-ray Emission Spectroscopy (VtC-XES). Based on our understanding in heterogeneous catalysis, the reaction mechanisms are structure dependent so different active sites will favour different reaction mechanisms. In the Cu-CHA catalyst, at high Cu loading, there are a variety of Cu active sites with different structures. Those active sites have different ways of breaking O-O bond, including the dimer and nitrate mechanisms.

**Experimental/methodology.** The oxidation half cycle can be studied by switching from reductive NO + $NH_3$ atmosphere to NO + $O_2$ or pure $O_2$. The comparison between these two conditions can determined the role of NO in the $Cu^{II}NO_x$ mechanism. 1AlCu (3%Cu-CHA SAR25) and 2AlCu (1%Cu-CHA SAR13) were studied with time resolved *in situ* XAFS.

**Results and discussion.**

**Heat map (Figure a,b,c) and Linear Combination Fitting (LCF) result (Figure d) for 1AlCu and 2AlCu in different gas conditions**

At low Cu loading (< 1wt%) and 200 °C, the Cu is mainly in the form of 2AlCu and the reaction proceeds with dimer mechanism. This is based on the linear relation between $(Cu/Al\ ratio)^2$ and SCR rate as reported in literature. At high Cu loadings (> 1wt%) and 200 °C, a variety of 1AlCu, 2AlCu and CuO clusters are formed, leading to different reaction pathways that contain single-site (nitrate), dimer and cluster mechanisms. At 400 °C, regardless of Cu loading, the linear relation between $(Cu/Al\ ratio)^2$ and SCR rate is no longer observed. The Cu site is no longer mobile and coordinates with the framework oxygen. Therefore, both nitrate and cluster mechanisms are possible and dimer mechanism is less likely to happen.

# Evolution of Chemical States of Pt during CO Oxidation over the $Pt/CeO_2$ Dominated with Pt-O-Ce and PtOx

Mingzhi Wang, Yige Zhang, Zhuangzhuang Wu, Yanping Zheng, Zhaohui Zhou, Weizheng Weng*

*State Key Laboratory of Physical Chemistry of Solid Surfaces, Department of Chemistry, College of Chemistry and Chemical Engineering, Xiamen University, Xiamen, 361005, PR China*

**Keywords:** Ionic Pt, PtOx, metallic Pt, CO oxidation, *in situ* IR

**Introduction.** $CeO_2$ supported Pt catalysts play an important role in exhaust emission catalysis. Because of the interactions between catalyst and reactants under complex reaction conditions, Pt species may exhibit dynamic structural changes as a function of the reactant pressure and reaction temperature, making it difficult to determine the structure-performance relationship. In this study, the chemical states and dynamics of several typical Pt species, including PtOx, Pt–O–Ce and reduced Pt nanoparticles (NPs), in CO oxidation reaction and their correlations with activity were explored.

**Experimental.** The $Pt/CeO_2$ catalysts with Pt loading of 1wt% were prepared by impregnation method using $H_2PtCl_6$ (CPA), $(NH_4)_2PtCl_6$ (AHCP), $(NH_4)_2PtCl_4$ (ATCP), $(NH_3)_4Pt(NO_3)_2$ (TAPN) and $(NH_3)_4PtCl_2$ (TAPC) as precursors. After impregnating for 24 h, the samples were dried at 80 ºC and calcined in 21%$O_2$/$N_2$ mixture at 400 ºC for 4 h with a heating rate of 2 ºC/min. The obtained catalysts are denoted as $Pt/CeO_2$(CPA), $Pt/CeO_2$(AHCP), $Pt/CeO_2$(ATCP), $Pt/CeO_2$(TAPN), and $Pt/CeO_2$(TAPC). CO oxidation activity measurements were performed in a fixed-bed quartz tube reactor with 5 mm inner diameter using 1%CO/1%$O_2$/He (30 mL/min) as reaction feed. The reactor containing 50.0 mg catalyst was heated from 20 ºC to 350 ºC at a rate of 2 ºC/min with subsequent cooling and repeated heating in the reaction mixture.

**Results and discussion.** Based on the results of Raman, $H_2$-TPR and $O_2$-TPD characterizations, it can be concluded that the $Pt/CeO_2$ catalysts prepared with anionic Pt precursors (i.e. CPA, AHCP, ATCP) generate mainly Pt–O–Ce species that interact strongly with $CeO_2$, while those prepared with cationic Pt precursors (i.e. TAPN, TAPC), the PtOx species with relatively weak interaction with the $CeO_2$ are mainly formed. It was found that, for the CO oxidation over the oxidized catalysts, the Pt–O–Ce species with strong Pt–O bonds remained in the ionic state during the light off reaction, while PtOx species that interacted weakly with $CeO_2$ could be easily reduced to metallic Pt, which also exhibited better activity due to the enhanced reducibility of the Pt NPs-$CeO_2$ interface. Although the initial activity of the $Pt/CeO_2$ catalyst can be improved through reduction with $H_2$, the metallic Pt NPs, especially derived from the reduction of Pt–O–Ce dominated catalysts, can get reoxidized to the less active $Pt^{n+}$–O–Ce (n = 2–δ) species during the light off reaction (Fig. 1 & 2). A detailed *in situ* characterization revealed that the oxidation of metallic Pt NPs arises from oxygen reverse spillover from the $CeO_2$ support. This study shows that understanding the reaction-driven structural dynamics of Pt species is essential for exploring the reaction mechanism and elucidating how the catalyst is activated and deactivated in the reaction.

**Keywords:** PdH, $^1$H NMR, DFT, Pd@PdO core shell

**Introduction.** $^1$H chemical shift of the β phase over powdered palladium as a function of hydrogen pressure to be in between 20-34 ppm between vacuum and atmospheric pressure was reported by various studies[1]. Less commonly, a shielded peak is reported by solid state $^1$H NMR studies in the literature[2] and assignment of this signal to α-PdH was discussed[3]. Herein, we report an experimental and DFT study which was conducted to reveal nature of the $^1$H NMR chemical shifts of α and β PdH phases in Pd/$TiO_2$.

**Experimental/methodology.** A home-built high-vacuum glass manifold was used to probe $H_2$ adsorption under *in situ* conditions where the catalyst (10wt% Pd/$TiO_2$) resided in the sample chamber of a 43 MHz Magritek Spinsolve NMR spectrometer. NMR data was collected using Spinsolve Expert Software. For DFT calculations, we used projector augmented wave (PAW) method as implemented in VASP (Vienna *Ab-Initio* Simulation Package)[4]. The DFT–NMR chemical shift calculations were performed based on the linear response GIPAW method[5].

**Results and discussion**. In situ NMR measurements revealed that the appearance of the shielded peak at ~ -20ppm (Figure 1- left) was only observable if PdO was partially reduced. The results supported DFT estimations revealing similar NMR chemical shifts due to hydrogen adsorbed at the interface between the metallic core and surface segregated oxide layers of palladium (Figure 1 - right). For fully reduced Pd, DFT estimations shows a linear dependency of $^1$H chemical shifts for 0.02≤H/Pd ≤1, due to the anionic character of hydrogen atom within the local electronic structure. This result posed an additional coverage dependency on the β hydride signal in addition to the fast exchange interpretations between β hydride and α hydride phases. This finding was also supported by the $^1$H NMR spectra of β PdH collected at higher pressures (not shown).

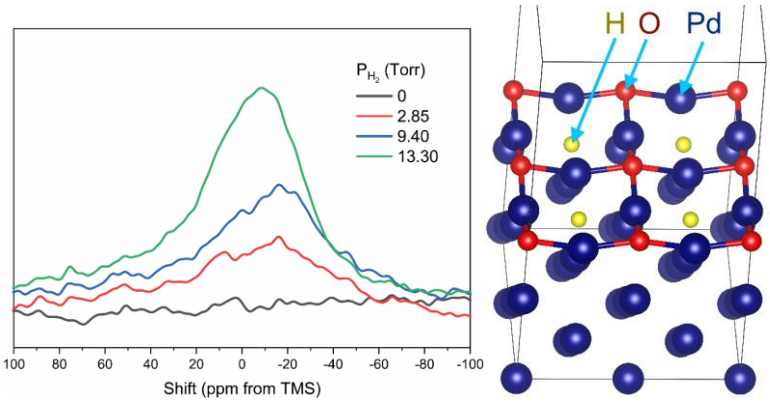

**Figure 1. $^1$H NMR spectra (left) over pre-reduced 10wt% Pd/$TiO_2$ under low $H_2$ pressures give rise to a shielded resonance, DFT estimations of the NMR shifts assign this resonance to protons accomodated between a metallic core and oxide shell (right)**

**Introduction.** With a world production of more than 2.75 million tons of maleic anhydride (MA) in 2018[1] and an expected growth rate of 6.7 % until 2025,[2] MA represents one of the key intermediates in chemical industry. Since the 1970's, the ternary vanadium phosphorous oxide (VPO) system is well known for its catalytic activity in the partial oxidation of *n*-butane to MA. However, despite this high economic importance, and approx. 50 years of research, a clear picture of the atomistic details of both the reaction mechanism and the respective active catalyst surface is still lacking. Part of the problem is the inherent complexity and chemical flexibility of the V-P-O system that makes a comparison of VPO catalysts of different origins extremely challenging.

**Experimental/methodology**. Industrially the VPO catalyst's activity is reversibly reduced in the process by continuously co-dosing a P containing species e.g. trimethyl phosphate (TMP) at a ppmv level. [3] Since such low amounts of P-species already result in a decisive reduction of activity, these P-species have to directly interact with the active centres on the VPO surface. This interaction is utlizied in the present study to gain knowledge about the active centres on a state-of-the-art inductrial VPO catalyst (SynDane®) via selective poisoning at different P levels. This way of modifying the catalyst surface led to a series of differently active VPO catalysts without any changes in the preparation that could impact the catalyst performance as well.
Using this approach, we report a multi-method approach with complementary techniques (XPS, FTIR, SEM, XRD, TG-MS) to identify and analyse active centres for the activation of *n*-butane on the VPO catalyst surface.

**Results and discussion.** Kinetic measurements done on fully equilibrated VPO catalysts after P poisoning confirms that such a P-treatment leads to a reduction of the active centres for the *n*-butane activation without changing the reaction barrier. At higher P-dosing, the appearance of a highly active but unselective surface state is detected. Via an analytical multi-method approach, this state of the catalyst is related to the appearance of β-$VO(PO_3)_2$. FTIR measurements with CO as probe molecule on all the differently P-doped VPO catalysts reveal several surface adsorption sites. A thorough deconvolution of the IR dataset and quantitative comparison with the P surface concentration and the kinetic data identifies two CO adsorption species being directly correlated with the active sites for *n*-butane activation! A deeper analysis of the FTIR spectra allows first speculations about the number and chemical nature of these sites responsible for *n*-butane activation on the VPO surface.

[*]*calligaro.rudy@spes.uniud.it*

**Keywords:** Ball milling, Ceria, $Ce^{4+}/Cu^{+}$ interfaces, methane activation, *in-situ* DRIFT, *operando* NEXAFS,.

**Introduction.** Ceria/Copper interfaces are of particular interest because of their unique capacity to activate small molecules for their valorization.[1,2] In this work ceria-copper composites were prepared by ball milling on the hypothesis that mechanical energy may facilitate a charge transfer between $Ce^{3+}/Ce^{4+}$ and $Cu^{2+}/Cu^{+}$ redox couples. This contributed to create catalytic sites with superior reactivity in methane activation as shown by a multi-technique approach which couples *in-situ* DRIFTS and *operando* soft X-rays NEXAFS spectroscopies.

**Experimental/methodology.** A series of catalysts with a $CeO_2$ loading between 20% and 80% wt. were prepared by mixing $CeO_2$ and CuO in a ball mill and compared with samples prepared by impregnation. Materials were characterized by means of XRD, TPR, BET, SEM, *in-situ* DRIFTS and *operando* NEXAFS. Theoretical calculations were performed in order to confirm the experimental results.

**Results and discussion.** The *operando* NEXAFS experiments performed on the $CeO_2$/CuO milled samples has shown the formation of $Cu^{+}$ and the disappearence of $Ce^{3+}$ during the activation phase at 300°C under inert conditions, thus demonstrating a promotion of charge tranfer between $Ce^{3+}$ and $Cu^{2+}$. Moreover, in contrast to the behaviour of impregnated samples and to the pure CuO and $CeO_2$, in the milled samples activation of methane at the relatively low temperature of 250°C occurs, as evidenced by formaton of methoxy and formate species upon exposure to a a 10%$CH_4$/He atmosphere. The intensity of the $Cu^{+}$ feature increased during the exposition to methane atmosphere, thus indicating the pivotal role of $Cu^{+}$ atoms in its activation. During the exposition in pure He the features related to this copper species remained stable, and disappeared following exposition in 5%$O_2$/He atmosphere, in agreement with the fate of methoxy and formates observed by DRIFTS. Traces of the partial oxidation products (formaldehyde and methanol) were observed in addition to $CO_2$ and water by monitoring reaction products during the *operando* NEXAFS. Repeated cycles of $CH_4$/He/$O_2$ returned the same results confirming a reversible behaviour. Theoretical calculations support the experimental evidence of a charge transfer between $Ce^{3+}$ and $Cu^{2+}$ and show that oxygen vacancies are easily created at the interface between the two oxides. Moreover, methane activation through C-H bond cleavage at the interface is considerably facilitated compared to the two isolated parent oxides, in agreement with DRIFT measurements.

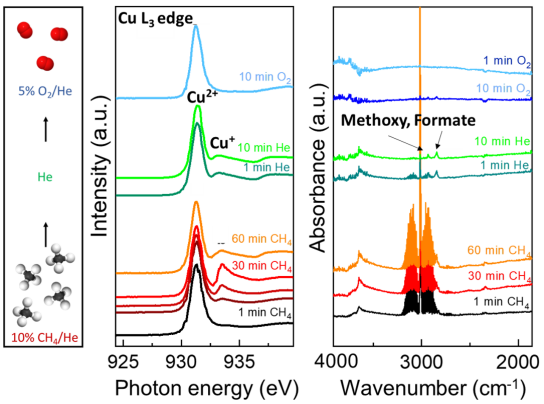

**Figure 1:** evolution of the Cu $L_3$ adsorption edge (left) upon exposure to methane (red), inert (green) and oxygen (blue) and corresponding DRIFT spectra (right).

**Keywords:** XRD, Tomography, MTH, Shaped objects

**Introduction.** Most frequently the academic sector studies pure catalyst powders, while in industry catalysts are usually formulated into objects whose composition, size and shape are optimized for a given process and reactor. Extrudates in cylindrical (Fig 1a) or other shapes are common, but spray-dried particles [1] (Fig 1b) can also be used. We recently used *operando* X-ray diffraction computed tomography (XRDCT) to image cylindrical extrudates using crystal structure parameters [2-3], showing how radial coking gradients develop in such objects during MTH [4]. In this work, we use *operando* XRDCT to follow the coke burning process during temperature-programmed oxidation (TPO) of the coked cylindrical extrudates.

**Figure 1: *a*) Photo of cylindrical extrudates. *b*) SEM picture of spray dried spheres**

**Results and discussion.** Fig 2a shows the evolution of radial coke gradients with temperature during TPO, which suggests that coke is removed from inside out. XRDCT with a spatial resolution of 300 nm on coked spray dried spheres (Fig 2b), show an even spread of coke through the whole object, suggesting that there are no diffusion limitations within the small spheres and consequently, that the latter shaping process could be worthwhile. Nano-CT imaging of the spheres (Fig 2c) at the same spatial resolution confirm the distribution of bubbles and alumina support crystallites in the walls of the spheres in 3D.

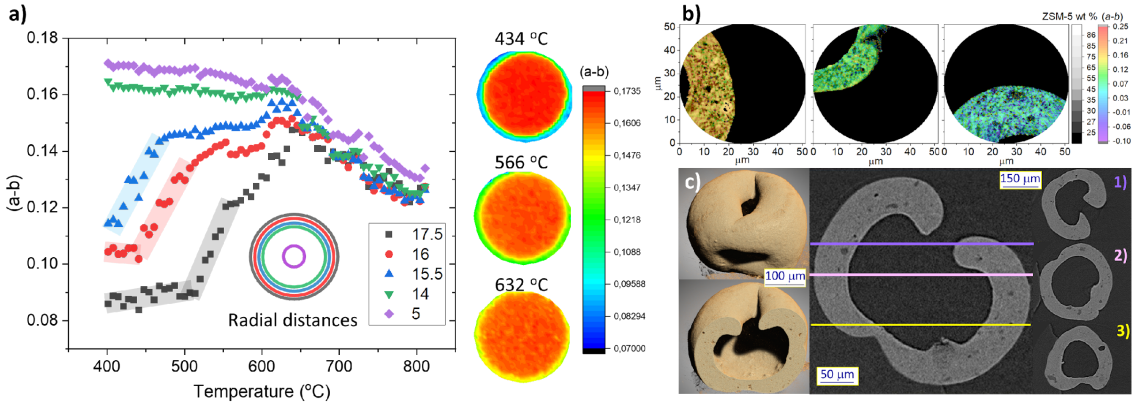

**Figure 2: *a*) XRDCT slices of a cylindrical extrudate at 3 temperatures during TPO and *(a-b)* descriptor evolution at different radial distances averaged. *b*) coke distribution in the sphere walls at 0.3 µm$^2$/pixel resolution for fresh, partially and fully deactivated spheres. *c*) Nano-CT 3D reconstruction of the sphere showing voids and density variations in the walls**

# Crystallite Size Dependent Oxidation of Ni Catalysts Revealed by *in situ* Magnetometry

D. de Oliveira[1], N. Fischer[1], M. Higham[2], C.R.C. Catlow[2] and M. Claeys[1,*]

[1]*Catalysis Institute, University of Cape Town, Cape Town, South Africa*

*michael.claeys@uct.ac.za*

**Introduction.** Nickel catalysts are known for their industrial use in both steam reforming and methanation reactions[1]. In addition to being active for these two reactions, Ni is also used in the $CO_2$ methanation reaction, which has gathered much recent interest due to the global climate crisis and need to lower $CO_2$ emissions[2]. $CO_2$ methanation has the potential to act as a means of energy storage of renewable forms of energy, which have an intermittent supply. In these reactions, the catalysts are exposed to the presence of steam, high temperatures and high pressures. Deactivation typically occurs *via* sintering and carbon deposition, however some studies have also reported small amounts of oxidation[1]. This observation is particularly interesting, since the oxidation of nickel is not thermodynamically feasible at the conditions relevant to these processes. This observation is thought to be due to the size dependent oxidation of nano-crystallites[3]. This work investigates the size dependent oxidation of a model nickel catalyst system, using an *in situ* magnetometer.

**Experimental/methodology.**, The catalysts were prepared by homogeneous deposition precipitation. These were reduced at both 400 °C and 700 °C to produce the nanoparticles with 2 different sizes. The in house developed UCT *in situ* magnetometer[4] was used to conduct the oxidation testing experiments, which was carried out at 250 °C under a simulated gas environment of $H_2O/H_2$ while the magnetic measurements were recorded. The $P_{H2O}/P_{H2}$ was varied from 0 to 400 to induce the oxidation of the catalysts, with each condition being held at 1 hour.

**Results and discussion.** The samples reduced at 400 °C and 700 °C had average sizes of 4 nm and 8 nm respectively, with nanoparticles distributed over the support (Figure 1A-B) and minimal overlap of size distributions (Figure 1C). Since Ni is the only magnetic phase in this system, a decrease in the magnetization indicates the oxidation of Ni to a non-magnetic phase (such as NiO or a Ni-based support compound). Figure 1D shows that the smaller nanoparticle size is more susceptible to oxidation, with the 3.5 nm sample oxidizing significantly at a $P_{H2O}/P_{H2}$ of 30, while the 7.5 nm only oxidized at ratio of 200. These results were then validated against thermodynamic calculations for the size dependent oxidation, which showed good agreement with the experimental results, providing direct evidence for the size dependent oxidation behaviour of Ni nanoparticles.

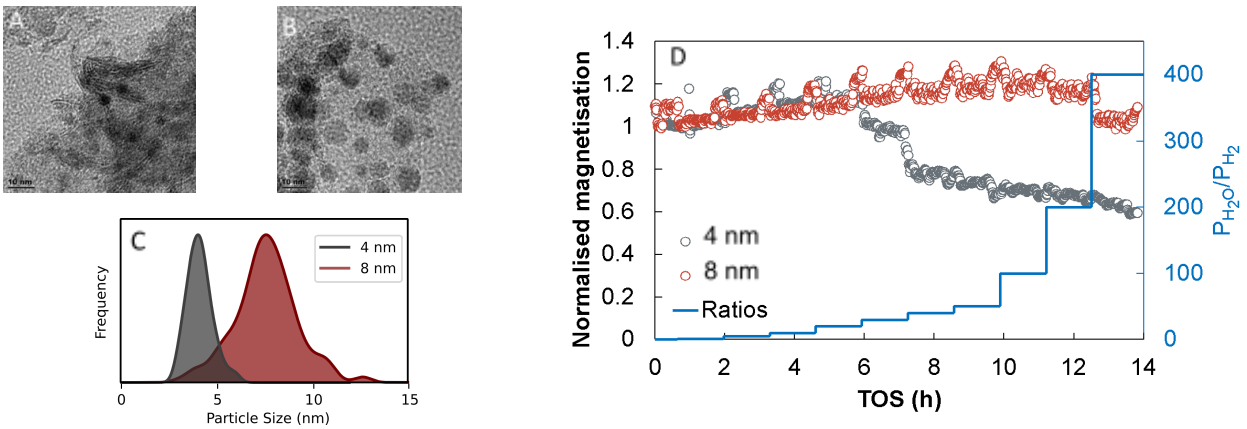

**Figure 1: A) TEM images of 4 nm sample B) 8 nm sample and C) size distriubtions. D) Oxidation testing results from magnetometry experiments.**

**Keywords:** Fuel Cell Hydrogen, CO-PrOx, $Co_3O_4$ Nanoparticles, Support Effects, *In Situ* Characterisation

**Introduction.** The preferential oxidation of CO (CO-PrOx) to $CO_2$ remains the most viable catalytic process for removing the trace poisonous amounts of CO (0.5 – 2%) in the $H_2$-rich reformate gas mixture before being fed into polymer electrolyte membrane fuel cells. Cobalt(II, III) oxide ($Co_3O_4$) is a promising catalyst for CO-PrOx but often undergoes deactivation *via* reduction to $Co^0$ at high reaction temperatures (>200 °C) because of the high amounts of $H_2$ (40 – 75%) in the CO-PrOx feed [1]. The presence of $Co^0$ causes an undesired change in the conversion pathway of CO from oxidation to hydrogenation, thus forming $CH_4$ instead of $CO_2$. Therefore, this (already published) study [1] aimed at anchoring $Co_3O_4$ nanoparticles (NPs) on various metal oxide support materials to evaluate their effect on the phase stability as well as the CO oxidation activity and selectivity of $Co_3O_4$ NPs under model (or dry) CO-PrOx conditions.

**Experimental.** Supported $Co_3O_4$ catalysts (with 10 wt.-% $Co_3O_4$) were prepared *via* the incipient wetness impregnation of the supports $ZrO_2$, $TiO_2$-rutile, $TiO_2$-anatase, and $Al_2O_3$ with aqueous $Co(NO_3)_2.6H_2O$. *In situ* catalyst characterisation and evaluation during CO-PrOx involved instruments developed at the University of Cape Town (South Africa), namely, a low-frequency vibration sample magnetometer [2] and PXRD capillary-based reaction cell [3], between 50 and 450 °C at atmospheric pressure, using a GHSV of 60000 $mL/g_{Co3O4}/h$. The reaction feed composed of CO (1%), $O_2$ (1%), $H_2$ (50%), and $N_2$ (48%).

**Results and discussion.** The $Co_3O_4/ZrO_2$ catalyst achieved the highest $CO_2$ yield (91.5%), followed by $Co_3O_4/TiO_2$-rutile (60.7%), $Co_3O_4/TiO_2$-anatase (51.5%), and $Co_3O_4/Al_2O_3$ (26.6%) at 200 °C. However, the degree of reduction (DOR) of $Co_3O_4$ to $Co^0$ was highest on $ZrO_2$ (100.0%), followed by $TiO_2$-rutile (85.9%), $TiO_2$-anatase (76.4%), and $Al_2O_3$ (16.2%) at 450 °C. In the spent $Co_3O_4/TiO_2$-anatase catalyst only, $TiO_x$-encapsulated $CoO_x$ NPs were observed *via* STEM analysis. Undesired $CH_4$ production occurred over the $Co^0$ NPs formed on $ZrO_2$ (100%), $TiO_2$-rutile (73.7%), and $Al_2O_3$ (57.8%), while no $CH_4$ was formed over the $Co^0$ NPs on $TiO_2$-anatase possibly due to their encapsulation by $TiO_x$ species. The observed trends in terms of $CO_2$ yields and DOR can be attributed to the nature of the nanoparticle-support interactions (NPSI) in each supported catalyst. For example, the weak NPSI in $Co_3O_4/ZrO_2$ resulted in high CO oxidation activity *via* the Mars-van Krevelen mechanism, which requires the catalyst surface to be easily reducible and re-oxidisable [4]. However, these weak NPSI also led to the undesired high DOR and $CH_4$ yield reached at 450 °C. On the other hand, the strong NPSI in $Co_3O_4/Al_2O_3$ caused the catalyst to be the least reducible and least CO oxidation active.

**Keywords:** Catalytic support, NMR cryoporometry, Diffusion, Porous media, Tortuosity

**Introduction.** Many heterogeneously-catalysed industrial processes are diffusion-limited. In addition, many processes suffer from solids deposition, liquid condensation, and/or sintering of the catalyst, such that the pellet structure evolves during usage. In many processes, the harsh thermochemical conditions mean that only amorphous materials can be used, since delicate controlled pore-size materials rapidly degrade. Hence, there is a need to understand how the random pore structure influences mass transport, to the extent that the tortuosity factor can be predicted. However, the typically complex, hierarchical nature of pellet structure often means that a so-called "brute force" approach is beyond the reach of current computing power, and some selection of the key structural features to incorporate in a model is necessary. In this work, the combination of NMR cryoporometry and pulsed-field gradient (PFG) NMR, known as cryodiffusometry, has been used to investigate the relative importance of different aspects of the void space, and various bins within the pore size distribution, to mass transport rates in bimodal amorphous gamma alumina support pellets, with different degrees of controlled macroporosity.

**Experimental/methodology.** NMR cryodiffusometry experiments, using water as the probe fluid, were performed using both boundary and scanning, and both melting and freezing curves, to comprehensively dissect the void space and isolate key features that determine mass transport rates. These experiments were coupled with complementary DSC thermoporometry to coroborate the cryoporometry results, and also FEG-SEM and FIB-SEM experiments to aid the interpretation of the NMR data.

**Results and discussion.** The shapes of the hysteresis loops in cryoporometry scanning experiments initiated from sample states, wherein the macroporosity was still frozen, have indicated differences in the incidence and pervasiveness of the macroporosity, to compare with statistics from the imaging data. The data was used to assess the contribution of the macroporosity to mass transfer rates, and also explore the rind effect detected in microscopy experiments, illustrated in Figure 1. The cryodiffusometry experiments have also been used to test for blinding of the interface between macropore and mesopore networks, that would greatly hinder Knudsen regime gas-phase transfer between the two [1].

**Keywords:** $NH_3$-SCR, chabazite, Cu, hydrothermal aging, dealumination, IR spectroscopy

**Introduction:** $NO_X$ selective catalytic reduction by $NH_3$ ($NH_3$-SCR) is commonly used to reduce emissions of polluting $NO_X$ from combustion engines exhaust gases. Of all known catalysts for $NH_3$-SCR, Cu-zeolites, and specifically Cu-CHA, present the best hydrothermal stability and performance in the 180-300 °C range, maintaining it for higher temperatures [1,2]. This makes Cu-CHA an important $NH_3$-SCR catalyst, as increasing fuel efficiency drives down combustion temperatures [2]. However, repeated exposure to the high temperatures of exhaust systems in the presence of water, may cause dealumination [3]. This deactivates the catalyst, since the Cu active sites are stabilized by the negative charge induced on the framework by Al atoms. This project aims to study the structure of Al and Cu after dealumination, and how differently dealumination affects zeolites with different Cu and Al contents.

**Experimental/methodology:** Fresh and hydrothermally treated (650 °C for 100 hours) Cu-CHA catalysts with different Si/Al ratio (6.7 and 15) and Cu content (0, 3.2 and 0.8 wt%) were characterized about their structural and textural properties and by in situ IR spectroscopy .

**Results:** XRD and gas-volumetric measurements indicate that after aging the crystallinity and textural properties of the samples are maintained. However, IR spectra collected in $N_2$ flow at 350 °C highlight that the intensity of the Brønsted sites signals (3600 and 3575 $cm^{-1}$) decreases after aging, whereas the intensity of the partial extraframework AlOH (3650 $cm^{-1}$) slightly increases in both Cu-CHA samples (Figure 1), indicating dealumination. Also, the Si/Al = 6.7 aged sample presents a new signal at 3624 $cm^{-1}$, which we attribute to newly formed Brønsted sites as a result of local structure damaging from dealumination. Further studies are ongoing to investigate the nature of the defective sites and the effect of dealumination on the Cu sites active in $NH_3$-SCR reaction.

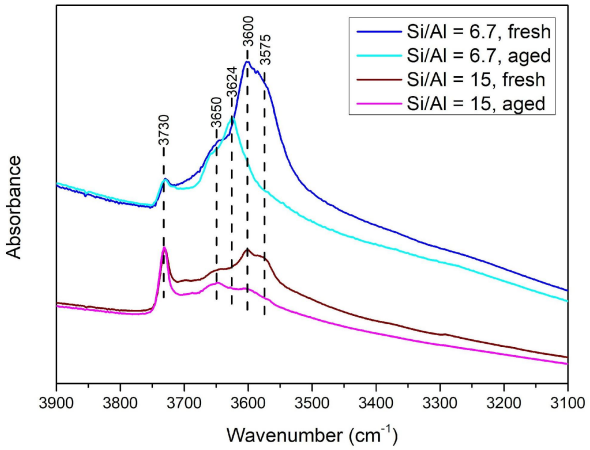

**Figure 1 - IR spectra of OH stretching region of fresh and aged Cu-CHA samples with 3.2 Cu wt% at 350 °C in $N_2$ flow**

**Keywords:** CO-Oxidation, Perovskites, Cobalt, DRIFTs, MES, Steady State Catalysis

**Introduction.** Perovskites are an interesting alternative to noble-metal catalysts, offering high flexibility in their composition and showing high reactivity in different reactions.[1-3] In this work, we focus on the most interesting $LaFe_{1-x}Co_xO_3$ catalysts (x=0 and x=0.25) from a previous study in our group.[1] The samples were studied via steady-state gas-phase analysis to estimate activation energies. To have a more in-depth look into the reaction mechanism, diffuse reflectance infrared Fourier transform spectroscopy (DRIFTS) combined with modulation-excitation-spectroscopy (MES) was employed.

**Experimental/methodology.** The precursors were synthesized via co-precipitation in an automated lab reactor (*OptiMax 1001, Mettler Toledo*) at 10 °C and a pH of 9.5. They were thermally decomposed to the perovskites in a muffle furnace at 600 °C under air atmosphere. Steady State CO-oxidation experiments were carried out in a home-build setup with a feed gas of 2% CO and 1% $O_2$ in nitrogen as a carrier gas over 100 mg of sieved catalyst (250-355 µm). Following a temperature programmed oxidation (TPO) at 250 °C, data was recorded in six steps from 100-250 °C for 2 hours per temperature. DRIFTS-MES was recorded on a *ThermoFisher Nicolet™ iS20* FTIR spectrometer with the *Praying Mantis™* (*Harrick Scientific Products Inc.*) accessory and a nitrogen cooled MCT-detector, coupled with *OMNISTAR™ GSD 320* mass spectrometer (MS) at four different temperatures per catalyst.

**Results and discussion.** The steady state studies showed a higher conversion and reaction rate for the Co-containing sample, as was expected from our previous study (Figure 1 a)).[1] The resulting activation energy of CO was also lower on that sample, supporting the findings of the transient experiments. The higher $CO_2$ rate was also observed on the Co-containing sample in the DRIFTS-MES experiments on the MS, which was corroborated by the $CO_2$ band in the IR spectra. Further analysis of the carbonate region showed interesting trends on the formation of different bands at different temperatures. Shoulders at 1569 $cm^{-1}$ and at 1354 $cm^{-1}$ are more pronounced at higher temperatures. Furthermore, a band at 1386 $cm^{-1}$ is seen predominantly on the Co-containing catalyst at lower temperatures. Phase delay analysis further revealed a faster formation of the carbonates at higher temperatures on the sample without Co, while the Co-containing sample showed only minor changes in the phase delay for all recorded species. Another point of interest is the hydroxide region, which is not visible on the Co-containing sample, but on the Co-free sample is clearly visible, especially at 200 °C. All these finding indicate a possible different reaction mechanism with different transition states, which is under further investigation through DFT-based calculations.

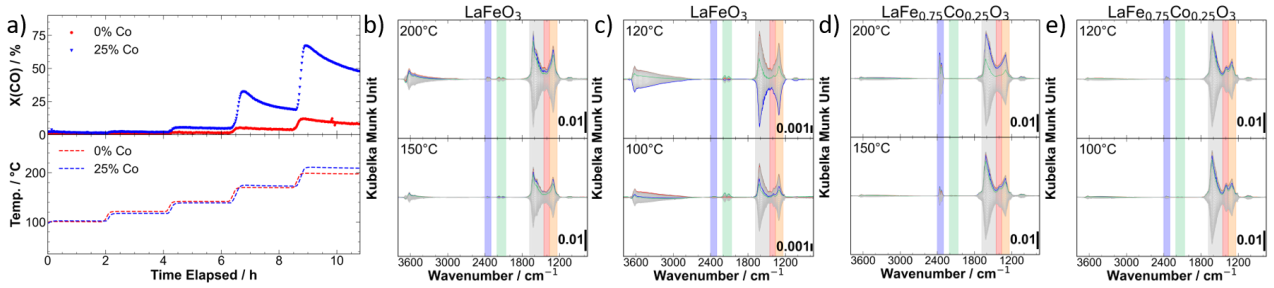

**Figure 1: a) CO consumption rate and temperatures during steady state experiments; MES spectra at 200, 150, 120 and 100 °C for the Co-free (b and c) and Co-containing (d and e) samples.**

**Keywords:** nano-shaped ceria, CO oxidation, CO-PROX, DFT calculations, reaction mechanism, DRIFTS

**Introduction.** Ceria-based materials have been extensively used as CO oxidation catalysts due to their unique redox features [1]. A particular niche of this application is the preferential CO oxidation (CO-PROX), which is the preferred catalytic strategy towards the removal of CO impurities from $H_2$ reformate streams. As an intrinsic characteristic of CO-PROX, CO selectivity drops with temperature, and the steepness of the fall mainly depends on the difference between the CO and $H_2$ oxidation reaction onsets. Interestingly, although there are comprehensive reports addressing the competitive nature between CO and $H_2$ oxidation reactions on $CeO_2$ -based catalysts, the underlying interaction of hydrogen with CO oxidation is still an unresolved question. Herein, we present a theoretical description of the CO-PROX reaction mechanism within the CO selective regime on the low-index $CeO_2$(111), $CeO_2$(110) and $CeO_2$(100) surfaces by means of periodic density functional theory (DFT) calculations combined with an experimental spectroscopic study.

**Experimental/methodology.** Polycrystalline ceria was prepared by simple nitrate calcination while $CeO_2$ cubes and $CeO_2$ rods were synthesized by adapting reported hydrothermal methodologies [2]. CO-PROX ($CO+O_2+H_2$) and CO-TOX ($CO+O_2$) operando DRIFTS experiments were performed to monitor surface species during the reaction. DFT(+U) calculations were performed with the VASP package implementing the Perdew–Burke–Ernzenhof (PBE) exchange correlation functional and projector augmented wave (PAW) potentials with a kinetic cut-off energy of 500 eV. Gibbs adsorption energies were computed and transition states (TS) for the relevant steps were located by means of the climbing image nudge elastic band method (CI-NEB).

**Results and discussion.** The low-index $CeO_2$ surfaces display different features that have a momentous impact on their catalytic behavior. In CO oxidation, the (110) termination of ceria is the most favorable due to a facile oxygen vacancy formation owing to its open structure**.** Our results reveal that hydrogen improves the interaction between CO and ceria, although the reaction onset is not lowered compared to the H2-free environment due to the lack of available O surface sites, which become hydroxylated in the presence of $H_2$. The carbonate to bicarbonate route is feasible on the (110) and (100) surfaces, but not on the main (111) facet, and only provided the reaction occurs at low temperatures [3].

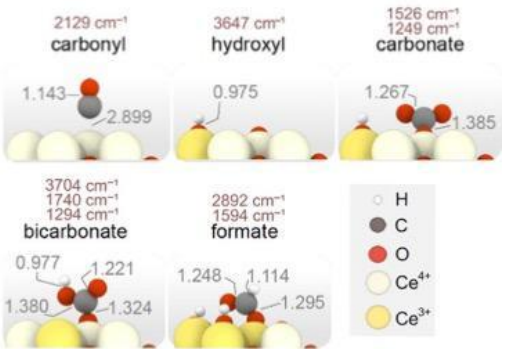

Figure. Adsorption modes for CO, $CO_2$ and $H_2$ on stoichiometric $CeO_2$(111), vibrational frequencies and bonding distances (in Å).

**Introduction.** Even if rather demanding, due to the high therodynamic stability of $CO_2$ molecules, catalytic valorization of $CO_2$ is important from both environmental and technological viewpoints. On one hand, it is crucial for efficient reduction of $CO_2$ emissions, yet $CO_2$ conversion can also provide such important market products, like e.g. synthesis gas, hydrogen or methanol. In this paper, our attention is focused on supported copper- and zinc-containing catalysts for $CO_2$ hydrogenation to methanol. For at least a decade, copper-based systems have been known to be active in this reaction. Commercial gamma alumina and cenospheres (Cen) from fly ashes have been tested as catalytic supports. The use of the latter support is an emblematic example of a circular-economy-based approach at designing catalytic materials. Our goal was to explain the effect of copper and zinc concentrations on structural, textural and functional parameters which can control the catalytic properties of the supported systems. Additionally, the effect of nature of both active phase and support has been understood and elucidated in more detail.

**Experimental/methodology.** Two series of γ-$Al_2O_3$- or cenosphere-supported catalysts, containing copper (0.5-10.0 mol.%) or a combination of copper and zinc (0.2-4.0 mol.%) as active components have been synthesized via modfied impregnation method. All samples have been calcined in air at 400°C for 4h. Commercial cenospheres of 300 mm in diameter have been used. The studied samples have been structurally (XRF, XRD, RS), texturally (SEM/EDS, porosimetry) and functionally (RS, DRIFT and UV/Vis-DR) characterized.

**Results and discussion.** The obtained results clearly suggest that for a given copper content, calcination temperature, nature of the support and the presence of zinc additives can influence the dispersion and speciation of copper sites exposed on catalyst surface. The same parameters can thus be decisive for both catalytic performance and stability of the studied systems. Cenospheres used as one of our catalytic supports distinctly favor stabilization of nanocrystalline CuO and ZnO 3D entities on catalyst surfaces, whereas γ-$Al_2O_3$ support facilitates higher dispersion of the deposited active components. In the latter case, only for copper contents above 10 mol. % the appearance of the CuO forms was confirmed. Regardless of loadings, heterogeneity of surface hydroxyls stabilized on cenosphere-supported catalysts was distinctly stronger in comparison to that observed for γ-$Al_2O_3$-supported samples. The presence of octahedral $CuO_6$ surface centers was confirmed for almost all investigated samples. Larger $CuO_x$ surface clusters were stabilized on catalyst surfaces at higher copper loadings. The addition of zinc additives modified surface architecture dependently on its loading and on the initial copper content.

# Kinetics of hydrogen release in mono- and bimetallic PdX nanoparticles probed by QEXAFS and synchrotron XRD

D.E. Doronkin[1,2*], T.J. Eldridge[1], S. Wang[2], S. Behrens[2], J.-D. Grunwaldt[1,2]

[1]*Institute of Chemical Technology and Polymer Chemistry, Karlsruhe Institute of Technology, Engesserstraße 20, 76131, Karlsruhe, Germany;* [2]*Institute of Catalysis Research and Technology, Kalrsruhe Institute of Technology, Hermann-von Helmholtz Platz 1, 76344 Eggenstein-Leopoldshafen, Germany*

[*]*dmitry.doronkin@kit.edu*

**Introduction.** Supported mono- and bimetallic Pd-based catalysts are the catalysts of choice for selective hydrogenation reactions such as direct hydrogen peroxide [1] and semi-hydrogenation of alkynes [2]. Under typical hydrogenation conditions (relatively low temperatures and high partial pressures of $H_2$) Pd nanoparticles are present as surface and bulk hydrides, and it is the hydride H which is believed to be the hydrogenating agent. The nature of hydride H is believed to define the hydrogenation pathways with surface hydrogen (typically found in α-$PdH_x$) being the selective "mild" hydrogenating species and bulk H (from β-$PdH_x$) favoring total (over-)hydrogenation reactions [2]. Alloying Pd with a second metal can be used to alter its H uptake capacity and therefore activity and selectivity of the resulting catalysts [3]. However, so far studies of hydride formation and decomposition of mono- and bimetallic Pd nanoparticle based catalysts were performed in the steady-state regime and it is still unclear how tuning the Pd nanoparticle size and shape as well as alloying Pd with other metals affects kinetics and the mechanism of hydrogen uptake and release including transformations between Pd metal, α-$PdH_x$, and β-$PdH_x$.

**Experimental/methodology.** A combination of quick scanning X-ray absorption spectroscopy (QEXAFS) and synchrotron XRD allowed probing realistic supported Pd and PdX (where X = In, Sn, Zn, Ga etc., approx. 6 wt% total metal loading on $TiO_2$ P25) hydogenation catalysts [4] with subsecond time resolution during fast switching of the gas atmosphere between pure $H_2$ and pure He at 298 K and 1 bar. A standard quartz capillary (2 mm o.d., 0.02 mm wall thickness) was used as an in situ cell with a plug flow geometry. Complimentarity of XANES/EXAFS (sensitive to both surface and bulk hydrides) and XRD (sensitive only to bulk hydrides) allowed indirect probing of H in the bulk and in the subsurface regions of Pd(X) nanocrystals.

**Results and discussion.** Combination of XAS and XRD with subsecond time resolution allowed establishing a multi-step pathway of hydrogen release from the surface and the bulk of Pd(X) nanoparticles which start with gradual β-$PdH_x$ lattice contraction and followed by stepwise abrupt restructuring to α-$PdH_x$ and Pd metal structures (indistinguishable by XRD, Fig. 1) with the corresponding rates obtaineble from QEXAFS (not shown). Changes in Pd particle size and shape as well as alloying Pd with other metals directly influence both the amount of stored hydrogen and kinetics of its release.

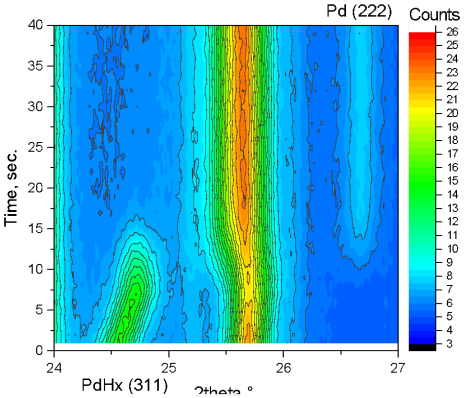

Figure 1. Temporal evolution of $Pd/TiO_2$ XRD patterns after switching from $H_2$ to He atmosphere.

# Operando XAS Study of Pd species during $H_2$-SCR of NOx

Thomas J. Eldridge, Michael Borchers, Patrick Lott, Dmitry E. Doronkin, Olaf Deutschmann, Jan-Dierk Grunwaldt

*Karlsruhe Institute of Technology (KIT), Karlsruhe, Germany*

**Keywords:** $H_2$-SCR, Operando, XAS

**Introduction.** Among strategies for reducing engine-out emissions, hydrogen has been investigated for use in combustion engines. For such applications carbon emissions are negligible, however, NOx still forms as a pollutant. In this case, selective catalytic reduction (SCR) of NOx using $H_2$ is a promising candidate. While $NH_3$ is commonly used as a reducing agent in SCR of NOx, $H_2$ shows higher levels of activity relative to $NH_3$ at lower temperatures and is convenient due to the direct availability from the fuel tank. However, a challenge of $H_2$-SCR is combating the competitive direct oxidation of $H_2$ to $H_2O$, which becomes the favored reaction pathway at high temperatures.[1] Additionally, besides direct $H_2$-oxidation, several reactions are simultaneously occurring over the catalysts bed, including $NH_3$ formation and subsequently $NH_3$-SCR, leading to gradients in reaction product concentrations and in catalyst structure. In this context, our study focuses on the indentification of the the different $H_2$-SCR stages along a catalyst bed by means of spatially resolved X-ray absorption spectroscopy measurements.

**Experimental/methodology.** A 1 wt.% Pd/5%$V_2O_5$/20%$TiO_2$-$Al_2O_3$ catalyst, previously investigated in our laboratories,[1] and several Pd containing zeolites samples were investigatedby QEXAFS measurements (DESY P64 beamline, PETRA III) under *operando* $H_2$-SCR conditions at multiple spatial positions along the catalyst bed, in order to study the formation and decomposition of oxides, hydrides, and nitrides expected to form on Pd-nanoparticles under $H_2$-SCR conditions.[2-4]

**Results and discussion.** Among the findings, the reduction of Pd species was observed for the 1 wt.% Pd/5%$V_2O_5$/20%$TiO_2$-$Al_2O_3$ catalyst during the $H_2$-SCR reaction at temperatures between 150 and 225 °C., according to linear combination fitting of XANES spectra, as shown in Figure 1. The corresponding and gradual increase in $H_2$ conversion across the same temperature range, as indicated by the light-off curve in Figure 1 (left), suggests that Pd reduces shortly before $H_2$ becomes active in SCR, which is in good accordance with previous observations [1]. Rapid oxidation of Pd occurs as NO converts and $H_2$ is consumed.

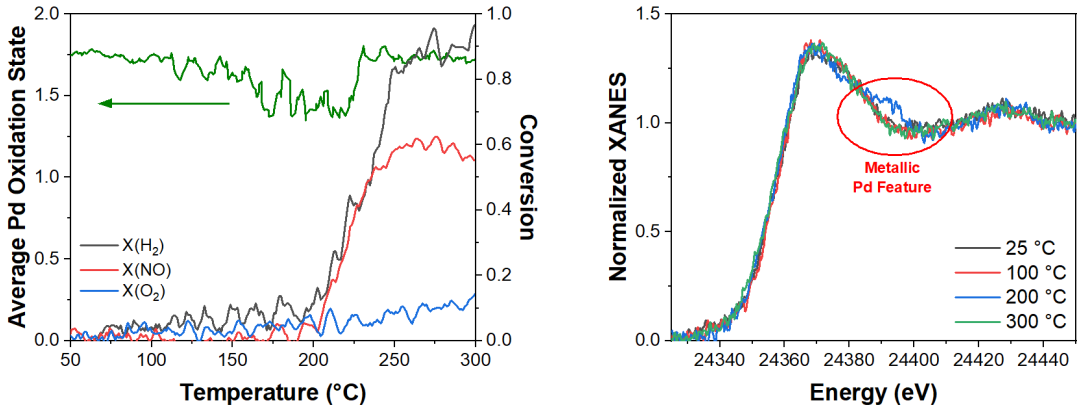

Figure 1: (left) ratio of oxidized Pd in a 1 wt.% Pd/5%$V_2O_5$/20%$TiO_2$-$Al_2O_3$ catalyst and corresponding conversions of $H_2$, NO, and $O_2$ as a function of temperature; (right) corresponding QEXAFS spectra at the Pd K-edge at different temperatures; 50 mL/min flow of 1000 ppm NO, 5000 ppm $H_2$, and 10% $O_2$ (He balance)

**Keywords:** Operando, Catalysis, X-Ray Absorption Spectroscopy, X-Ray Diffraction

**Introduction.** NOTOS [1] is the last beamline from the ALBA Synchrotron Light Source open to external users which started operation in April 2022. This beamline, co-funded by the European Regional Development Fund (ERDF) within the pluri-regional operational program of Spain, is devoted to XAS, XRD, and metrology applications in the energy range of 4.5 – 30 keV with the capability to perform XAS and XRD investigations in a quasi-simultaneous way. NOTOS, as a new tool open for the scientific community, allows to study the electronic structure, short- and long-range order by XAS and XRD within a wide range of scientific disciplines: chemistry, catalysis, energy science, nanomaterials, condensed matter and environmental science. In particular, NOTOS has been further developed to focus on *in situ* and *operando* measurements on heterogeneous catalysis and electrochemistry.

**Experimental/methodology.** Two different stations are available (Fig.1A,B). The first one consists of a 2.0 x 0.8 m table open to perform metrology measurements and suitable to XAS investigation in transmission and fluorescence mode by means of three ion chambers and one 13-elements SDD detector respectively. This endstation is being commissioned and is open to future developments, depending on the needs identified together with the user community, but it basically offers a big space to adapt for example catalytic reactors from the users in an easy way. The second station is equipped with a two circle diffractometer and 10-channel Ge(111) analyzer detector for high resolution XRD and a position sensitive detector for powder diffraction (Mythen, 6 modules). In this case, XAS can also be performed in transmission and fluorescence configuration. For both endstations, a setup to dose gases (up to 11 gas lines) at controlled flow (different flow ranges < 50 mL/min per gas) and pressure (currently up to 20 bar) and fully integrated in the beamline control system has been built (Fig.1C).

**Results and discussion.** In this contribution, we will show the new *state-of-the-art* tools that NOTOS offers and that can be applied to foster catalysis research.

# Understanding the Impact of Reaction Conditions on Methanation Catalyst Structure and Performance using *in-situ* Total Scattering

B. Fahl[1*], F. Manzoni[1], F. Müller[1], M. Zobel[1]

[1]*Institute of Crystallography, RWTH Aachen University, Aachen, Germany*
[*]*Benjamin.Fahl@rwth-aachen.de*

**Introduction.**
*In-situ* total scattering enables real-time observation of catalyst structures during catalysis for improved catalyst design and performance. We apply this technique to study the effects of hydrogen dropouts, emulating the fluctuations found in renewable hydrogen feedstocks, to optimize the methanation reaction [1]. Using a heterogenous urea precipitation-based Ni@γ-$Al_2O_3$ catalyst we follow particle growth and further structural changes while simultaneously tracking activity and selectivity with mass spectrometry (MS).

**Experimental/methodology.**
The pair distribution function (PDF) is a technique used in high-energy X-ray total scattering experiments to determine the pairwise distances of atoms in a material. This information can be used to study the size, structure and morphology of nanoparticles on a support [2,3]. By utilizing sensitive, fast 2D detectors at synchrotron radiation sources sub-second time resolution can be achieved. Moreover, our flow cell design permits for a sample environment that closely represents laboratory-based catalytic reactions, that we coupled with MS directly at beamline ID15 at the ESRF using an X-ray energy of 65 keV.

**Results and discussion.**
Our study demonstrates the utility of the *in-situ* PDF technique coupled with MS for investigating catalytic reactions in real-time. We were able to capture detailed structural information about the reaction process over a 6-hour period, including 5 catalysis and 4 drop-out cycles, with a time resolution of 100 ms (Fig. 1). By simulating real-world conditions, such as hydrogen dropouts in solar-based hydrogen production, we were able to examine how these fluctuations impact particle growth and deactivation. Additionally, we observed ongoing structural changes in the catalyst during extended dropout conditions, evident in the increasing lattice parameter during dropouts, while the lattice parameter remained comparably constant throughout methanation. These findings highlight not only the impact of dynamic conditions, but also the significance of prolonged hydrogen absence on the catalyst structure and performance.

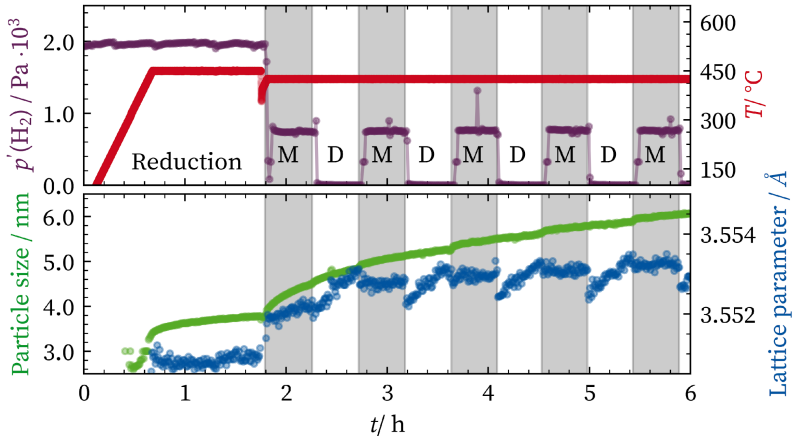

**Fig. 1 Structural evolution of Ni@□-$Al_2O_3$ methanation catalyst during reduction and catalysis refined from *in-situ* total scattering experiments. # Synthesis and characterization of mixed metal $NH_2$-MIL-125 based metal-organic frameworks for use as catalysts

Leidy Figueroa-Quintero[1*], Javier Narciso[1], Enrique V. Ramos-Fernandez[1]

[1]*Instito Universitario de Materiales (IUMA), Inorganic Chemistry Department, University of Alicante, Alicante, Spain*

[*]*leidy.figueroa11@ua.es*

**Introduction.**

Metal-organic frameworks (MOFs) are a class of crystalline micro-mesoporous hybrid materials with an extended three-dimensional framework that have shown a wide variety of potential applications. MOFs have great potential as heterogeneous catalysts and photocatalysts [1],[2]. The so-called $NH_2$-MIL-125(Ti) structure has photocatalytic activity and a very high specific surface area, which makes it a promising material for various photocatalytic processes. However, to make it more versatile and applicable to different photocatalytic reactions, it is necessary to precisely tune its band gap and valence band position. To achieve this, we have developed a post-synthesis methodology in which part of the metal constituting the MOF (Ti) has been replaced by another metal M (M: Ce, Zr, Nb or Sc). In this way, we were able to modify the photocatalytic properties of the MOFs. The synthesised materials were tested in the photodegradation of dyes.

**Experimental/methodology.**

For the synthesis of the starting material the following procedure was carried out: in a mixture of DMF and methanol was put titanium isopropoxide and aminoterephthalic acid with constant stirring, the mixture was heated at 150˚C for 24h and the solid was separated by centrifugation, being this washed 2 times with DMF to remove the unreacted ligand and 2 times with methanol and finally the material was activated at 150˚C under vacuum for 12h. To perform the metal ion exchange, the metal M salt was placed in a DMF:methanol mixture, then the starting MOF was supended, heated at 80˚C for 3 days and washed with methanol in a soxhlet extractor. The resulting materials were characterized by XRD, $N_2$ adsorption isotherms, TG, XPS, SEM, TEM, UPS and Uv-Vis.

**Results and discussion.**

The synthesized materials are crystalline, their XRD pattern matchs with the characteristic peaks of the starting MOF ($NH_2$-MIL-125), suggesting that the crystallinity of the material does not change with exchange. The morphology of the crystals also remained unchanged to the initial one (disk-shaped crystals). The specific BET surface area of the materials decreased (700-1000 $m^2/g$ aprox.) with respect to the starting MOF (1114$m^2/g$), however, the isotherms of all of them are characteristic of microporous materials (see Figure 1). All the materials show thermal stability up to 400˚C. The band gap of the materials was determined by UV-Vis diffuse reflactance, and it is evident that with the inclusion of M metals the value of this band has shifted to lower values, the band gap values are between 2.13eV and 2.41eV, which makes these materials can be used in photocatalysis under visible light.

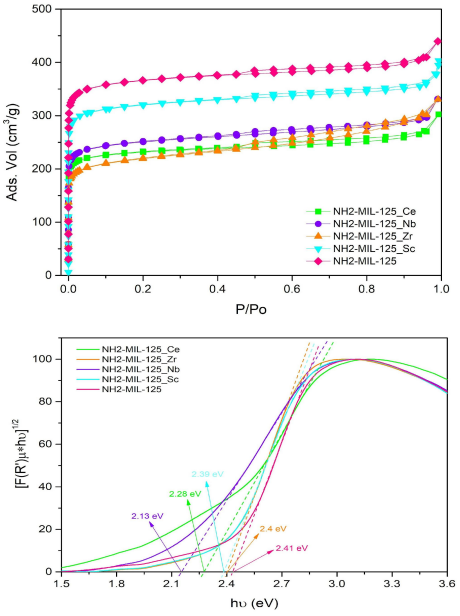

Figure 1. $N_2$ adsorption isotherms (up), Tauc Plots (down).

**Keywords:** Cu-MOFs, direct methane to methanol, operando spectroscopy

**Introduction.** The activation of C-H bonds is a key challenge in modern chemistry: indeed, considering partial oxidation reactions, the conversion of light hydrocarbons to the corresponding industrially valuable alcohols (e.g. direct methane to methanol, DMTM) would be a stepping stone towards a circular economy. Cu catalysts from biological origin, have proved their effectiveness in such processes but are fragile [1], while the synthetic analogues showed moderate activity and require reaction times beyond those applicable in an industrial context [2][3]. Cu-MOFs, featuring thermal and chemical stability intermediate of inorganic and organic systems, and containing a local Cu environment mimicking that of efficient enzymatic systems (e.g., LMPO) could overcome such limitations, potentially yielding a system with high turn-over frequency (TOF) and -number (TON) at mild temperatures.

**Experimental/methodology.** A set of potentially active Cu-MOF catalysts have been synthesized, thoroughly characterized and tested for DMTM. An isothermal (150 °C) stepwise protocol, adopting $O_2$ as the oxidant, was designed on the basis of previous literature.[3] Samples belonging to the UiO-6X family have been modified with bio-inspired anchoring sites for Cu ions. Beside basic characterization, each material has been investigated through operando spectroscopies (UV-vis and XAS), unveiling relevant details on the redox behavior of the Cu ions during the sequential reaction steps while quantitatively assessing the catalytic performances.

**Results and discussion.** Some of the considered materials (e.g., both Cu-UiO-66 featuring histidine as anchoring site and Cu-UiO-67 whose original linker has been partially replaced by methylated bipyridine) presented interesting features, exhibiting a quantitative redox cyclability among Cu(I)/Cu(II) by modifing the gaseous environment from inert to reducing/oxidizing. These materials also displayed excellent hydrothermal stability after the treatment, making them interesting candidate catalysts for the direct methane to methanol conversion at mild temperature.

**Keywords:** FT-IR spectroscopy, Acidic Oxides, Niobia, Phosphoric Anhydride, Silica.

**Introduction.** The $Nb_2O_5$-$P_2O_5$-$SiO_2$ (Nb-P-Si) mixed oxide system is reported as an environmentally friendly and performant solid catalyst in the field of conversion of biomass-derived chemicals [1-3]. In fact, the ensemble of moderately strong protonic acid sites and Lewis acid sites results in an efficient activation of n-type bases such as oxygenates compounds. The tunable distribution of both Brønsted and Lewis acidic sites combined with high stability towards hydrolysis given by Nb–O–P bonds make this catalytic system of increasing importance in industrial chemistry. In this work we report results on the nature and the amount of exposed acidic sites, that have been investigated through complementary techniques, and on ethanol and diethylether conversion on niobium-phosphorus-silicon mixed oxides.

**Experimental.** Two samples were prepared with different Nb/P molar ratio, whose nominal composition are $2.5Nb_2O_5{\cdot}2.5P_2O_5{\cdot}95SiO_2$ and $5Nb_2O_5{\cdot}2.5P_2O_5{\cdot}92.5SiO_2$, according to the hydrolitic sol gel synthesis procedure previuosly described [4]. Acid site titration has been carried out in solid-liquid phase using 2-phenylethylamine (PEA) as probe and by ammonia adsorption and thermodesorption (TPD) experiments. FT-IR surface transmission experiments have been carried out over pure powder disks activated in vacuum and following adsorption of Pyridine, Ethanol and Diethylether. Spectra of the pure powder disks were recorded at each adsorption/desorption step, using a Thermonicolet Nexus instrument (100 scans, DTGS KBr detector). Experiments on ethanol conversion have been realized both in the Temperature Programmed Reaction mode and in steady state conditions (1 mol%, and 2.5 or 3 mol% of ethanol in pure $N_2$ or in $O_2/N_2$ mixture) in tubular fixed bed reactor using FT-IR spectrometer as detector.

**Results and discussion.** Amorphous Nb-P-Si catalysts have been obtained with a combination of mesoporosity and microporosity and retaining a surface area around 400-350 $m^2/g$ after calcination. IR experiments show a quite heterogenous surface characterized by the presence of Si-OH, POH and/or NbOH groups. Therefore, the samples posses weakly acidity together with Brønsted acidity sufficiently strong to protonate pyridine and medium-strong Lewis acidity due to $Nb^{5+}$ exposed ions. Both IR experiments and ammonia adsorption and thermodesorption experiments indicate that acidity increases at increasing Nb concentration. On the other side, the use of a bulky molecules such as PEA for adsorption experiments in liquid phase evidences the different accessibility of acid sites, lower in the sample having the lower Nb content due to smaller micropores. It is confirmed that the increased amount of niobia results in an increased concentration of surface acid sites. These materials are active in the gas-phase, acid-catalyzed, ethanol dehydrogenation to ethylene starting from around 500 K, while the formation of diethylether is minimal. Traces of acetaldehyde from ethanol dehydrogenation are also detected. The sample richer in niobium is indeed more active. In our conditions, some catalyst deactivation is found, which is more significant at low temperature. IR spectra confirm the data of catalytic experiments, showing the formation of adsorbed species, likely alkoxides, that decompose mostly to ethylene above 500 K [5]. The spectroscopic analysis of the spent catalyst shows that the surface is still hydroxylated, with a small increase in the Bronsted sites/Lewis sites ratio.

**Keywords:** SMSI, operando electron microscopy, heterogeneous catalysis

**Introduction.**

Strong metal-support interaction (SMSI[1]), i.e. the reversible encapsulation of platinum group metals under reducing atmosphere and high temperature is known to modify the catalyst's adsorption properties, thereby altering its selectivity[2] and enhancing its resistance to sintering.[3] However, the details of how the overlayer interacts with the metal surface and the gas molecules during the catalytic cycle can only be studied operando since the system will undergo significant transformations when removed from the reaction chamber.(Environmental) TEM proved vital in this research[4] but despite significant discoveries, and partly due to resolution and pressure constraints,[5] the full picture of SMSI remained elusive.

**Experimental/methodology.**

We recently performed a series of operando TEM experiments in an attempt to expand the conceptual understanding of SMSI and its potential applications. Operando TEM, in contrast to environmental TEM allows to study the catalyst under high pressures, and therefore, insights into the catalyst structure under conditions typically used in catalysis studies is possible. As most of SMSI research traditionally focused on the catalyst's state under reducing atmospheres, little is known about the mechanism responsible for overlayer retraction, its state under reactive conditions or under oxidative conditions.

**Results and discussion.**

Our experiments revealed that the encapsulated state of platinum particles is maintained when the catalyst is exposed to oxygen at high temperature, in this case by an oxidized form of the SMSI layer.[6] Targeted encapsulation under oxygen prevents the evaporation and sintering of platinum when exposed to oxygen at high temperature.[7] The overlayer retracts in the co-presence of hydrogen and oxygen and, under reactive redox conditions, i.e. during the simultaneous presence of hydrogen and oxygen, the system adapts a dynamic behavior and thus reveals yet another manifestation of metal support interactions.[8]

The work shows that the state of the catalyst under reactive conditions differs significantly from the well-studied, classical SMSI state, highlighting the need for operando TEM studies for our understanding of the behavior of an active catalyst and thus, the structure activity correlation relevant for catalytic function. It also reveals how the exact sequence of treatments determines the stability of the nanoparticles induced by the presence respectively absence of titania overlayers. Reversible overlayer formation in oxygen has the potential to operate noble metal catalysts in harsh environments and to protect such catalysts from sintering during burn-off cycling.

# Lithium/copper/aluminum oxides based on LDH structures: redox and acidobasic properties

K. Frolich*, J. Malina, O. Chovanec, M. Hájek

*Department of Physical Chemistry, Faculty of Chemical Technology, University of Pardubice, Studentská 573, 532 10 Pardubice, Czech Republic*
**karel.frolich@upce.cz*

**Keywords:** LDH, mixed oxide, lithium, copper, aluminum, redox, acidobasicity

**Introduction**

Present contribution is dedicated to the preparation and characterization of layered double hydroxides (LDH) and derived mixed oxides comprising lithium (I) and aluminum (III) ions. The possibilities to introduce copper (II) ions during the LDH synthesis in order to produce precursors of Li-Cu-Al mixed oxides with tunable redox and acidobasic properties are studied. The aim is to highlight main specifics related to previously described copper (II) containing LDH/mixed oxides with Mg (II) ions and Al (III) ions (hydrotalcite-like materials). Prepared Li/Cu/Al LDH are considered as catalysts or catalysts precursors which can be exploited for example in the Guerbet reaction [1,2] for conversion of primary alcohols to higher alcohols, as it comprises de/hydrogenation steps (redox centers), aldol condensation step (basic centers) and dehydration step (acidic centers).

**Experimental**

The urea method [3] is introduced for preparation of the Li-Al type LDH precursors. A batch reactor with reflux condenser at atmospheric pressure was used for the co-precipitation. Respective amounts of lithium, aluminum (and copper) nitrates at specified molar ratios of metals were dissolved in redistilled water. Solution was transferred into a batch reactor, followed by heating near to the boiling point. The urea was added to adjust pH and start the co-precipitation of hydroxides. The LDH precursors were calcinated to obtain mixed metal oxides. The chemical composition of prepared LDH was studied by the ICP-OES. The phase purity and LDH to oxide transformation was studied by the X-ray diffraction. The textural properties were derived by the $N_2$-physisorption. The redox properties related to copper were studied by the $H_2$-TPR method. The acidobasic properties were studied by the $CO_2$- and $NH_3$-TPD methods.

**Results and discussion**

Sharp XRD diffraction lines related to the LDH structure verified succesfull synthesis of Li-Al LDH by the co-precipitation with urea. Well crystalline LDH products were obtained. LDH precursors precipitated with Li/Al molar ratio of 1/2 (maximum), a stoichiometric excess of lithium in the solution was needed. The addition of copper during the co-precipitation with urea led to production of ternary Li-Cu-Al LDH, but the amount of introduced copper was limited. The LDH precursors were transformed to mixed metal oxides, which properties were related to the metal ratio in the parent co-precipitation solution. Standard $H_2$ reduction profiles with repeated oxidation/reduction cycles suggested the interaction of copper with the Li-Al support. The desorption experiments showed that the total concentration of Lewis basic sites and population (density) of strong basic sites ($O^{2-}$) was higher to often studied LDH derived Mg-Al mixed oxides. LDH based Cu-Li-Al mixed oxides represent relatively cheap tunable bi-functional catalyst.

**Keywords:** Cu-based catalysts, EPR, copper distribution, copper relocation, redox properties

**Introduction**

Copper exchanged zeolites or molecular sieve are attractive because they facilitate various oxidation reactions and redox cycles.[1] This includes selective catalytic reduction of NOx using ammonia ($NH_3$-SCR), NO decomposition and selective oxidation of methane to methanol. Copper is present as several different species depending upon the local zeolite structure and has high mobility at reaction conditions which challenges the characterization and detailed knowledge about these catalytic reactions.[2],[3] In this work, we will try to investigate the distribution and mobility of copper species in Cu-molecular sieve catalysts with different topology (CHA, AEI, MOR). We are also aiming to investigate effects on copper distribution in Cu-MOR synthesized by solvent-free methods.

**Experimental/methodology.**

Copper molecular sieves are synthesized using aqueous ion exchange at different copper concentrations. Both commercial and synthesized zeolites have been investigated.

Powder X-Ray diffraction (XRD) patterns, Scan electron microscopy (SEM), Solid-state NMR, and X-ray fluorescence spectroscopy (XRF) were employed to investigate the physical and chemical properties of the catalysts. In-situ and ex-situ EPR experiments were conducted to investigate the distribution and speciation of copper species in these catalysts.

**Results and discussion.**

Figure 1. Cu distribution in different Cu-molecular sieves determined by ex-situ and in-situ EPR.

The amount of redox-active Cu species differs significantly between the samples, although they have a similar amount of EPR active Cu in the fresh samples. Cu-CHA possessed the highest amount of redox-active Cu. The redox-active Cu in Cu-CHA-10 and Cu-AEI-50 can be assigned to one type of copper site (Site B in Fig. 1). Xue et al.[4] concluded that Site B in Cu-SAPO-34 is the main active site in low temperature (100-200°C) SCR reaction. We propose that the small amount of Site B in Cu-AEI-50 is the reason for the observed poor redox performance at 150°C.

The series of samples with the MOR topology have comparable amounts of Site A and B. The amount of redox active copper is not influenced by the synthesis method.

**Keywords:** ammonia synthesis, cobalt molybdenum nitrides, ammonolysis

**Introduction.** The calculated volcano-shaped relationship between ammonia synthesis activity and nitrogen adsorption energy [1] indicates that the active sites consisting of cobalt and molybdenum atoms are located near the top of that curve. The high catalytic activity of Co-Mo nanoparticles supported on $CeO_2$ [2] and the bulk cobalt molybdenum nitrides $Co_2Mo_3N$, $Co_3Mo_3N$ [3,4] was experimentally proven. The method for the synthesis of cobalt molybdenum nitrides consists of the preparation of the oxidic precursor and the subsequent ammonolysis [5]. The parameters of the precipitation process affect the composition of the precursor, and properties of the catalysts. Despite the large number of works regarding cobalt molybdenum bimetallic oxides, there are very few reports about their transformation to the nitride state. Thus, this work focuses on the influence of the precursor structure on the active phase formation and catalytic properties of cobalt molybdenum nitrides.

**Experimental.** Oxidic precursors were obtained by precipitation from water solutions of cobalt(II) nitrate and ammonium heptamolybdate at different pH values controlled by the addition of aqueous ammonia. The ammonolysis of the precursors was investigated with the use of the reaction chamber attached to a diffractometer. This approach allowed *in-situ* X-ray powder diffraction studies of the ammonolysis process. The activity of catalyst in ammonia synthesis was measured with the use of a plug-flow laboratory reactor.

**Results and discussion.** The precursors obtained from acidic solutions consist of $CoMoO_4 \cdot 0.9H_2O$ phase, whereas those precipitated from basic solutions consist of $NH_4Co_2OH(MoO_4)_2 \cdot H_2O$ phase. The water removal from the $CoMoO_4 \cdot 0.9H_2O$ phase or water and ammonia removal from the $NH_4Co_2OH(MoO_4)_2 \cdot H_2O$ phase takes place during calcination, in the both cases resulting in formation of the cobalt molybdate $CoMoO_4$ phase. The further decomposition of the $CoMoO_4$ proceeds yielding the bimetallic oxide $Co_2Mo_3O_8$ and the cobalt(II) oxide CoO. Exposure of both oxides to the ammonia atmosphere results in the formation of the intermetallic compound $Co_3Mo$ and metallic cobalt as intermediates. During further nitriding these phases form cobalt molybdenum nitrides $Co_3Mo_3N$ and $Co_2Mo_3N$. The catalyst obtained from the precursor precipitated at pH 5.5 was composed of $Co_3Mo_3N$ and $Co_2Mo_3N$ nitrides, and the catalyst obtained from the precursor precipitated at pH 7.5 additionally contained the $Co_3Mo$ intermetallic compound. The catalyst obtained from the precursor precipitated at pH 7.5 was the most active. The presence of the $Co_3Mo$ intermetallic phase in the catalyst was shown to have a positive effect on the activity of these materials in the ammonia synthesis process. Both catalysts are more active in the ammonia synthesis reaction than the industrial iron catalyst.

**Introduction**

Nitrous oxide (N2O) is one of the most impacting greenhouse gasses that significantly contributes to climate change. In 2017, Europe alone emitted around 18 million tonnes of N2O, mainly from agricultural activities and the production of nitric acid. [1] Scientist are constantly searching for effective new deN2O catalysts that can be used in real-world applications. One crucial aspect of this research is the industrial aging of catalysts. This process simulates the conditions under which catalysts will be exposed to in industrial environments, including high temperatures and exposure to pollutants. By conducting representative industrial aging tests, researchers can gain a better understanding of how catalysts will perform over time in real-world settings and make necessary adjustments to improve performance and lifetime. Additionally, this process allows researchers to identify potential degradation mechanisms and optimize catalyst design, thus reducing N2O emissions in the final stages of catalyst use. In this study, the performance of Fe-FER and Fe-ZSM5 catalysts were evaluated through simulated industrial aging tests.

**Experimental/methodology**

Industrial Fe-FER and Fe-ZSM5 catalysts were prepared by the French company ALSYS on an industrial scale. [2] The catalysts were exposed to a simulated accelerated aging procedure, which was created to model a specific catalytic aging process. This was done to study the deNOx/deN2O catalytic behavior at the end of the catalyst's life. The deNOx/deN2O catalytic performance was tested under relevant industrial conditions in an Inconel reactor. The conditions for deN2O reaction were as follows: NO 70 ppm, $NO_2$ 30 ppm, $N_2O$ 900 ppm, $O_2$ 3.0%, $H_2O$ 0.3% and $N_2$ balance. The conditions for deNOx were as follows: NO 325 ppm, $NO_2$ 325 ppm, $N_2O$ 40 ppm, $NH_3$ 650 ppm, $O_2$ 3.0%, $H_2O$ 0.3% and $N_2$ balance. A very high space velocity was used to stress the differences in catalytic activity between the catalysts that were tested. The aging treatments were conducted for 150 hours at two temperatures, 600 and 700°C. The detector used was FT-IR coupled with a lambda probe for oxygen measurement.

**Results and discussion**

This study compares the catalytic activity of Fe-FER and Fe-ZSM5 catalysts for $NO_x$ and $N_2O$ abatement in a simulated nitric acid process. The study examines the structural, through XRD, and catalytic evolution of the catalysts upon aging under representative industrial conditions. The results show that Fe-FER has higher catalytic activity and structure stability than Fe-ZSM5, particularly after the aging procedure. Fe-ZSM-5 experiences loss in deN2O activity, while Fe-FER retains its catalytic activity under these conditions. The stability of the Fe-FER catalyst is believed to be responsible for its higher catalytic activity and better preservation of deN2O activity. The study also highlights the importance of using representative industrial aging treatments and real industrial test conditions when studying new catalysts, as these conditions can greatly affect the catalytic activity and structure of the materials. Further research is needed to fully understand the mechanism of the catalytic activity of Fe-FER and Fe-ZSM5 under real industrial conditions.

# The Power of Operando Lab-based X-ray Absorption Spectroscopy: Unravelling Synergistic Effects in Bimetallic $CO_2$ Hydrogenation Catalysts

N.S. Genz[1], A.-J. Kallio[2], F. Krumeich[3], S. Huotari[2], F. Meirer[1], B.M. Weckhuysen[1*]

**Keywords:** Lab-X-ray Absorption Spectroscopy, Operando Characterization, Multi-Metal Catalysts

**Introduction.** Thermocatalytic conversion of $CO_2$ towards value-added products constitutes a promising starting point to mitigate continuously increasing global $CO_2$ emissions and associated climate change. Ideally, the captured $CO_2$ is converted with only sustainably produced hydrogen into value-added products. However, for achieving this goal, the search for the optimal catalyst constitutes a major challenge. For the rational design of next generation catalyst formulations, appropriate characterization tools and performing *operando* experiments are indispensable for deducing a fundamental understanding of structure-performance correlations of catalysts.[1] In this context, the new possibility to perform *operando* lab-based X-ray absorption near-edge structure (XANES) analysis quasi-simultaneously at multiple absorption edges paves the way for a new era of catalyst characterization.[2] Here, we showcase the power of *operando* lab-XANES by unravelling insights into synergistic effects of bimetallic $CO_2$ hydrogenation catalysts.

**Experimental/methodology.** The catalysts comprise Ni-Fe and Ni-Cu bimetallics supported on a $SiO_2$ support with a total metal loading of 6 wt%. The self-designed *operando* lab-based XANES setup is based on a Johann geometry, where the spherically bent crystal analyzers are located in a crystal exchanger and the catalyst is deposited in a motorized sample cell stage being connected to a gas chromatograph.

**Results and discussion.** Based on detailed *operando* studies, we unraveled a correlation between decreasing Ni/Fe ratio and decreasing particle size, increasing reoxidation of the Ni and Fe species during $CO_2$ hydrogenation, and a shift of the product selectivity towards CO together with the production of C-C coupling products. Interestingly, the reducibility was found to be Ni/Fe ratio-independent except for a ratio of 2. Moreover, exchanging Fe by Cu induced a facilitated reducibility of the Ni species and a more stable selectivity during $CO_2$ hydrogenation with CO being the main reaction product, while the reoxidation behavior remained unaffected. The presented results from catalyst screenings with *operando* lab-XANES showcase the power of such studies and their importance for justifying and planning topically focused synchrotron-based studies, which, in combination with lab-based studies, are essential in taking steps towards a more rational design of improved catalysts and our journey towards a more circular society.

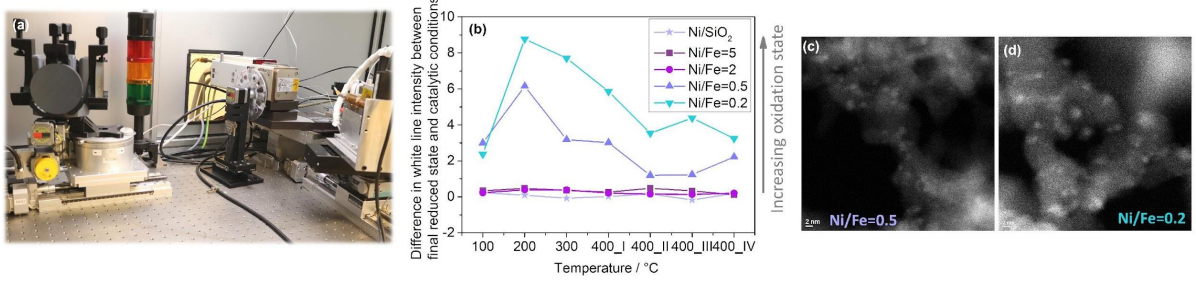

**Fig.:** *Operando* lab-based X-ray absorption near edge spectroscopy (XANES) setup (a), difference in the white line intensity of the Ni K-edge XANES under $CO_2$ hydrogenation conditions ($H_2/CO_2$=4, 1 bar, b), and high-angle annular dark field scanning transmission electron microscopy (HAADF-STEM) images for two different Ni/Fe ratios (c, d).

**Keywords:** singleatom catalysis, operando X-ray absorption spectroscopy, acetylene hydrochlorination.

**Introduction.** Vinyl chloride (VCM) manufacture via acetylene hydrochlorination is a longestablished industrial process that runs over toxic mercurybased catalysts,[1] demanding sustainable alternatives. Carbonsupported Pt singleatom catalysts (SACs) have emerged as compelling candidates owing to their high activity and unparalleled stable performance.[2] Still, their catalytic behavior is largely dependent on the metal speciation and properties of the carbon host,[2] calling for mechanistic studies to identify structureperformance relations and ultimately unlock the potential of carbonsupported metal SACs.

**Methodology.** Herein, we investigate the synthesis and catalytic function of Pt single atoms with varying $Cl^-$ ligand coordination on different carbons via operando Xray absorption spectroscopy.

**Results and discussion.** We unveil the role of Pt sites as the mediators of chlorine supply to the carbon matrix, which adsorbs $C_2H_2$ and catalyzes VCM evolution (**Fig. 1**). The chlorination activity is found to depend on the metal atom coordination environment, dictated by the synthetic strategy as well as the carbon host composition and properties. These insights, corroborated by the analysis of other noblemetal SACs, pinpoint the role of both the metal sites and the carbon host to develop acetylene hydrochlorination sustainable catalysts.

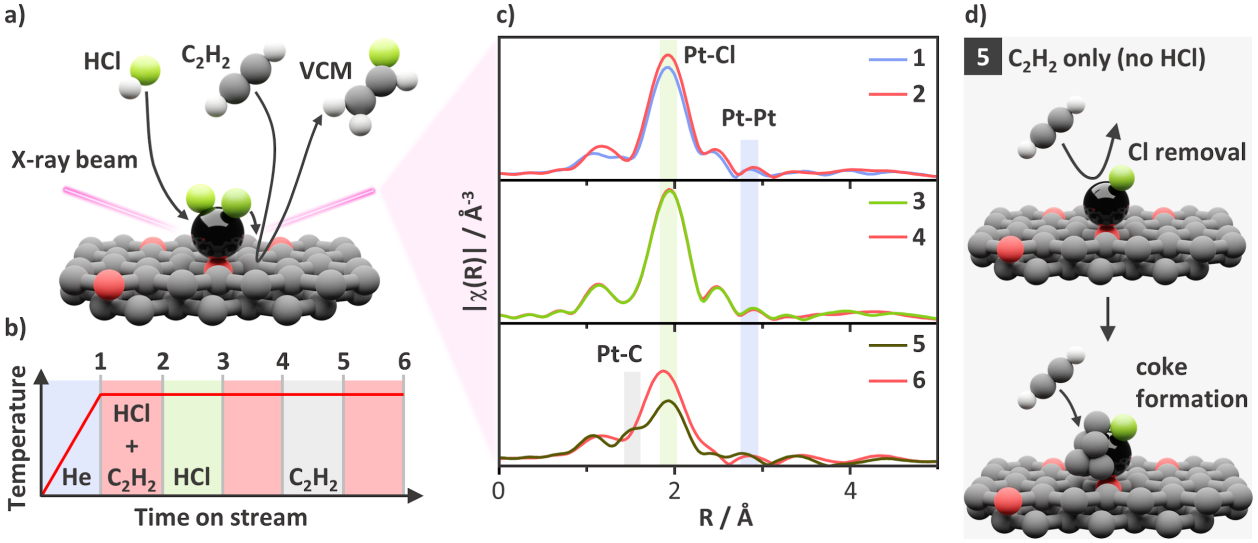

**Figure 1. (a) Schematic representation of the catalytic function of Pt single atoms derived via timeresolved XAS analysis (b) under varying reactive atmospheres, together with (c) the corresponding Pt $L_3$ EXAFS spectra. (d) Representation of the impact of a $C_2H_2$ atmosphere on the metal sites. In the absence of HCl, $C_2H_2$ progressively dechlorinates the metal site and binds onto it, eventually forming coke.**

# Methane oxidation to methanol by operando UV-vis-IR spectroscopy. The role of type, location and number of Fe sites in mordenite.

K.A. Tarach[1], J. Sobalska[1], A. Held[2], K. Góra-Marek[1]

[1] *Faculty of Chemistry, Jagiellonian University, Kraków, Poland*
[2] *Faculty of Chemistry, Adam Mickiewicz University, Poznań, Poland*

**Introduction.** Extra-framework Fe species are considered as the active site for the formation of an α-oxygen species which are formed by decomposition $N_2O$ over the α-$Fe^{2+}$ site. After oxygen addition mononuclear $Fe^{4+}=O^{2-}$ (or $Fe^{3+}$-$O^{\bullet-}$) or dinuclear oxo-bridged $Fe^{3+}O^{2-}Fe^{3+}$ species were proposed as the most appropriate models for the α-oxygen active site. Very recently, oxygen molecule activation over Fe-ferrierites was achieved by two cooperating distant Fe cations [1, 2]. This binuclear cationic Fe(II) centers are close enough to cooperate in splitting $O_2$ at RT resulting in the a pair of α-oxygen species. This reveal facile oxidation of Fe(II) cations can be explained by the unique topology of the ferrierite zeolite offering a proper Al atoms arganization in 8-MR channels, namely two negatively charged Al atoms in Al–O–Si–O–Si–O–Al sequence. In mordenite, the conditions required for balancing a bare divalent cation are met for the cations in 8-ring channels rather than in 12-ring channel. Therfore we investigated the catalytic performance of Fe-mordenites of various Fe loading and Al content assuming that this two papameters influence most the speciation of iron sites.

**Methodology.** The methane oxidation over Fe-MOR catalysts (Si/Al=8.4 and 14.6) of various Fe-loading (0.1, 0.5, 1.0 % wt.) and H-counterparts was monitored by *operando* DR-UV-vis-GC-MS and *operando* Vis-NIR-MIR-CG-MS to get the insigth into the nature of adsorbed species (IR) and recognize the coordination sphere and the evaluation of the metal–ligand interaction strength during the reaction (UV-Vis-NIR). Finally, the correlation between catalytic activity and selectivity was established.

**Results and discussion.** Our results indicate that at the lowest Fe content, the redox species are located in 8-ring channels forming either isolated $Fe^{2+}$or $Fe^{III}$-OH sites as major species in zeolites of lower and higher Al content in framwork, respectively. Methane oxidation to methanol identified by its IR and UV-vis spectroscopic features has to be assigned exclusively to α-O sites originating from $Fe^{2+}$ ions located in 8-ring channels. The mononuclear $Fe^{4+}=O^{2-}$ formed in the reaction of $Fe^{2+}$ with $O_2$ are more reactive than $Fe^{III}$-OH or binuclear $Fe^{III}$-(O)-$Fe^{III}$ in selective oxidation of methanol. The oxidation ability of the latter has however negative impact on methanol selectivity at higher temperatures.

**Introduction. Metodology.**Time-resolved IR spectroscopic studies conducted over a temporal range counted from seconds to several dozen milliseconds provide the possibility to detect short-living intermediate reactive species and their mutual relationships crucial for a thorough understanding of the reaction pathways. Rapid scan spectroscopy (IR, UV-Vis) enables to track the phenomena inherent to each catalytic process, i.e. diffusion, adsorption, and surface reaction, all of them in the appropriate time domain and under conditions required for the working catalyst (*operando*). Operando aproach successfully combines all the UV-Vis and IR spectoscopic characteristics with catalyst activity and selectivity and allows to describe reaction pathway under realistic conditions. Working in *operando* rapid scan regime (high temperature, flow conditions) results in collecting the very extensive spectrum data of extremely both low intensity and complexity of the bands. Implementation of two-dimensional correlation analysis to spectroscopic data (2D COS RS UV-Vis-IR spectroscopy) attained for catalytic processes affords identification of spectral features of intermediate species confined inside the micropores of zeolites and the sequence of the appearance of the intermediate on the catalyst surface.

**Results and discussion.** Transformation of zeolite-confined small hydrocarbons and hydrocarbons derivatives was investigated to define nanoscale effects, reaction path, thus catalytic properties. Several cases, most representative of the 2D COS IR and UV-vis methodology, are cited.

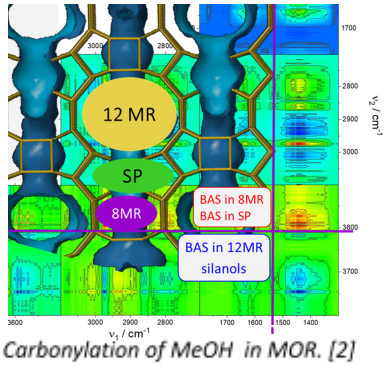

***Fig. 2.*** *Carbonylation of MeOH in MOR. [2]*

The roles of ketene and its derivates (i.e. acylium ion and surface acetyl) associated with direct C-C bond coupling during carbonylation reaction investigated thoroughly by 2D COS rapid scan IR spectroscopy [1, 2]. Unique acylium ion was observed exclusively in H-MOR confirming the specificity of the 8-MR pores activity. In contrast, the surface acetyl species were identified in H-SSZ-13 as the predominant species. The FT-IR time-resolved *operando* study revealed also that the reaction pathway in ethanol transformation over ZSM-5 is controlled by the proximity of aluminium atoms in the framework. The zeolite ZSM-5 containing mostly isolated Al atoms was found to transform ethanol in the associative pathway, while over ZSM-5 containing a dominating fraction of two aluminium atoms in one ring the ethanol molecules were converted in the dissociative route. The combined 2D COS UV-vis and 2D COS rapid scan IR methodologies were beneficial in resolving the EtOH oxidation path by defining the status of manganese phase and the speciation of surface intermediate species. Finally, the mechanisms of EtOH oxidation governed by the basicity of ZSM-5 were discriminated. All these findings indicate that the 2D COS spectroscopy is a versatile tool particularly addressed to understanding the transformation of small molecules confined in zeolites.

**Keywords:** copper oxides, cerium oxides, cerium-copper, ammonia oxidation

**Introduction.** Ammonia, $NH_3$, is one of the air pollutants thats' release is strictly monitored due to its high impact onto both, human's health and environment. Modern catalysis gives the opportunity to reduce the ammonia release by the application of the selective catalytic oxidation process ($NH_3$-SCO). This topic was the main theme of our previous research [1-3]. We studied the relation between physico-chemical properties of copper oxide species and its efficiency as catalysts of $NH_3$-SCO. We put the special effort to study aspects like copper accessibility on surface, its dispersion, reducibility or interaction with the Ce as surface dopant.

**Experimental/methodology.** Our work focused on the Cu-containing mixed metal oxides obtained by calcination of hydrotalcite-like materials at temperature 800 °C. The goal was to obtain the thermally stable material of complex phase composition, that will not show any effects of structure re-organisation (*memory effect*). At second step of study, we incorporated cerium onto the materials surface to study synergistic redox relation between the Cu and Ce.

Materials characterisation was performed with use of several techniques: XRD, $H_2$-TPR, $O_2$-TPO, $NH_3$-TPD, reactive frontal chromatography, SEM(EDS) or XPS. The catalytic test was performed in self-build quartz-flow reactor system with the online FTIR detection.

**Results and discussion.** Our materials were complex mixture of simple oxides (MgO, CuO) and the spinel structure of general stoichiometry close to $M^{2+}Al_2O_4$. We have found that the copper loading approx. 10 - 15 mol. % allowed total ammonia conversion up to 350 °C. However, the high catalysis activity was not accompanied by satisfactory $N_2$ selectivity. On the other hand, materials with lower Cu loading (5 - 7 mol. %) showed better $N_2$ selectivity, but lower catalytic activity. Comparison of catalytic tests results with the materials characterisation allowed us to connect the formation of bulk-like and dispersed forms of CuO with the catalysts activity and selectivity, respectively.

At the same time addition of cerium was found to improve both $N_2$ selectivity and activity, regardless the copper mol. % loading. The XPS technique reveals occurrence of monovalent/divalent forms of Cu and trivalent/tetravalent forms of Ce. It allows us to consider possible Cu-Ce redox interactions. Occurrence of copper-cerium pairs results in formation of oxygen vacancies, thus improvement of $O_2$ storage capacity. Present of vacancies changed the reaction pathway, leading to rapid changes of Cu and Ce oxidation states: $Cu^{+} \leftrightarrow Cu^{2+}$ and $Ce^{3+} \leftrightarrow Ce^{4+}$, followed by release/refill of $O_2$. Oxygen reacts with adsorbed ammonia leading to the improvement of $N_2$ selectivity.

**Keywords:** cobalt catalyst, ZSM-5 zeolite, silicalite, ethanol steam reforming, hydrogen production.

**Introduction.** In the face of climate change and the projected depletion of fossil fuel reserves, scientists are looking for alternative energy carriers. In this context, hydrogen is an important raw material, which production is becoming essential. It can be produced from bioethanol in the catalytic steam reforming process (ESR) using a wide range of catalytic systems including those based on the cobalt phase was investigated. The cobalt phase is usually spread over an oxide support e.g. $Al_2O_3$, $CeO_2$, or $SiO_2$ [1]. Zeolites with high porosity and a large specific surface area seem to be interesting to be applied as supports for the ESR cobalt catalysts. Relatively low interest in these materials results from their high selectivity towards the undesired $C_2H_4$ caused by their high acidity [2]. Fortunately, the path of ethanol dehydration to ethene can be significantly reduced or even eliminated by a controlled modification of the zeolite properties. The acidity of a zeolite catalytic system can be successfully adjusted either by doping with alkali or by decreasing the aluminum content in the structure.

**Experimental/methodology.** We synthesized a series of catalysts based on zeolite ZSM-5 with increasing Si/Al ratios (32, 750, Al-free zeolite) and different morphology (nanometric zeolite and micrometric) and tested their performance in the ethanol steam reforming process (500˚C, EtOH:$H_2O$ 1:12, 21 h). We have checked the effect of potassium introduction on the Co|ZSM-5 catalyst. The samples were characterized with a wide range of methods (e.g. XRD, *in situ* XPS, SEM, TEM/EDX, $H_2$-TPR, RS, TG/DSC) and studied with the unique *operando* UV-Vis and FT-IR spectroscopy technique under the ESR conditions.

**Results and discussion.** The results pointed out a key role of the zeolite support acidity and morphology and indicated that their adjustment allows us to get the ESR catalyst with extraordinary catalytic parameters. The best catalyst, based on Al-free nanometric zeolite indicated 100% conversion of ethanol with >90% selectivity to $H_2$, elimination of $C_2H_4$ production, and >160 h stability in reaction conditions. Such great performance of the catalyst corresponds to a relatively low degree of carbon deposit formation, confirmed by the extensive *post-mortem* characterization and in-depth insight into the reaction mechanism with *operando* spectroscopic ESR studies. We attributed the strong advantage of nanometric zeolite support to the highest reducibility and dispersion of the cobalt phase. We also obtained promising results for the potassium-exchanged high-silica (Si/Al = 750) catalyst, still, the sample cannot compete with the one based on pure silica zeolite. The results of this study overthrow the existing paradigm of low activity and stability of zeolite-based ESR catalysts, opening the way to the development of competitive catalysts with a high application potential. To this end, new synthesis protocols should be optimized to obtain pure silica versions of zeolite materials.

**Introduction**

The hydrodeoxygenation (HDO) is a crucial step for valorization of lignocellulosic biomass derived pyrolysis oils. It is commonly conducted in the liquid-phase at high pressures (up to 150 bar) and moderate temperatures (100-250 °C). As the fast pyrolysis of lignin is done at T ≈ 500 °C and $p$ ≈ 1 atm, these HDO conditions cause ineffective energy consumption and make it difficult to compete with cheap crude oil products.[1] Carry out the HDO process in gas-phase, would be an energy-efficient approach with regard to the entire process. This reaction can be done at 300 – 400 °C at normal pressure, near the pyrolysis conditions. Besides noble metal catalysts, $MoO_3$ is discussed as a catalyst that has a good activity and high arene selectivity.[2] In this study, we investigated Ni-doped $MoO_3$ catalysts, which tend to form a metal molybdate phase. Their catalytic behavior was tested, and investigations to understand the formation of active phases were performed.

**Experimental/methodology**

Phase pure $MoO_3$ and $NiMoO_4$ catalysts were used, as well as Ni/$MoO_3$ catalysts, where Ni is embedded as $NiMoO_4$. The Nickel loadings were 1 wt.% and 5 wt.%. Catalytic tests were conducted in a fixed-bed flow reactor for the gas phase HDO with anisole as a model substrate at 325 °C and $p$ = 1 atm. Additionally, liquid-phase experiments were performed for comparison. In-situ XRD experiments were carried out to elucidate the active phase with a hydrogen/hydrocarbon treatment. Experiments using DRIFTS, TG-MS and XPS were conducted for supplementation.

**Results and discussion**

In most catalysts, a $MoO_xC_yH_z$ phase was observed after the reaction. This phase seems to have an influence on the catalytic activity, in agreement with reported results.[3] In the case of catalysts containing a small amount of nickel, the content of the $MoO_xC_yH_z$ phase was significantly increased (Fig 1.). It was also observed that phase pure $NiMoO_4$ is highly active, but shows a comparatively high methane selectivity. In these catalysts, the $MoO_xC_yH_z$ phase was not detected after the reaction nor during in-situ XRD experiments. The nickel is assumed to be the most active phase for hydrogen activation in this system. The obtained results will be compared to catalytic performance with other substrates (e.g., benzene) to gain further insights into the behavior of different active phases and the different factors for optimizations.

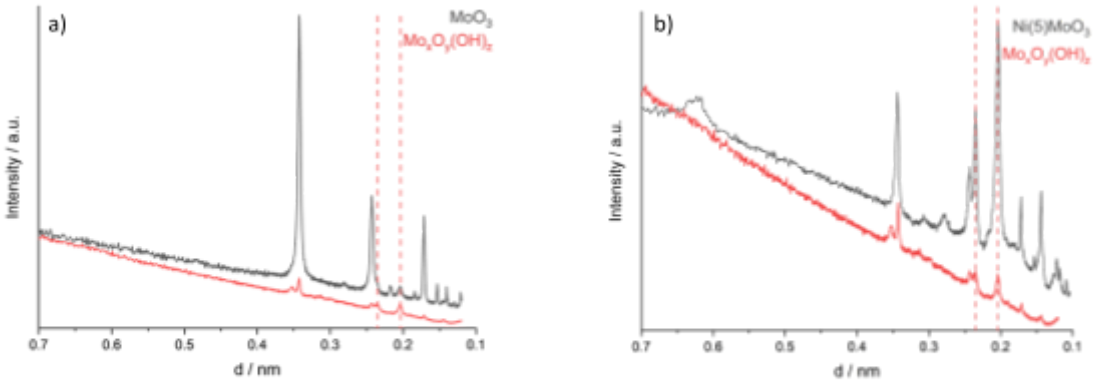

**Figure SEQ Figure * ARABIC 1:a) Formation of $MoO_xC_yH_z$ in $MoO_3$ b) Formation of MoOxCyHz in Ni(5)$MoO_3$ compared to the result starting from molybdenum blue ($Mo_xO_y(OH)_z$) Both treated at 325 °C in $H_2/CH_4$ (1:1); — $MoO_xC_yH_z$ phase**

**Introduction.**

To be able to face the challenges brought on by climate change, there is an urgent need to reduce the heavy dependence on fossil fuels. Bio-oil is one such renewable and carbon-neutral replacement that has shown promising potential. A key step in making bio-oil commercially feasible is the improvement of the catalytic hydrodeoxygenation (HDO) process. [1] One method to further develop the process is to improve the catalyst performance by the addition of promoters. Nickel and cobalt have commonly been used as promoters for Mo-catalysts [2], but there is potential for further improvement of the catalysts if other promoters can be found. This study aims to investigate the effects of adding four different noble metals to Ni-Mo oxide catalysts supported on δ-$Al_2O_3$ using two different synthesis methods.

**Experimental/methodology.**

The noble metal-NiMo/δ-$Al_2O_3$ catalysts were synthesized using incipient wetness impregnation. Two methods of including the noble metals in the catalyst synthesis were investigated, where the stage at which the noble metal was included in the synthesis was varied. To investigate the effect of the added noble metal, the reductive characteristics of the catalysts were studied using Quantitative Temperature Programmed Reduction (TPR). Furthermore, compositional analysis was performed using SEM-EDX.

**Results and discussion.**

Through the use of TPR we were able to identify a clear influence of the noble metal on the reduction behavior of the surrounding Ni-Mo oxide. The TPR curves for NiMo and Ir-NiMo catalysts are shown in Fig 1.

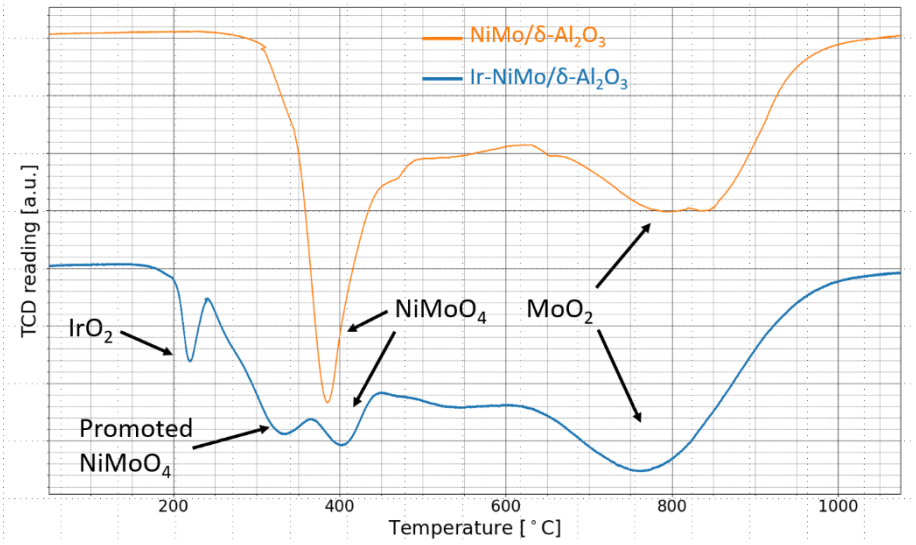

**Fig. SEQ Fig. * ARABIC 1 Reduction characteristic of the studied catalysts.**

Through the use of quantitative TPR the first peak of the Ir-NiMo curve could be identified as $IrO_2$. Further, a lowering of the reduction temperature of part of the Ni-Mo oxide could be observed when iridium was added to the catalyst. Being able to determine the influence of the noble metal even though a loading of 0.5wt% was used shows the power of TPR as an analytical method for the characterization of catalysts.

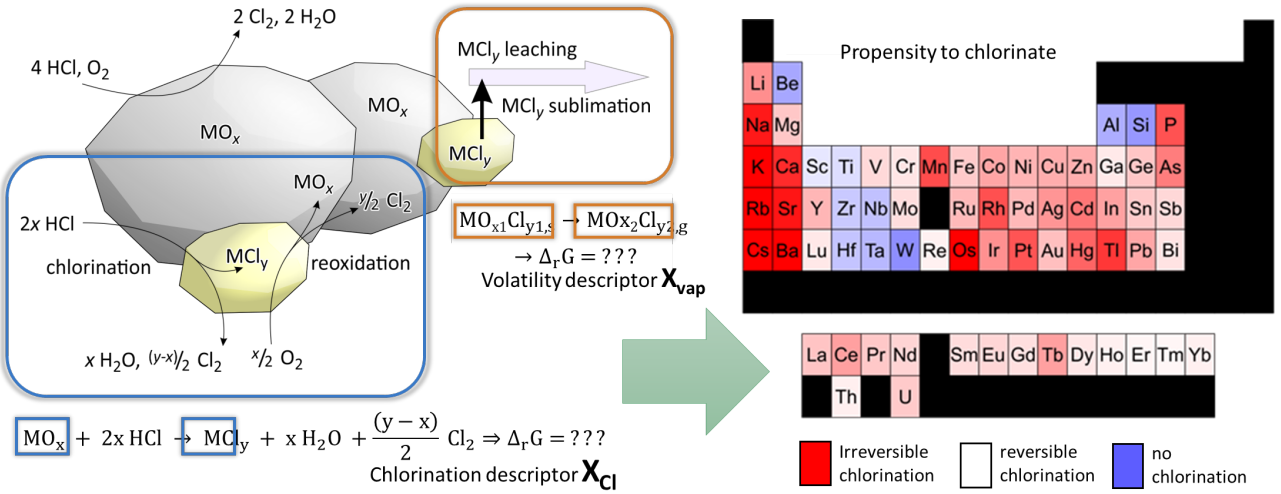
# The search for a new Deacon catalyst: modeling catalyst stability across the periodic table



F. Hess[1,*]

[*]*Institute of Chemistry, Technical University Berlin, Straße des 17. Juni 124, 10623 Berlin, Germany*

**Keywords:** catalyst degradation, modeling, screening, materials stability, Deacon process

**Introduction.** Catalysts degrade over time, which means that they lose catalytic activity or selectivity due to a variety of aging processes. While catalyst screening (both experimental and theoretical) regarding activity and selectivity is well-established in catalysis research, screening with respect to stability is experimentally difficult due to the long time scales of catalyst degradation. Computational catalyst screening can complement experimental studies aiming at the identification of new catalyst materials that are stable under operating conditions.

**Experimental/methodology.** In the HCl oxidation in the Deacon process using an oxide catalyst $MO_x$, the main catalyst degradation mechanisms are catalyst leaching in the form of volatile M-O-Cl compounds (see Figure), as well as bulk phase transformation of oxide catalysts into less catalytically active chlorides (see Figure). We present a catalyst screening approach based on experimental thermodynamic data for the compounds in the M-O-Cl system. In this approach, we divide the M-O-Cl system into four groups of compounds, oxides, chlorides, condensed and gaseous species and compute two descriptors .

**Descriptor calculation for bulk chloride formation and leaching of volatile chlorides, and screening result displayed in the periodic table.**

**Results and discussion.** It can address specific reaction conditions by computing the driving forces ($\Delta G$) of chlorination and sublimation as a function of temperature, reactant feed composition and conversion. We apply it to the M-O-Cl compounds of 66 elements, regarding chlorination and volatility as separate descriptors. According to previous experimental studies, catalyst degradation starts at the reactor inlet and is driven by water formation [1]. At the target reaction conditions (T < 650 K, dry, $p(HCl)/p(O_2) \approx 1$, conversion < 1 %), the volatility and chlorination descriptors are largely complementary, which provides an explanation why it has historically been so difficult to identify stable catalyst materials for this reactions. However, 13 oxides and oxychlorides are identified as suitable candidates. While some of the candidates ($TiO_2$, $ZrO_2$, $Al_2O_3$, and $SiO_2$) are inactive (but already employed as catalyst supports in the Deacon process and known to be stable), other candidates are ruled out for safety concerns (BeO, $ThO_2$, $UO_3$). The most promising candidates are those exhibiting low volatility and medium propensity toward bulk chlorination. The results suggest that $Nb_2O_5$, $Ta_2O_5$, and the late rare earth oxychlorides (Dy, Ho, Er, Tm, Yb, Lu)OCl may be suitable catalyst materials for the Deacon process. [1]

# Influence of Water Vapor Treatment for $NH_3$-TPD on Solid Acid Catalysts

J. Adolphs[1*], Y. Konishi[2]

**Keywords:** Ammonia TPD, solid acid catalysts, zeolites

**Introduction**

Temperature programmed desorption of ammonia ($NH_3$-TPD) is commonly used to evaluate the acidity (acid amount, acid strength) of solid acid catalysts such as zeolites. In many cases, there are two peaks, *l*-peak (low temperature) and *h*-peak (high temperature) in the TPD spectrum.

**Experimental/methodology**

The *l*-peak is derived from ammonia molecules which are adsorbed by hydrogen bonding on $NH_4^+$ cation on acid sites and is not considered to indicate the acidity. However, in the case of zeolites with weak acidity, such as Y-type zeolites, the *l*-peak and *h*-peak overlap, making it difficult to evaluate acidity. $NH_3$ TPD measurement with steam treatment is considered being effective to eliminate the *l*-peaks. In this contribution the procedure, and precautions are described. Ammonia as probe molecule is adsorbed onto the zeolite sample until it reaches equilibrium. Then the temperature of the sample is continuously increased, causing an enrichment with the desorbed molecules in the inert carrier gas (Helium). The standard TCD (Thermal Conductivity Detector) measures the total adsorbed amount and not the specific desorbed constituents. However, since zeolite adsorbs water in its pores, it is necessary to use a detector that can detect water and ammonia separately when measuring TPD. Also, since water vapor is introduced at high temperature, this method is not applicable to samples whose properties are changed by water vapor. Therefore, a quadrupole mass spectrometer is used to detect the desorbing ammonia at mass number 16. Mass number 17 was not used because the peak at 17 can be affected by the desorbed water.
$NH_3$-TPD measurements were performed under the following conditions.

| | |
|---|---|
| Measuring equipment | : BELCAT II + BELMASS |
| Sample | : MFI, 50 mg |
| Temperature ramp rate and target temperature | : 10°C/min, 610°C |
| Adsorption gas | : $NH_3$/He 5% |

According to Igi et al [1], in their experiments the steam treatment was performed by repeating the evacuation of the sample cell with following steam introduction. Differently, the catalyst analyzer BELCAT II is a dynamic flow type equipment operating permanent at atmospheric pressure. Fully saturated water vapor is generated by an advanced bubbling method with inert gas at room temperature under atmospheric pressure.

**Results and discussion**

The experimental results show that steam treatment eliminates the *l*-peak and leaves the *h*-peak shape almost unchanged, indicating that steam treatment in $NH_3$-TPD measurement is very effective for eliminating the *l*-peak and examining the *h*-peak in detail. To perform NH3-TPD measurement with BELCAT II, the vapor option and a quadrupole mass spectrometer BELMASS is necessary.

**Keywords:** characterisation, passivation, methanol synthesis, ammonia synthesis

**Introduction.** To improve our knowledge of catalyst materials and their performance, it is crucial to characterise catalyst samples after testing them in a catalyic reaction. While it is preferable to investigate a catalyst *in operando*, this is not always a feasible option. Instead, a transfer of the materials to the characterisation setup, in air or in a controlled and inert atmosphere (e.g., a glove box), is often performed, or the catalyst may be passivated. However, this might change the properties of the samples, particularily in the case of metal catalysts. For this reason, careful attention has to be paid to the methods used for transferring activated catalysts from reactors to characterisation setups [1].

**Experimental/methodology.** We assessed Cu- and Fe-based catalysts used for the synthesis of methanol and ammonia, respectively [2,3], each after various methods of transferring the samples from the reactor to the characterisation setups. These methods included the inert transfer of the materials via a glove box, and various methods of passivation, applicable where an inert transfer is not feasible. The investigated passivation methods included treatments with dilute $O_2$ or dilute $N_2O$, as well as the gradual exposure of the samples to ambient air. As a control, an air flow was applied to some samples directly in the reactor. During the treatments in the reactor, the increase in temperature caused by the treatment was recorded. After the completion of the treatment, the materials were carefully characterised using various methods probing the entire sample (BET/BJH, XRD) or resulting in local sample information (TEM/EDX/EELS).

**Results and discussion.** Monitoring the increase in sample temperature as a result of the passivation treatment can provide an indication whether or not the passivation treatment was successful. The samples subjected to passivation treatments were partially oxidised to varying degrees depending on the treatment, as evidenced by spectroscopic and crystallographic analysis (EDX, EELS, and XRD). Despite this, the passivation treatments preserved other aspects of the samples, for example their mophology (Fig. 1), and can therefore be useful where it is impossible to inertly transfer samples to characterisation setups.

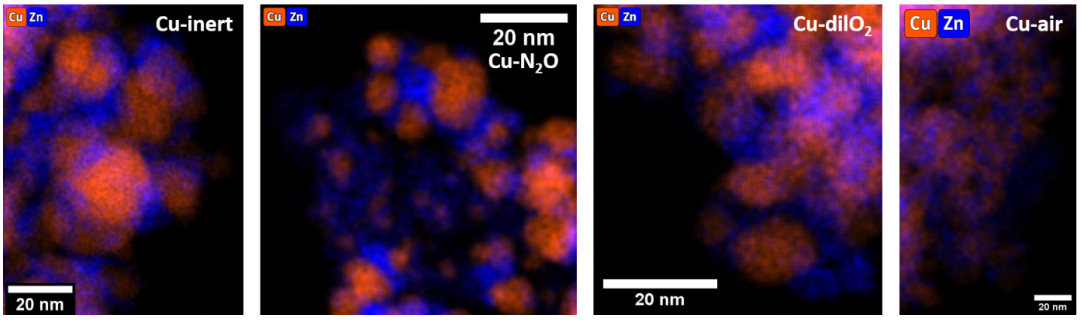

**Figure 1: STEM-EDX Cu and Zn maps of a Cu-based methanol synthesis catalyst after various treatments.**

**Keywords:** Catalytic Fast Pyrolysis, Fe-ZSM-5, XES, HERFD-XANES, Beamline I20 Diamond Light Source.

**Introduction.** Designing an effective, integarted biorefinery relies on developing robust processes for upgrading biomass to to fuels and chemicals [1]. This includes the production of high-value chemicals, such as benzene, toluene and xylene (BTX) from biomass. BTX are especially important as platform chemicals and are currently produced almost exclusively from fossil resources. A promising and well-developed process for producing BTX from biomass is Catalytic Fast Pyrolysis (CFP), during which pyrolysate vapour is upgraded into monoaromatic species using a catalyst. Zeolites such as ZSM-5 are known to be effective catalysts for hydrodeoxygenation of lignocellulosic biomass to high value BTX and monoaromatic hydrocarbons during CFP [2]. Recent research has shown that the addition of ca. 1 % wt. Fe to ZSM-5 has a notable impact on the selectivity of the reaction, typically increasing the BTX yields, when compared to non-Fe-modified zeolite [3]. It is believed that Fe sites in Fe-ZSM-5 zeolite are both selective and active towards monocyclic aromatic hydrocarbon (MAH) formation and suppress further polymerisation and the formation of oxygenates [4]. However, little is currently known about the mechanistic role of Fe in CFP.

**Experimental/methodology.** The aim of this project is to study the function of Fe during CFP of biomass. In the past, the study of these Fe sites has been challenging, due to the relatively low concentration (ca. 1.0 wt%) of Fe present in the zeolite. Modification of the zeolite using incipient wetness impregnation with Fe results in the formation of both mononuclear and polynuclear Fe sites (**Fig 1a**) [5]. This project exploits the recently commissioned 14 crystal analyser X-ray emission spectrometer at beamline I20 of Diamond Light Source (**Fig 1b**) to perform operando Resonant X-ray Emission Spectroscopy (RXES) and High Energy Resolution Fluorescence Detection (HERFD) X-ray absorption spectroscopy. The reaction was performed by injecting 1.5 µLmin$^{-1}$ of a biomass model compound (furan) into a flowing stream of 30 mLmin$^{-1}$ He gas) over 50 mg of the catalyst held at a series of temperatures and monitoring the evolution of BTX (**Fig 1c**). Fe $K_\beta$ and valence-to-core emission spectra, as well as high energy resolution flouresence detection (HERFD) XANES were collected in-situ.

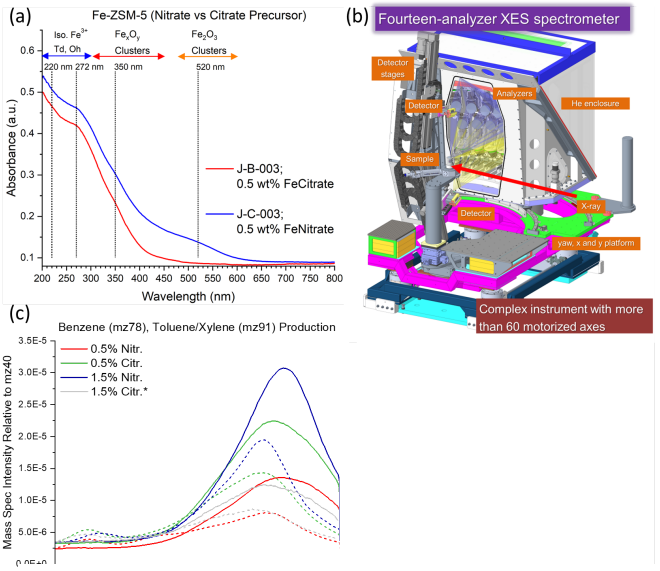

Figure SEQ Figure * ARABIC 1: (a) UV-Vis spectroscopy shows mononuclear and polynuclear Fe clusters present on modified ZSM-5 zeolite. (b) 14 analyser spectrometer at I20 DLS (c) Laboratory mass-spectrometry shows increasing evolution of BTX with higher Fe concentration.

**Results and discussion.** In this poster presentation, we present the recent advances made at beamline I20 as well as preliminary results showing changes in Fe speciation during CFP of furan over Fe-ZSM-5 catalysts. Initial results demonstrate significant mechanistic differences between plain ZSM-5 and Fe-ZSM-5, as well as pointing to changes in Fe speciation dependent on the intial distribution of mononuclear and polynuclear Fe sites.

# *In-Situ* Deactivation Measurements on bifunctional catayst for One-Step DME synthesis

Felix Hilfinger[1], Samuel F. Gatti[2] and Ingo Krossing[1]*

[1]*University of Freiburg, Material Research Center, Freiburg, Germany*
[2]*Paul Scherrer Institut, Villigen PSI, Switzerland*
[*]*ingo.krossing@ac.uni-freiburg.de*

**Keywords:** $CO_2$ Hydrogenation, DME Synthesis, DRIFTS, Catalyst Deactivation

**Introduction.** In recent years, the concentration of $CO_2$ in the atmosphere has been constantly increasing, having an impact on global climate change.[1] Therefore, a growing number of countries and researchers are interested in developing technologies to reduce $CO_2$ emissions and developing efficient carbon dioxide utilizations systems.[2] In the BioDME project, funded by the federal ministry of education and research Germany, we focus on developing a pilot plant for the hydrogenation of $CO_2$ to gain highly selective dimethyl ether (DME). The goal is further investigate the stability, economy and sustainability of this process in daily operation.[3] The direct synthesis of DME from $CO_2$ requires two catalyst parts: A metal oxide, usually Cu/ZnO/Al2O3 (CZA) or Cu/ZnO/ZrO2 (CZZ), for MeOH production, and a solid acid, usually zeolites like H-ZSM5, for the dehydration of MeOH to DME. Although, combination of the surface basic metal oxide and the acidic zeolite results in mutual deactivation, which limits the performance of the hybrid system. In this work, an all-new experiment to measure *in-situ* surface related deactivation of the acidic H-ZSM5 and the surface-basic $CO_2$ hydrogenation catalyst was developed. The underlying principle of the measurement is related to adsorption of pivalonitrile (PN) or acetonitrile (AN) on surface exclusive terminal silanol functions of H-ZSM5-type zeolites. These functional groups are strongly acidic and, due to their location on the surface, react with the surface-basic metal oxide. Therefore, the amount of residual silanol groups depends on the amount of deactivation or amount of surface-basic sites on the $CO_2$ hydrogenation component.

**Experimental/methodology.** Beside the house-made metal oxide CZZ, a commercial available H-ZSM5 zeolite was used and characterized by DRIFTS (*Diffuse Refelection Infrared Fourier Transform Spectroscopy*). Here, only the diffuse reflected part of the initial IR radiation is measured. Because of the low penetration depth of the diffuse reflected IR radiation, the DRIFTS method does not measure any bulk-related, but only surface related absorptions.[4]

**Results and discussion.** In Figure 1 the normalized raw spectra of different H-ZSM5 to CZZ ratios are shown. All of them resemble the expected bands at 3740 $cm^{-1}$ with a negative intensity due to the perturbation of the SiOH-vibration introduced by PN adsorption. As expected, differential spectroscopy showed a decreasing area of the band assigned to surface exclusive terminal silanol groups at 3740 $cm^{-1}$ with increasing CZZ content. Therefore, the deactivation of the acidic sites on the catalyst surface by the surface-basic metal oxide can be measured directly.

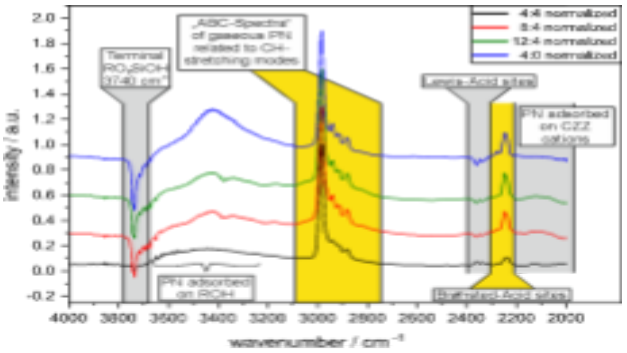

**Figure 1**: Differential DRIFTS-deactivation measure-n Figure ments for different H-ZSM5 to CZZ ratios in the range of 4000 $cm^{-1}$ to 2000 $cm^{-1}$. Spectra normalized to the maximal intensity in the ABC-Spectra.[5-7]

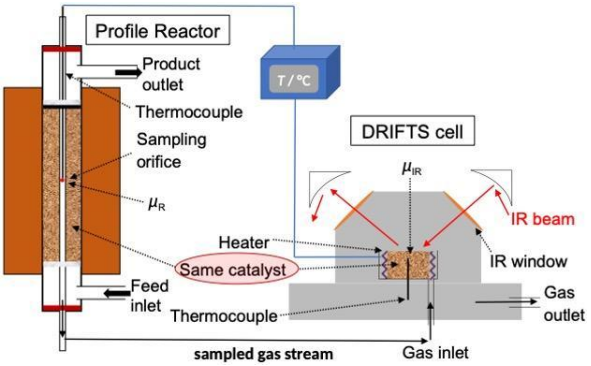
**Keywords:** operando spectroscopy, fixed-bed reactor, DRIFTS, Raman, XRD

**Introduction.** Operando spectroscopic measurements are traditionally conducted in miniature reactors by gathering spectroscopic data at defined temperatures, contact times and mixing patterns while simultaneously recording reactant conversion and product selectivity at the reactor outlet. Spectroscopic studies on catalysts directly in industrial reactors are almost not existing because industrial reactors are too large and opaque to electromagnetic radiation. Isopotential operando spectroscopy [1] is based on the hypothesis, that catalyst structure, adsorbates and reactivity are determined by the chemical potential of the reaction mixture the catalyst is exposed to ($\mu=\mu(T,p,\mathbf{x})$) and as such by temperature T, pressure p and local chemical composition **x** of the reaction mixture in the reactor. If the same catalyst, which is in the catalytic reactor, is put in a spectroscopic cell and is exposed to the same local chemical potential as in the reactor, the catalyst should display the same structure, adsorbates and reactivity as the catalyst locally in the reactor. This allows separating catalytic reactor and spectroscopic measurement cell, allowing to perform, at least in principle, operando spectroscopy inside industrial catalytic reactors. Any spectroscopic method can be used which is applicable for all T,p,**x** combinations encountered in the catalytic reactor. Because the spectroscopic cell must no longer serve simultaneously as catalytic reactor, it can be optimized from a spectroscopic point of view without any restrictions.



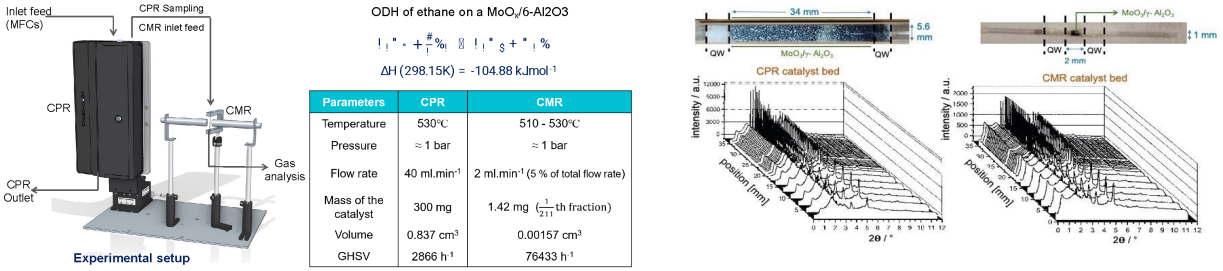


**Fig. 1: Concept of isopotential DRIFTS spectroscopy.**

**Experimental/methodology.** The present contribution demonstrates the concept of iso-potential operando spectroscopy by means of DRIFTS, Raman spectroscopy and XRD. Isopotential operando spectroscopic measurements are performed by equipping a catalytic reactor with spatial sampling and spatial temperature measurements and combining it directly with the spectroscopic measurement cell as shown schematically in Figure 1 for DRIFTS as example.

**Results and discussion.** Figure 2 shows exemplarily high energy (100 keV) XRD data of a $MoO_x$ catalyst during ethane ODH measured at beamline P07 at PETRAIII/DESY. The reaction was performed in a Compact Profile Reactor (CPR). Spatial XRD patterns were recorded along the reactor by putting i) the CPR directly into the beam and ii) by putting a Capillary Micro Reactor (CMR) in the beam connected by isopotential coupling to the CPR and containing a small amount of the same catalyst as in the reactor. Almost identical XRD patterns and Mo reduction profiles were obtained.

| Parameters | CPR | CMR |
|---|---|---|
| Temperature | 530°C | 510 - 530°C |
| Pressure | ≈ 1 bar | ≈ 1 bar |
| Flow rate | 40 ml.min$^{-1}$ | 2 ml.min$^{-1}$ (5 % of total flow rate) |
| Mass of the catalyst | 300 mg | 1.42 mg ($\frac{1}{211}$ th fraction) |
| Volume | 0.837 cm$^3$ | 0.00157 cm$^3$ |
| GHSV | 2866 h$^{-1}$ | 76433 h$^{-1}$ |

**Fig. 2: Spatial XRD profiles measured at beamline P07 at PETRAIII/DESY in a Compact Profile Reactor vs. those measured in a Capillary Micro Reactor connected in isopotential coupling to the CPR.**

# Methane Pyrolysis on NiMo/MgO: Details of the Synergetic Effect

A. Horváth[1*], M. Németh[1], T.I. Korányi[1], A. Beck[1], Gy. Sáfrán[1], Zs.E. Horváth[1], I. Rigó[2]

[1]*Centre for Energy Research, Budapest, Hungary*

[*]*horvath.anita@ek-cer.hu*

**Introduction.** Hydrogen may be an important energy source of our clean and sustainable future. For hydrogen production, the fossil natural gas-based steam reforming must be replaced with new routes that do not produce waste $CO_2$. A perspective way of $CO_2$-free utilization of abundant natural gas is the pyrolysis of methane ($CH_4 \rightleftharpoons C+2H_2$), yielding only pure $H_2$ and solid carbon. A very promising but less studied catalyst system for this reaction is composed of nickel and molybdenum, but the details of the prevailing bimetallic interactions need to be further clarified.

**Experimental/methodology.** MgO supported 7% Ni, 13% Mo and three bimetallic NiMo catalysts with high and low Mo content (~4% or 13%) were prepared by adsorption/precipitation of the metal precursors on MgO at room temperature or at 80°C, followed by washing, centrifugation, calcination at 550°C and reduction at 800°C. Samples are differentiated by the Mo/Ni atomic ratio (MoNi0.4 and MoNi1.2) and the synthesis temperature (MoNi0.4_RT). The bulk composition of the catalysts was determined by the ICP-OES method, the structure was characterized by transmission electron microscopy (TEM) and STEM-EDS studies, X-ray diffraction (XRD), temperature programmed reduction (TPR), X-ray photoelectron spectroscopy (XPS) and Raman spectroscopy. The catalytic properties were determined a) in a MIC AutoChem device with QMS analysis using 1% $CH_4$/He flow with temperature ramp or at constant 700°C; and b) in a horizontal pyrolysis reactor with GC gas analysis using a 50% $CH_4$/Ar flow at 800°C. The amount of carbon produced after pyrolysis was determined by mass measurement or from the amount of decomposed methane, and its structure was analyzed by Raman spectroscopy and high-resolution TEM.

**Results and discussion.** According to the TPR results, the bimetallic samples could be fully reduced at around 800 °C, but in the case of the monometallic samples the reduction was not complete. The average metal particle size by TEM varied between 5 and 8 nm in all samples. The XRD indicated alloyed NiMo-particles for MoNi0.4 and MoNi0.4_RT catalysts, but for MoNi1.2 only the MgO reflections could be detected (finest dispersion). STEM-EDS showed that the larger bimetallic particles were always extremely rich in Ni, but areas with numerous smaller particles displayed higher Mo/Ni ratios different for each sample. According to the XPS, nickel has still 60% oxidic contribution in the reduced Ni/MgO and 20% in MoNi1.2 sample. Molybdenum is mainly metallic in Mo/MgO and MoNi1.2, but there is more $Mo^{4+}$ present in the other two low-loaded bimetallic samples. It was also deduced from XPS that MoNi1.2 surface is enriched in Mo (Mo/Ni=1.7), while MoNi0.4 is depleted (Mo/Ni=0.2). In the temperature ramped $CH_4$ decomposition, Ni/MgO resulted constant 10% $CH_4$ conversion starting at 500 °C, Mo/MgO became steeply active only above 700 °C, while the bimetallic catalysts were active in both temperature ranges. In both, the AutoChem and the horizontal pyrolysis reactor, we found a synergistic effect of the bimetallic catalysts, and the MoNi1.2 sample was the best. According to the Raman and HRTEM results, the carbon formed on Ni/MgO was the most graphitic ($I_G/I_D$=7.7), while on Mo/MgO it was the most defective ($I_G/I_D$ =0.4), just a few layer thick coverage around particles but resulted in rapid deactivation of both samples. On the best MoNi1.2 catalyst with 300% carbon yield, partially defective ($I_G/I_D$=3), multi-walled carbon nanotubes with a maximum diameter of 10 nm were obtained. The exceptional activity of the bimetallic MoNi1.2 sample can be explained by the high and stable dispersion of bimetallic NiMo particles with a special ~1:1 composition. This means that the interaction of Ni with sufficient Mo partners creates new active sites that allow the continuous carbon dissolution and nanotube formation, thus good catalytic performance during $CH_4$ decomposition.

**Keywords:** OER, Perovskites, Electrolyte impurities, Electrode-Electrolyte Interface, *In-situ* Raman studies

**Introduction:** Oxygen evolution reaction (OER) is the bottleneck of electrochemical water splitting[1] Therefore, intensive research is ongoing in developing efficient and low-cost catalysts, among which perovskites have demonstrated excellent OER activities.[2] Studies show that the catalytic performance is enhanced by Ni/Fe impurities present in the electrolyte. Nevertheless, the mechanism is still not completely understood.[3] Mixed Ni-Febased perovskites, $LaNi_xFe_{1-x}O_3$, also show catalytic enhancement for OER in the presence of electrolyte impurities for alkaline water electroylsis.

**Experimental/methodology:** Perovskites are synthesized via the modified solution combustion method. All samples have been investigated by electron microscopy and diffraction as well as Raman spectroscopy and X-ray photoelectron spectroscopy before and after OER. All samples are tested under alkaline OER conditions. The electrode-electrolyte interface is studied by operando Raman spectroscopy.

**Results and discussion:** $LaNiO_3$ shows the highest activity with an overpotential of 280 mV at a current density of 10 $mAcm^{-2}$ and excellent electrochemical stability after 15 h of testing. Rietveld analysis and Fourier difference analysis reveal a deviation from the perfect crystal structure and transmission electron microscopy confirms the presence of stacking faults which are correlated to the excellent OER performance. The electrocatalytic activity of Ni-Fe based perovskites is influenced by the impurities present in the alkaline electrolyte, 1M KOH (Fig.1c). For $LaNiO_3$, the active oxy-hydroxide species (around 477 and 555 $cm^{-1}$) are observed at the onset potential of OER in 1M commercial KOH. However with the addition of Fe impurities in the purified electrolyte the formation of the oxy-hydroxide species is observed at potentials as low as 1.35V. (Fig. 1a, 1b and 1d) Simiar trend is observed for $LaFeO_3$ in the presence of Ni impurities. In the mixed system, $La(NiFe)O_3$ as per the raman studies, nickel and iron atoms are the initial catalytic sites but at higher potentials Fe atoms significantly contribute to the active catalytic centers.

# Influence of Support Composition and Potassium Ion Doping on the Properties of Cerium-doped Zirconia Supported Silver Catalysts

Ewa Iwanek (nee Wilczkowska)[1*], A. Siwiec[1], S. Siennicka[1], and Z. Kaszkur[2]

**Keywords:** ceria-zirconia support, soot combution, solid solutions, potassium ions, $ZrO_2$ polymorphic forms

**Introduction.** Catalytic soot combustion is a reaction which is often carried out on a supported silver catalyst. It is known that potassium ions also catalyze the reaction. As in the case of coal gasification, the role of the catalyst is to enable oxygen to react with carbon to form $CO_2$. Although zirconium-ion doped ceria is often used a catalyst or a catalyst support, relatively little is known about the solid solutions in which a part of the zirconium ions have been substituted with cerium ions. Multicomponent supports have been rarely investigated in this reaction, hence the reported research investigated the various Ce/Zr ratios on the properties of the catalysts. The influence of the presence of potassium ions on the activity of such systems has been tested and presented herein.

**Experimental/methodology.** The supports were synthesized using co-precipitation using either zirconyl nitrate or zirconyl chloride and ammonium ceric nitrate mixed in the proper amounts to obtain solids with the compositions $Zr_{1-x}Ce_xO_2$ ($x<0.15$). Ammonia water (25%) was used as the precipitating agent. The formed gel was washed until a neutral pH of the filtrate was obtained, calcined at 550°C or 650°C in either air or argon for 4 h, crushed and sieved. The silver was deposited onto the grains of the supports using wet impregnation with silver nitrate to get a final loading of 1 wt.%, 5 wt.% and 10 wt.%. The catalyst precursor was then dried and calcined for another hour at 550°C. $K_2CO_3$ was deposited in the final step by wet impregnation. The catalysts were characterized by XRD, SEM-EDX, nitrogen physisorption, TPR, etc. Activity tests were carried out on an STA 449C thermobalance (NETZSCH) equipped with a mass spectrometer.

**Results and discussion.** The addition of the cerium ions led a higher surface area than that of undoped $ZrO_2$. The X-Ray diffraction results have shown that the cerium-doped zirconia supports crystallize solely in the tetragonal structure when the cerium ion content is 7at.% or higher. In contrast, when there is 3 or 5at%, the monoclinic $ZrO_2$ is also present. Its content was found to depend not only on the cerium ion content, but also on the calcination conditions, i.e., the temperature and atmosphere of calcination. An important finding was that the supports were found to exhibit reducibility, unlike undoped $ZrO_2$. The temperature of the beginnng of $H_2$ consumption was inversly correlated with the amount of monoclinic phase present in the support. The distribution of the silver was uniform in catalysts with 1wt% Ag (Figure 1a), whereas large crystals were observed when 5wt.% (or 10) was deposited onto the support (Figure 1b). The addition of $K^+$ was beneficial, especially for the systems with 1wt.%Ag.

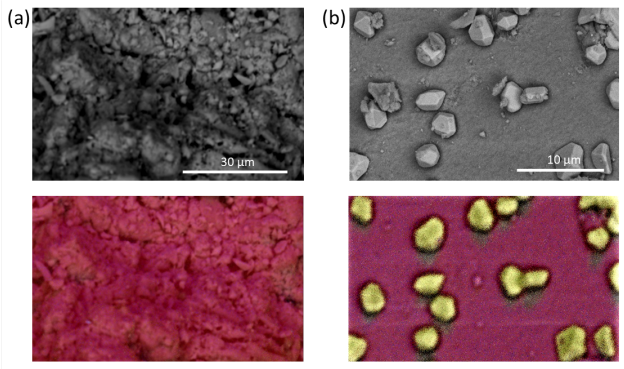

Figure 1. SEM images and the EDX color maps of (a) 1wt.%Ag and (b) 5wt.%Ag on $Zr_{0.90}Ce_{0.10}O_2$.

**Keywords:** Fe-FER, $O_2$ dissociation, alpha oxygen

**Introduction.** To oxidise hydrocarbons by $O_2$ its activation over heterogeneous catalysts is needed. Recently, it was found that iron ferrierite (Fe-FER) exhibited extraordinary properties toward O2 dissociation over binuclear cationic centres [1,2]. It was shown that the cooperation of divalent bare Fe located in β cationic positions of FER split $O_2$ and formed an active oxygen form $[Fe(IV)=O^{2-}]^{2+}$ (α-oxygen), which is used for further methane to methanol oxidation already at ambient conditions. In this work, we focused on the study of the oxidation properties of binuclear centres in methane oxidation at elevated temperatures.

**Experimental/methodology.** Iron was introduced to FER(Tosoh Corp., Si/Al 9) by impregnation method, in which organic medium was used as solvent. The Fe-FER prepared by this method with Fe/Al 0.08 was considered (due to the occupation of β cationic positions by Fe(II)) as a model material for studying the kinetics of the α-O formation by cleavage of $O_2$, its thermal stability, and reactivity in methane oxidation under in-situ conditions at 220 °C using FTIR and Mössbauer spectroscopy. The products of methane oxidation were analyzed by FTIR and mass spectrometry methods.

**Results and discussion.** FTIR and Mössbauer spectroscopy results confirmed that in studied Fe-FER sample, iron is mainly observed as divalent cations located in β cationic positions. This arrangement guarantee the formation of binuclear Fe(II) centres. Analysis of in-situ FTIR study recorded in $O_2$ flow shows that within interaction time 0 - 60 min the intensity of the band at 907 $cm^{-1}$, assigned to Fe(II) in β cationic position, decreases with increasing intensity of the band characteristic for the α-O at 897 $cm^{-1}$ (Fig. 1a).[2] This correlation between decreasing concentration of β sites (band at 907 $cm^{-1}$), estimated from FTIR spectra, and formation of the band at 897 $cm^{-1}$ are depicted in Fig. 1b. To oxidize all Fe(II) in β sites and to reach the highest intensity of the band typical for α-O the time of 60 min is required. Interaction of the α-O with $CH_4$ at 220 °C results in the instantaneous vanishing of the band at 897 $cm^{-1}$, and formation of the band at 907 $cm^{-1}$ typical for Fe(II) siting in β position in FER. This result confirms that $[Fe(IV)=O]^{2+}$ is reduced by $CH_4$ with the restoration of Fe(II) species initially observed in the FTIR spectrum of evacuated Fe-FER. FTIR and mass spectrometry results confirmed the formation of methanol in the gas stream as products of the reaction of $O_2$ and $CH_4$ over Fe-FER at 220 °C. The results confirmed that the iron binuclear centres effectively split $O_2$ and transform methane to methanol at higher temperature (220 °C).

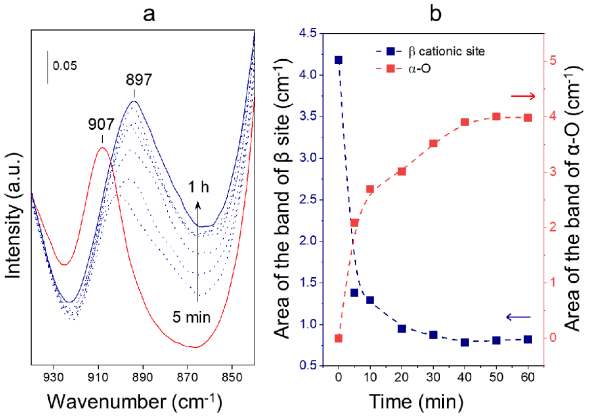

**Figure 1.** FTIR spectra of the kinetics of α-O formation over Fe-FER at 220 °C (a), and temperature dependence of the evolution of the bands characteristic for α-O and Fe(II) in β sites (b).

# Structural characterization of molecular organic frameworks and single atom catalysts for heterogeneous catalysis

I. Kappel[1,2*], M. Vennewald[2], R. Palkovits[2], C. Weidenthaler[1]

[1]*Max-Planck-Institut für Kohlenforschung, Mülheim an der Ruhr, Germany*

**Keywords:** Single-atom catalysis, Characterization

**Introduction**

Aiming at more sustainable chemical processes, the development of efficient catalysts plays a major role. In that context, the development of single-atom catalysts has a huge potential since they can bridge the gap between homogeneous and heterogeneous catalysis due to unique performance, better catalyst separation and handling as well as maximum metal utilization [1]. Single-atom heterogeneous catalysts (SAHCs) based on carbon-nitrogen polymers with low metal loadings have shown applicability for several catalytic systems [2,3]. However, the question arises whether the single-atoms are the active species in the reactions. Therefore, gaining a comprehensive structural understanding especially under reaction conditions is a key feature in order to be able to establish rational synthesis and treatment procedures for efficient SAHCs.

**Experimental/methodology**

We synthesized a palladium single-atom catalyst (0.5wt.%) on exfoliated gCN (ECN) by impregnation with $Pd(NH_3)_4(NO_3)_2$ (ECN-Pd-SA) as well as a palladium nanoparticle catalyst (ECN-Pd-NP). Both were tested towards their respective catalytic activity in ethylene hydrogenation. Aberration-corrected scanning transmission electron microscopy was used to analyse the catalysts before and after the catalytic reaction. *Ex-situ* and *in situ* X-ray photoelectron spectroscopy and X-ray absorption spectroscopy were applied in order to identify the active species. Furthermore*, ex-situ* and *in situ* synchrotron X-ray total scattering has been conducted to study both the structure of the ECN as well as a potential dynamic agglomeration process of the palladium single-atoms under reaction conditions.

**Results and discussion**

The conversion profiles revealed that the ECN-Pd-NP shows instantaneous activity at 50°C while the ECN-Pd-SA is inactive. Activation of the single-atom catalyst could be observed starting at 100°C and continuing with time and temperature. This activation could be attributed to an agglomeration of Pd single-atoms to clusters at 100°C in an atmosphere containing both hydrogen and ethylene [4].

However, due to the amorphous nature of the catalysts and the very low metal loading, the characterization comes with some challenges and is close to the detection limit of many techniques. Therefore, it is inevitable to apply multiple *ex-situ* and *in-situ* characterization techniques to both the polymeric support and the as-synthesized catalysts unravelling different detailed structural features and being able to derive valuable structure-property relationships.

# Effects of Hydrothermal Ageing on the Dynamic Nature of Active Sites in Cu-exchanged Small Pore Zeolites during $NH_3$-SCR

Rachit Khare[1*], Mirjam Wenig[1], Andreas Jentys[1], Johannes A. Lercher[1]

[1]*Department of Chemistry and Catalysis Research Center, Technical University of Munich, Garching*
[*]*rachit.khare@tum.de*

**Keywords:** $NH_3$-SCR, X-ray absorption spectroscopy, Operando characterization, DFT

**Introduction.** Cu-exchanged small-pore zeolites are currently the catalyst of choice for selective catalytic reduction of nitrogen oxides with ammonia ($NH_3$-SCR) owing to better hydrothermal stability and high catalytic activity across a wide range of temperature. During $NH_3$-SCR, Cu acts as a redox shuttle and exists in both $Cu^{1+}$ and $Cu^{2+}$ oxidation states coordinated either to the reactants or to the O atoms of the zeolite framework. The oxidation state and coordination environment of the active Cu species varies depending on the reaction conditions. During typical use, these catalysts are exposed to elevated temperatures in the presence of water resulting in a significant decrease in their catalytic activity over time. The decrease in the catalytic performance upon hydrothermal ageing is typically attributed to the changes in the coordination structure of active Cu species. However, the exact nature of this effect is still not fully understood. Utilizing *operando* X-ray absorption spectroscopy (XAS) supported with kinetic measurements and theoretical calculations, we present a comprehensive study elucidating the effects of hydrothermal ageing on the electronic and coordination structure of active sites in Cu-SSZ-13 and Cu-SSZ-39 during $NH_3$-SCR.

**Experimental/methodology.** SSZ-13 and SSZ-39 zeolites either were purchased commercially or were hydrothermally synthesized. The zeolites were ion-exchanged with aqueous copper acetate solution to achieve the desired Cu loading. The catalysts were hydrothermally aged by steaming at 1073 K for 16 h in 10% $H_2O$ in synthetic air. *Operando* Cu K-edge XAS measurements were performed at the P64/P65 beamlines of the German electron synchrotron (DESY), while Al K-edge XAS measurements were performed at the Phoenix beamline of the Swiss Light Source (SLS).

**Results and discussion.** *Operando* Cu K-edge XANES and EXAFS measurements were performed on fresh and hydrothermally-aged zeolites under $NH_3$-SCR reaction conditions between 373 K and 823 K. Using principal component analysis (PCA), MCR-ALS analysis, and linear combination fitting (LCF), the distribution of Cu-species in the zeolites was expressed as a combination of four different components: (i) mobile $Cu^{1+}$ coordinated to ammonia, (ii) mobile $Cu^{2+}$ coordinated to ammonia, (iii) $Cu^{1+}$ coordinated to the zeolite framework, and (iv) new $Cu^{2+}$ species formed upon hydrothermal ageing (Figure 1). The fourth component was only observed in the hydrothermally aged zeolite samples. The identity of these principal components was verified both experimentally by exposing the catalyst to different gaseous mixtures and measuring the *in situ* X-ray absorption spectra and computationally by DFT calculations. The $Cu^{2+}$ species formed upon hydrothermal ageing were shown to be primarily active for $NH_3$-oxidation, but not for $NH_3$-SCR, resulting in the decrease in the catalytic performance of hydrothermally ages zeolites, especially at high temperatures. Hydrothermal ageing also resulted in the formation of extra-framework Al (EFAl) as evidenced by Al K-edge XAS and $^{27}$Al NMR. Formation of EFAl resulted in a partial collapse of the zeolite structure thereby imposing further mass transfer limitations within the zeolite pores. The structural stability varied as a function of zeolite framework; with AEI framework showing better hydrothermal stability compared to CHA. The Cu-ion and zeolite structure stability also varied systematically with Cu loading as well as with Si/Al.

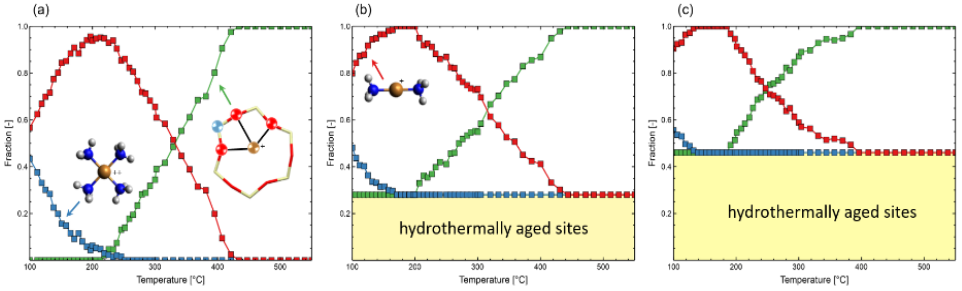

**Figure 1.** Distribution of identified Cu-species in Cu-SSZ-39 (a) and hydrothermally aged Cu-SSZ-39 (b) and Cu-SSZ-13 (c).

# Epoxidation of light olefins on titanium silicate catalyst

[1]M. Alvear, [1]Kari Eränen, [1]Dmitry Murzin, [1]N. Kumar, [1]Tapio Salmi
[1]Laboratory of Industrial Chemistry and Reaction Engineering, Johan Gadolin Process Chemistry Centre, Åbo Akademi, FI-20500 Turku/Åbo, Finland.
e-mail: matias.alvear@abo.fi

**Keywords:** epoxidation, hydrogen peroxide, titanium silicate and trickle-bed reactor.

**Introduction.** Since the discovery of titanium silicate more than 40 years ago, the epoxidation of propylene to propylene oxide with hydrogen peroxide has experienced of new technologies to produce this useful chemical compound. However, the commercial TS-1 catalyst used in methanol solvent gives methoxy species and glycols as secondary ring-opening products which are formed from the epoxide. The study of titanium silicate has brought up many new catalyst modifications. Nevertheless, the most promising one is Ti-MWW. The present work search to understand the differences between these two materials, TS-1 and Ti-MWW. TS-1 is more active in methanol, while, Ti-MWW is more active in acetonitrile.

**Experimental/methodology.** The laboratory-scale apparatus consisted of two main parts, a trickle bed reactor and a gas chromatograph. Solid titanium silicate catalyst TS-1 (ACS Materials, specific surface area 400 $m^2/g$, $SiO_2$:$TiO_2$>25) or Ti-MWW (in-house hydrothermally synthesized, specific surface area 485 $m^2/g$, $SiO_2$:$TiO_2$>20) particles (125-355 micrometer) were placed in the trickle bed between two sections of inert material [1-3]. In the laboratory-scale reactor, the aim was to compare the behaviors of both catalysts and the effect of the different process parameters on the product selectivity and reactant conversion. The FT-IR spectroscopic study comprised modulation excitation experiments. The effect of the modulation of a high and a low concentration over a ZnCe crystal with a layer of a catalyst was studied in these experiments.

**Results and discussion.** The reactor level results suggested important differences between both catalysts, nonetheless, both catalysts were highly active and selective in the epoxidation process. TS-1 displayed to be more active, however, the epoxide selectivities were lower than for Ti-MWW. The increase in the temperature displayed to be positive for Ti-MWW increasing the activity without decreasing the selectivity below 99%. Nevertheless, under similar conditions TS-1 exhibited to generate high concentrations of by-products and the catalyst activity decreased with the time-on-stream.

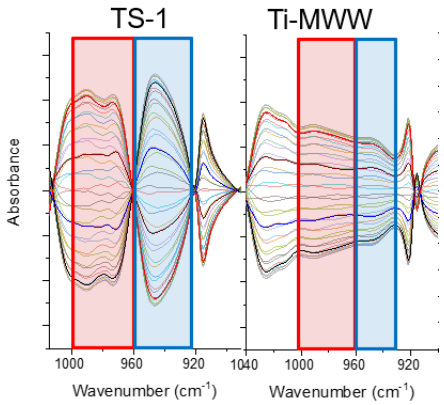

Figure 1. Modulation of water in acetonitrile, at 30 C.

The modulation excitation spectroscopy is a powerful tool to observe the presence of active surface species in the reaction system. During this work the study of the 960 $cm^{-1}$ delivered important insights. The interaction of the framework titanium with the water displayed to be different for the catalyst materials investigated. Figure 1 reveals the differences between the responses. TS-1 exhibited important changes in the structure of the 960 $cm^{-1}$ signal, while Ti-MWW displayed to not be highly excited by the water concentration.

# Catalyst materials characterization by Time-of-Flight Secondary Ion Mass Spectrometry (ToF-SIMS)

M.Kleine-Boymann[1*], Sven Kayser, Julia Zakel

[1]*IONTOF GmbH, Muenster, Germany*
[*]*matthias.kleine-boymann@iontof.com*

**Keywords:** TOF-SIMS, surface analysis, interface analysis, elemental and molecular mapping

**Introduction.** Time-of-Flight Secondary Ion Mass Spectrometry (ToF-SIMS) is a technique that has many properties that are well-suited to catalysis research, but it is not yet well-established as a standard technique for the analysis of heterogeneous and homogeneous catalysts. This may be because ToF-SIMS operates in ultra-high vacuum, is generally a semi-quantitative technique, and generates complex spectra. However, the technique's unique properties offer multiple opportunities for ToF-SIMS in the field of catalysis research, such as

- very shallow sampling depth (approximately 1 nm),
- sub-ppm detection limits,
- elemental and molecular information,
- parallel mass detection in all operation modes,
- sub 100 nm lateral resolution for elemental and molecular mapping,
- sputter profiles with high depth resolution (less than 1 nm).

In synthesis and subsequent characterization, features like trace element detection and high lateral resolution can be applied to study the quality of synthesized materials in the form of powders, as well as model catalyst systems like thin films. This method is not limited to inorganic substances and is also applicable for biocatalyst research.[1–5]

**Experimental/methodology.** ToF-SIMS data shown in this presentation were acquired on different instruments, often without any sample preparation after transport through air. Powder samples are typically compacted for easy analysis by limiting the topography and the mobility of individual particles under ion bombardment.
We have studied the existing literature on ToF-SIMS applied to catalysis materials and analysed common approaches. We will illustrate the features and limitations in the field of catalysis using examples from the literature and some original data acquired in collaboration with academic partners.

**Results and discussion.** Our study shows that ToF-SIMS is indeed applicable to a wide range of catalyst materials and research questions, especially when combined with other techniques like LEIS, XPS, or SEM/EDS to supplement and complement the limitations in quantification inherent in ToF-SIMS. The rich information in the spectra is often used to prove the selective presence of a metal on a distinct phase of a mixed support. The high lateral resolution is, for example, used to assess the homogeneity of the material, probe three-phase boundaries or other active sites. Furthermore, the excellent detection sensitivity is utilized when looking at materials with very low loading, contamination, or residues from the synthesis or use of the catalyst and their impact on material performance.

# Catalytic behaviour of boron based materials in propane ODH

Kateřina Knotková[1*], Mehran Sajad[1], Roman Bulánek[1]

[1*] *Department of Physical Chemistry, Faculty of Chemical Technology, University of Pardubice, Studentska 573, 532 10 Pardubice, Czech Republic*

**Keywords:** ODH, propane, boron, silica, alumina

**Introduction.** Catalytic activity of boron oxide supported by different supports has been studied in oxidative dehydrogenation of light alkanes (ethane, propane) since early nineties [1]. After ten years the interest in boron oxide-based catalysts decreased due to mediocre results but it was revived by Grant et al. in 2016 by presenting data concerning exceptional catalytic activity of hexagonal boron nitride (h-BN) in ODH of propane [2]. In this work, Grant et al. showed extraordinary selectivity of h-BN to olefins (propene + ethene) of 91 % at a conversion of 14 % and only negligible losses of hydrocarbon by over-oxidation to $CO_2$. Similar catalytic behavior has also been observed for various boron binary compounds and even elemental boron itself. In all cases, partial oxidation of the catalysts and formation of $BO_x$ groups was observed. The presence of these functionalities is considered to be responsible for the catalytic activity. This claim was proved by the synthesis of silica-supported boron oxide by incipient wetness impregnation. [3,4] However, $BO_x$-$SiO_2$ catalysts suffered from significant boron leaching from the catalyst surface under reaction conditions. Thus, the question of the nature of the active center, the role of boron speciation, the influence of the support and the stabilization of $BO_x$ groups on the surface of the support still remains unsolved. In our study we have compared catalytic behaviour of h-BN, $BO_x$-$SiO_2$ and $BO_x$- γ-$Al_2O_3$ and studiedproperties of boron particles present on the catalyst surfaces.

**Experimental/methodology.** Supported $BO_x$-$SiO_2$ and $BO_x$- γ-$Al_2O_3$ catalysts were prepared by impregnation method using triisopropyl borate (for synthesis, Sigma Aldrich) as the boron source. h-BN was purchased from Sigma Aldrich. The prepared catalysts were characterized by FTIR, Raman, XPS and XRD techniques. The catalytic test were performed using 100 mg of catalyst in total flow 20 ml/min and reaction mixture molar composition $C_3H_8/O_2/He$ = 6/3/11.

**Results and discussion.** There were prepared by the same procedure alumina- and silica- supported boron catalysts with low (0.2 wt. %), and high (2.4 wt. %) boron content. FT-IR and Raman spectroscopy revealed intensive sharp bands ~ 1380 $cm^{-1}$ and bands at ~1060 and ~1170 $cm^{-1}$ belonging to B-O from different boron-oxo species like boric oxide, metaborates and boroxol rings, respectively. Powder XRD confirmed presence of larger nanoclusters of $B_2O_3$ on silica support with the highest concentration of boron and on spent h-BN catalyst. XPS spectroscopy demonstrated that boron species are stable on alumina surface on the contrary to silica and that $BO_x$ species on h-BN are formed at expense of nitrogen. Activity and selectivity over individual catalysts differed in propane ODH. However, it can be stated that all three types of catalysts were dominated by olefins with a selectivity between 71 and 88% (propene, ethene), followed by CO (10-20%) and methane (0-5%). $BO_x$-$SiO_2$ showed the highest selectivity to olefins catalyst, the $BO_x$-$Al_2O_3$ system showed the highest ratio between C3 and C2 olefins. With increasing propane conversion, the overall selectivity to olefins decreased slightly and the relative content of ethene increased, more significantly on silica than on alumina. The obtained results prove that the stability of $BO_x$ species and at least the selectivity of ODH propane can be influenced by the character of the support. A more basic support stabilizes the surface $BO_x$ species more effectively and maintains a higher selectivity to propene. On the other hand, $Al_2O_3$ itself exhibits catalytic activity leading to the production of oxygenates and C4 hydrocarbons as by-products.

**Keywords:** operando spectroscopy, synthesis, metal-organic framework

**Introduction.** Metal-organic frameworks (MOFs) show great promise among nano- and micro-porous materials due to their intrinsic tunability and structural versatility, leading to their use in numerous applications in catalysis.[1] While the MOF field offers a great choice of materials after more than 30 years of development, one of the remaining challenges for their real-world implementation is the development of reliable synthetic procedures with speed, scale, and quality matching the industry requirements. Recently, aqueous-based room-temperature syntheses of certain MOFs, such as MOF-74/CPO-27 analogs were developed, allowing outstanding space-time yields of up to 18 720 kg $m^{-3}$ $day^{-1}$.[2] These green, high-yielding methods produce minimal waste and are promising for large-scale MOF implementation. However, there is a lack of understanding of the underlying mechanisms, which is crucial for further extension and optimization to other MOF families and the fundamental understanding of MOF formation pathways. In this work, we study the mechanism of the MOF-74 family formation in aqueous solutions on a preparative scale (> 0.5 g).

**Experimental/methodology.** *Operando* Attenuated Total Reflection IR spectroscopy (ATR-IR) was employed to study the mechanism of the MOF-74 family formation in an aqueous solution using a custom-made stainless steel batch reactor cell equipped with a ZnSe crystal (30°, 50x44x2 mm). Multivariate curve resolution-alternating non-negatively constrained least squares (MCR-AR-NNLS, as implemented in the pyMCR package)[3] of the ATR-FTIR data was utilized to extract the kinetic profiles of the species in the reaction mixture. The reaction products of the synthesis in the spectroscopy cell were isolated and characterized using powder X-ray diffraction, thermogravimetric analysis, and nitrogen physisorption.

**Results and discussion.** To study the proceeding of the synthesis, the solution of the sodium salt of 2,5-dihydroxyterephthalic acid was added using a syringe to the stirred solution of the Zn precursor in the ATR-IR cell. The reaction of MOF synthesis was found to proceed via the formation of an intermediate, which contains a twice-deprotonated ligand molecule (Figure 1). However, the nature and presence of the intermediate depend on the metal ion used in the synthesis. The kinetics of the MOF formation was also found to depend on the nature of the MOF metal ion and the synthesis temperature. The reaction products of the synthesis in the spectroscopy cell were pure MOFs and their excellent quality was confirmed by their conformity to the expected crystal structure and high BET surface area values exceeding 1350 $m^2g^{-1}$. Last, using the information revealed during the *operando* study, optimized synthetic protocols for MOF-74 materials are proposed.

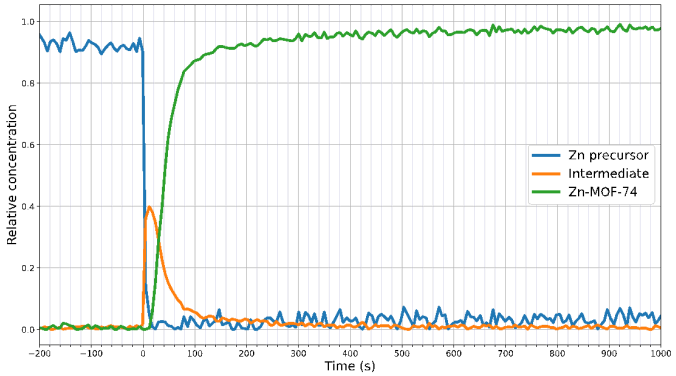

**Figure 1. Typical MCR results for a Zn-MOF-74 synthesis followed by *operando* ATR-IR**

**Keywords:** Acetylene, Cuprous acetylide, Ethynylation, Formaldehyde, Reppe chemistry

**Introduction**

In the 1940's Walter Reppe initiated the use of acetylene as raw material in industrial processes.[1] Today, the catalytic Reppe ethynylation reaction of acetylene and formaldedhyde to produce 1,4-butynediol represents an important C4 feedstock for high value-added downstream chemicals. The generally accepted catalytically active species in this reaction, cuprous acetylide, $Cu_2C_2$, has been experimentally identified only recently, probably due to its complex structure and explosive nature.[2]

Necessary safety precautions for handling of cuprous acetylides make analytical characterization very challenging. Motivated by Bruhm et al.,[2] who successfully identified $Cu_2C_2$ formed from copper oxide pre-catalysts, the formation of $Cu_2C_2$ during typical industrially applied catalyst activation procedures has been followed (pseudo) in situ in the present contribution. Particular safety protocols have been worked out and applied. Unsupported $Cu_2C_2$ model compounds were also synthesized for comparison.

**Experimental/methodology**

The synthesis of silica supported copper(II)oxide catalyst precursors was performed by co-precipitation followed by calcineation at 450°C. Activation is carried out under typical ethynylation conditions in formaldehyde solution at 1.2 bar acetylene and 90°C. The activated catalysts (wet, slurry) is analyzed by powder-XRD and Raman spectroscopy. The $Cu_2C_2$ quantity is deduced from thermal analysis.

**Results and discussion**

The mechanism of catalyst activation and formation of the active phase cuprous acetylide on silica could be deduced from the influence of various activation parameters as pH value/buffer systems, reducing agents, reactant concentrations, temperatures and additives. Thus, e.g. the Cu(II) precursor is not reduced by formaldehyde alone as generally assumed in the literature up to now. The formation of the catalytically active phase invloves CuO dissolution and $Cu_2C_2$ re-deposition steps. A p-XRD diffractogram of a slurry of an activated catalyst is shown in Figure 1. All activated catalysts were evaluated according to their performance in the ethynylation of HCHO to 1,4-butynediol.

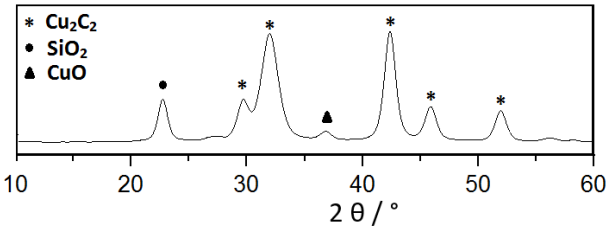

**Figure 1. Powder-XRD diffractogram of a silica supported copper oxide pre-catalyst activated under ethynylation reaction conditions. Reflexes of $Cu_2C_2$ and other components are assigned from crystalline $Cu_2C_2$ model compounds and reference data published by Bruhm et al.[2].**

# The functionality of binuclear centres in CHA in the dissociation of molecular oxygen

A. Kornas[1*], K. Mlekodaj[1], E. Tabor[1], D. K. Wierzbicki[2], S. Sklenak[1], H. Jirglová[1], J. Dědeček[1]

**Keywords:** binuclear centres, alpha oxygen, Fe-CHA

**Introduction.** A recent study showed that binuclear Fe(II) sites in zeolite of FER topology exhibit the unique ability to split molecular oxygen with the formation of α-oxygen species. Formed α-oxygen possesses an outstanding activity in the oxidation of $CH_4$ already at ambient temperature. Moreover, the products of this reaction were detected in the gas stream without an additional extraction step [1]. According to the current state of art, to form binuclear sites in the zeolitic matrix, a high population of closely located Al atoms (Al pairs), which stabilize divalent cations is required, as well as an axial geometry of two the cationic sites distanced by ~7Å. [1,2] However, this structural condition strongly limits the variety of zeolitic topologies efficient in the activation of $O_2$. The aim of this contribution was to investigate the ability of zeolites with non-axial coordination of Fe(II) sites to split $O_2$ and subsequently oxidize $CH_4$. For the study zeolite of CHA topology was chosen due to its low Si/Al guaranteeing a high population of Al pairs, enhancing the potential formation of binuclear sites, and sufficient distance and arrangement iron sites to activate molecura oxygen.

**Experimental/methodology.** DFT calculations (VASP program) including molecular dynamics were used to verify the possibility of $O_2$ splitting over iron sites in zeolites of CHA topology. CHA sample (Si/Al 2.1) was synthesized with the template-free procedure [3], and iron was introduced to the sample by the impregnation with an acetylacetonate solution of $FeCl_3$. Mössbauer and XAS spectroscopies were used to study the speciation and redox properties of iron sites after the evacuation of the zeolite at 450 °C, interaction with $O_2$, and subsequent reaction with $CH_4$ (as a testing reaction) at moderated temperatures (RT-220 °C). The activity tests in $CH_4$ oxidation were performed at various oxidation times and temperatures in three consecutive redox cycles with mass spectrometry detection of the reaction products.

**Results and discussion.** Synthetized sample CHA sample possesses typical structural parameters for zeolite of CHA topology (XRD, SEM), and the exclusive presence of framework Al atoms ($^{27}$Al MAS NMR). Mössbauer and XAS studies of evacuated Fe-CHA confirmed thepresence of atomically dispersed Fe(II) cations. Obtained spectral characteristics confirmed that the interaction of iron sites in CHA with $O_2$ led to the oxidation of iron Fe(II) $\rightarrow$(Fe(IV)=O)$^{2+}$, which was subsequently reduced to Fe(II) by $CH_4$. The analysis of the oxidation products revealed the presence of $CO_2$ and methanol detected directly in the gas stream. Moreover, the Fe-CHA works effectively in three consecutive reaction cycles. Gathered data allows the selection of optimal reaction conditions in order to obtain the highest productivity of oxygenates.

The results of this pioneering study confirm that $O_2$ can be efficiently activated over binuclear iron sites in CHA and further applied for the oxidation of such inert molecule as $CH_4$. Despite carrying the reaction over narrow-pored CHA topology, the oxidation products desorbed spontaneously from zeolite channels.

# The role of metal-support interactions in shape-controlled $TiO_2$ systems for photocatalytic hydrogen evolution

Elizaveta Kozyr,[1*] Francesco Pellegrino,[1] Silvia Bordiga,[1] Elena Groppo,[1] Aram Bugaev,[2] Lorenzo Mino[1]

[2]*SuperXAS beamline, SLS, Paul Scherrer Institute, Villigen, Switzerland*
[*]*elizaveta.kozyr@unito.it*

**Keywords:** *operando* spectroscopy, shape-controlled nanoparticles, XAS spectroscopy, photocatalysis.

**Introduction.**

One of the alternatives for future energy sources is hydrogen. This energy resource is attractive due to the possibility of obtaining it through green and renewable processes [1], such as photocatalytic water splitting. Noble metal nanoparticles (NPs) deposited on $TiO_2$ are among the most active systems for this reaction [2]. The rational design of a photocatalyst requires a detailed understanding of the relationship between structure and activity. In particular, the role of the different exposed $TiO_2$ surfaces and the chemical states of the supported metal NPs during the hydrogen evolution reaction needs to be clarified.

Combining multiple spectroscopic techniques in one experimental setup provides the possibility to look at catalytic systems from different perspectives and get comprehensive information.

**Experimental/methodology.**

We have investigated Pd NPs deposited on $TiO_2$ by photodeposition or deposition-precipitation techniques. To reveal the effect of metal-support interaction on the NPs reactivity we chose different $TiO_2$ morphologies, namely P25 and nanosheets. The catalyst was loaded inside a home-made cell, allowing to collect simultaneously also X-ray absorption spectroscopy (XAS), UV-Vis and mass spectrometry data. Pd *K*-edge XAS spectra were collected *in situ* during photodeposition of Pd on $TiO_2$ and subsequent hydrogen evolution reaction in liuid phase and in gas phase upon exposure to $H_2$ and $O_2$. UV-Vis spectra were collected *in situ* using Ocean optics and *ex situ* at different stages of the photodeposition. FTIR spectra using carbon monoxide as probe molecule were also measured in situ to assess the oxidation state and coordination of the surface exposed sites.

**Results and discussion.**

*Operando* XAS and UV-Vis spectroscopies revealed the reduction of Pd species during photodeposition from Pd(II) precursor to Pd(0) nanoaprticles acompained with the growing signal of the produced $H_2$. The redox properties of the formed metal NPs were probed in situ by exposure to molecular $O_2$ and $H_2$. Both morphologies with photodeposited metal on $TiO_2$ had stable Pd(0) NPs even at high tempertures in $O_2$ atmosphere, while samples obtained by the deposition-precipitation method were easily oxidized to Pd(II) oxide. Weak signal detected in difference XAS spectra suggested only surface Pd-$O_2$ interaction, which was stronger for $Pd/TiO_2$ nanosheets in comparison with $Pd/TiO_2$ P25. This was explained by stronger metal-support interaction in the case of {101} facets of $TiO_2$, dominating in P25, compared to the {001} ones, dominating in the nanosheets. Similar reactivity was proved by *in situ* IR spectroscopy using CO as a probe on the samples treated both under oxidizing and reducing conditions. FTIR spectra for CO adsorbed on $Pd/TiO_2$ samples after oxidation at 400°C shows two peaks at about 2120 $cm^{-1}$ and 2100 $cm^{-1}$ is due to to two contribution CO on ionic $Pd^+$ and CO on metallic Pd respectively, and CO absorption on $Pd^{2+}$ ion leads to the appearance of a band at 2160 $cm^{-1}$.

In conclusion, we succesfully performed a multi-technique in situ investigation to follow the evolution of active Pd sites in the Pd/TiO2 catalyst and highlight the role of the metal-support interactions as a function of the $TiO_2$ morphology and of the metal deposition method, allowing to correlate the catalyst structure with its photocatalytic properties.

# Effect of $H_2O$ Pre-exposure on $CH_4$ Oxidation and Passive $NO_x$ Adsorption Performance over Pd/zeolite Catalysts

Tala Mon, Jacob Concolino, Junjie Chen, Eleni A. Kyriakidou*

*Chemical and Biological Engineering Department, University at Buffalo, The State University of New York, Buffalo, NY 14260 (USA)*
**elenikyr@buffalo.edu*

**Keywords:** Pd/zeolite, $CH_4$ oxidation, passive $NO_x$ adsoprtion

**Introduction:** Pd speciation is essential to the investigation of Pd-based zeolite catalysts for passive $NO_x$ adsorption (PNA) and methane ($CH_4$) oxidation catalysts applications with ion-exchanged $Pd^{2+}$ and PdO nanoparticles as the active sites, respectively. The factors governing Pd speciation determine how Pd/zeolite catalysts should be stored and what pretreatments are required to restore the catalyst before use for PNA and $CH_4$ oxidation applications. Herein, the effect of $H_2O$ pre-exposure on Pd speciation in 0.5 wt.% Pd/BEA and Pd/CHA is investigated at ambient temperature (25 °C) with ambient moisture (3.1% $H_2O$). PNA and $CH_4$ oxidation evaluations are used as probe reactions to determine the presence of $Pd^{2+}$ and PdO species, respectively, before (fresh) and after $H_2O$ pre-exposure.

**Experimental/methodology**: $NH_4$-BEA (Si/Al = 12.5) (Zeolyst) were calcined at 500 °C/2 h to form H-BEA (12.5). Na-CHA (11) was synthesized as reported previously and was ion exchanged 3 times with 1 M $NH_4NO_3$ (80 °C/8 h), dried (110 °C/8 h), and calcined (550 °C/8 h) to produce H-CHA [2]. 0.5 wt.% Pd/BEA and Pd/CHA were synthesized by incipient wetness impregnation. The final catalyst was dried (110 °C/8 h) and calcined (500 °C/2 h). The $CH_4$ oxidation (1500 ppm $CH_4$, 12% $O_2$/Ar, 100 - 600 °C (5 °C/min)) and PNA (100 ppm NO, 12% $O_2$/Ar, adsorption: 100 °C/30 min) performance of the synthesized catalysts were evaluated in a packed bed micro-reactor (100 mg (250-500 µm), 333 sccm, 200 L $g^{-1}$ $h^{-1}$, pretreatment: 750 °C/1 h (20% $O_2$/Ar)). The catalysts were pre-exposed to 3.1% $H_2O$, 20% $O_2$/Ar at 25 °C/4 h for investigating the effect of $H_2O$ on Pd speciation. The presence of ionic Pd was determined by NO and CO diffuse reflectance infrared Fourier transform spectroscopy (DRIFTS).

**Results and discussion:** Small pore Pd/CHA (69%) outperformed large pore Pd/BEA (13%) as fresh catalysts at 600 °C suggesting the presence of more PdO in Pd/CHA compared to Pd/BEA (**Fig. 1A**). The $CH_4$ conversion of Pd/BEA was drastically improved after $H_2O$ pre-exposure from 13% to 98% at 600 °C with Pd/CHA (from 69% to 87%) improving less in comparison to Pd/BEA. NO-DRIFTS showed a decrease in ionic Pd(NO) (1875, 1845 $cm^{-1}$) after $H_2O$ pre-exposure over Pd/BEA suggesting that solvation of ionic Pd to form PdO may be responsible for the improved $CH_4$ conversion compared to the fresh Pd/BEA (**Fig.1B**).

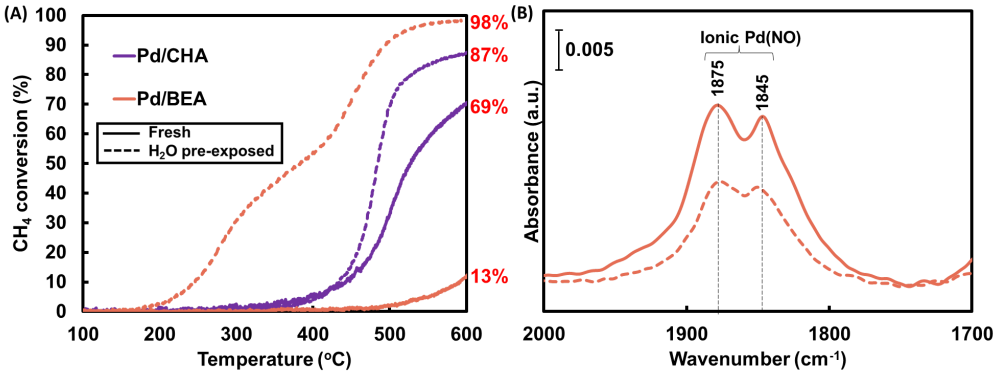

**Figure 1. (A) $CH_4$ oxidation light-off curves of fresh (solid line) and $H_2O$ pre-exposed (dashed line) Pd/BEA and Pd/CHA and (B) NO-DRIFTS of Pd/BEA**.

**Keywords:** Operando FTIR, Active site, Fe-FER, $N_2O$ decomposition

**Introduction.**

Nitrous oxide $N_2O$ is considered one of the major pollutants, the third one after carbon dioxide $CO_2$, and methane $CH_4$. $N_2O$ has a global warming potential around 300 times higher than $CO_2$, and like $CO_2$ it is long-lived spending an average of 120 years in the sky before disintegrating. In this context of global warming, continued interest in developing and understanding $N_2O$ decomposition is growing.

Reducing $N_2O$ emissions from industrial processes is a complex challenge. Low-temperature processes are being explored to minimize energy costs, while efforts are also being made to improve catalyst performance in the presence of different molecules contained in the industrial flow, such as $O_2$, NO, $NO_2$, $CO_2$, and $H_2O$, which can negatively impact catalyst activity or cause deactivation. According to the literature, Fe-FER and Fe-ZSM-5 catalysts have demonstrated the best results, with Fe-FER exhibiting superior activity in the presence of NO. Despite these efforts, the underlying mechanisms and key factors driving $N_2O$ decomposition remain uncertain and open to debate.

**Experimental/methodology.**

*Operando* FTIR spectroscopic techniques lead to providing further insight into $N_2O$ decomposition. In this work, different catalysts such as Fe-FER and Fe-ZSM-5 were studied. Industrial conditions were simulated (gas mixtures with $N_2O$, $O_2$, $H_2O$, etc.) working under pressure and adding different activity promoters, such as NO, CO, and $CH_4$ to the mixture. In addition, isotopic substitutions were used to better understand $N_2O$ decomposition steps.

**Results and discussion.**

As part of the results, the concentration of the active site, $Fe^{2+}$, of the different catalysts was quantified by in situ FTIR, using NO as a probe molecule. We have also discussed the correlation between the amount of $Fe^{2+}$ detected and the activity for $N_2O$ decomposition. By *operando* FTIR we have identified key steps in the mechanism by monitoring structural bands of the solid sensitive to the iron oxidation state. This provided important information on the reaction mechanism, revealing the oxidative role of active oxygen produced by $N_2O$ decomposition, the consecutive formation of HO-Fe species, and the effect of reducing gases addition in the flow to recover the $Fe^{2+}$ active sites. Additionally, we have demonstrated the role of water and its effect on the deactivation of $Fe^{2+}$ sites (also using $D_2O$), as well as potential solutions to mitigate this effect. Using $^{15}NO$ and $^{18}O_2$ isotopic gases we have shown the spectator role of molecular $O_2$ in the chemistry of the decomposition reaction, but also its effect as a physical competitor for adsorption on the catalytic surface.

All in all, the combination of *operando* IR spectroscopy in relevant industrial conditions and the use of isotopic species have permitted us to achieve a complete description of the catalytic decomposition of $N_2O$ on iron-based zeolites and a thorough description of active sites and their evolution during the reaction. This will allow designing a new generation of catalysts with enhanced properties for greenhouse gas elimination.

**Keywords:** Cu redox, in situ DRUVS, in situ DRIFTS, TD-DFT calculation, cage-confined Cu pair

**Introduction.** The low-temperature mechanism of chabazite-type small-pore Cu-SSZ-13 zeolite remains a debate and needs to be clarified for further improvement of $NH_3$-SCR performance. It is a consensus that the redox cycle of $Cu^{II} \leftrightarrow Cu^{I}$ dominates the overall activity of low-temperature SCR, involving the essential $[Cu^{II}_2(NH_3)_4O_2]^{2+}$ complexes formation generated by two mobile $Cu^{I}(NH_3)_2$ and $O_2$.[1, 2] Nonetheless, it is still not clear how the two Cu-complex intermediates are interconverted and whether there is any transient, less stable state during the interconversion.

**Results and discussion.** In this study, we established experimental protocols to follow the dynamic redox cycling (*i.e.*, $Cu^{II} \leftrightarrow Cu^{I}$) of Cu sites in Cu-SSZ-13 during low-temperature $NH_3$-SCR catalysis by diffuse reflectance *in situ* ultraviolet-visible spectroscopy (DRUVS) and *in situ* infrared spectroscopy (DRIFTS). Further integrating the *in situ* spectroscopic observations with time-dependent density-functional theory (DFT) calculations allows us to identify two cage-confined transient states, namely the $O_2$-bridged Cu dimers (*i.e.*, $\mu$-$\eta^2$:$\eta^2$-peroxodiamino dicopper) and the proximately paired, chemically non-bonded $Cu^{I}(NH_3)_2$ sites, and to confirm the $Cu^{I}(NH_3)_2$ pair as a precursor to the $O_2$-bridged Cu dimer. Comparative transient experiments reveal a particularly high reactivity of the $Cu^{I}(NH_3)_2$ pairs for the NO-to-$N_2$ reduction at low temperatures. Our study demonstrates for the first time, to the best of our knowledge, direct experimental evidence for the transient formation and high reactivity of proximately paired Cu sites under zeolite confinement, and provides new insights into the strongly debated low-temperature mechanisms of $NH_3$-SCR catalysis.

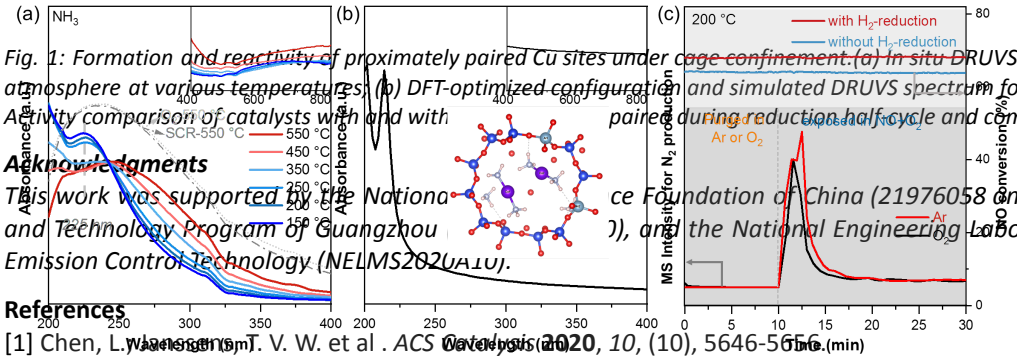

*Fig. 1: Formation and reactivity of proximately paired Cu sites under cage confinement.(a) In situ DRUVS spectra of Cu-SSZ-13 in $NH_3$ atmosphere at various temperatures; (b) DFT-optimized configuration and simulated DRUVS spectrum for the proximately paired; (c) Activity comparison of catalysts with and with paired during reduction half-cycle and complete $NH_3$-SCR reaction.*

**Keywords:** zeolites, vanadium active centers, DFT calculations, *α*–oxygen.

**Introduction.** The distant binuclear cationic sites were firstly identified using theoretical modeling in the context of the study of the $N_2O$ decomposition over the Fe(II) cation exchanged ferrierite, the beta zeolite, and ZSM–5 (i.e., Fe–ferrierite, Fe–beta, and Fe–ZSM–5, respectively) [1]. We devised that the presence of the active sites formed by the distant binuclear Fe(II) centers explained the exceptional activity of Fe–ferrierite in comparison with the Fe–beta and Fe–ZSM–5 catalysts [2]. The first chemical step of the $N_2O$ decomposition is the formation of the *α*–oxygen species [2,3] [i.e., $(Fe(IV)═O)^{2+}$] which exhibits unique oxidation properties reflected in an outstanding activity in the oxidation of methane to methanol at room temperature [3]. Furthermore, we predicted for the first time employing periodic DFT calculations and subsequently confirmed experimentally that the ferrierite zeolite exchanged with other transition metal cations able of the M(II) to M(IV) redox cycle could be employed for the preparation of the *α*–oxygen species [i.e., $(M(IV)═O)^{2+}$] using $N_2O$ [3].

Moreover, we firstly predicted using the power of periodic DFT calculations that these distant binuclear cationic sites were able to split dioxygen to yield pairs of the distant *α*–oxygen species. Subsequently, experiments were performed at room temperature and the theoretical prediction of a cleavage of dioxygen to give a pair of the distant *α*–oxygen atoms was confirmed experimentally and thus splitting dioxygen was discovered [4].

**Methodology.** Periodic DFT employing the VASP program.

**Results and discussion.** In this contribution, we report on our investigation regarding the structure and oxidation properties of the distant binuclear vanadium V(II) cationic sites as an example of the distant binuclear cationic sites formed by early transition metal cations.

**Keywords:** Heterogeneous catalysis, $CO_2$ hydrogenation, *in situ* DRIFTS, Mechanistic study, Ethanol

**Introduction** Climate change caused by increasing carbon emissions is one of today's greatest challenges. This challenge has sparked global interests in finding renewable, more sustainable fuels. One possibility is to combine emitted $CO_2$ with green hydrogen to synthesize fuels, closing the carbon cycle. It has been known for a couple of decades that certain promoted rhodium (Rh) catalysts can catalyze the $CO_2$ hydrogenation reaction to ethanol (EtOH).[1] However, still little is known about the reaction mechanism and the role of the promoters.[2] In this work transient *operando* DRIFTS studies in combination with multivariate curve resolution (MCR) analysis is used to gain more insight into the reaction mechanism and to understand exactly why the addition of Fe and Li promoters enhances the ethanol selectivity.

**Experimental/methodology** All the catalysts were prepared via impregnation method. Transient *in situ* DRIFTS experiments were performed using a Thermo Scientific Nicolet 6700 FT-IR spectrometer and a custom DRIFTS cell with a ZnSe window at a pressure of 20 bar. A four-way switching valve was used to apply perturbations to the system (e.g. switching between $CO_2$ and $H_2$ in 15-minute intervals). The product stream was continuously analyzed using a mass spectrometer.

**Results and discussion** It was found that the addition of promoters (Fe, Li) introduces formate on the catalyst surface, which might provide an additional carbon source for ethanol production. Additionally, it was found, during the $CO_2$-$H_2$ switching experiment (Fig. 1), that EtOH and $CH_4$ are formed during the $CO_2$ phase, while MeOH is formed during the $H_2$ phase. It was postulated that the promoters induce the presence of oxidized rhodium on which linear carbonyl species can bind. This linear carbonyl on oxidized rhodium might be more active in forming the acetyl species than linear carbonyls. This acetyl species could then be further hydrogenated to ethanol.

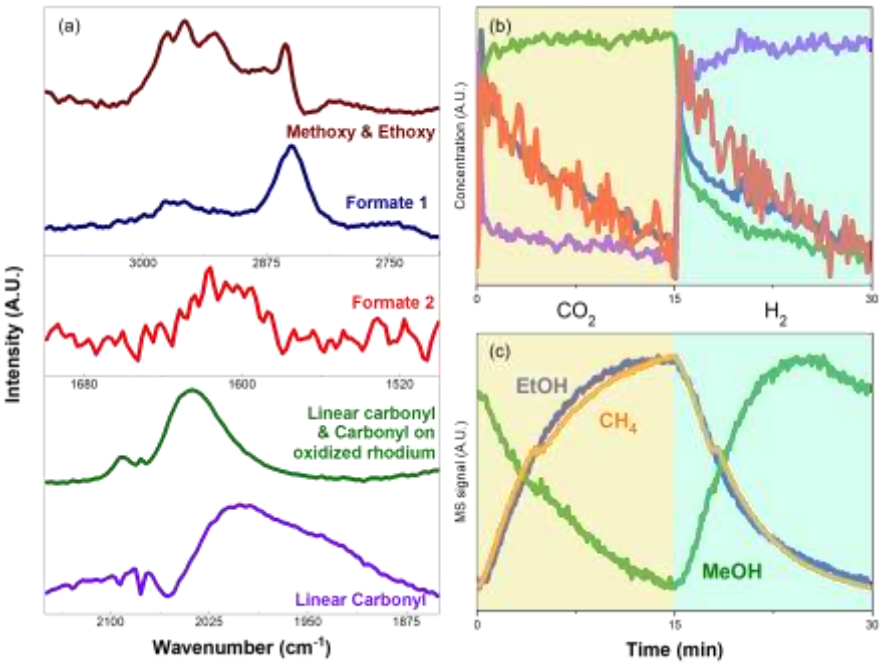

Figure 1 Reactant switching experiment on 1wt% $RhLi/SiO_2$, for 15 minutes a flow of 20 mL/min $CO_2$/He with a ratio of 1/3 is ran across the catalyst, after this for 15 minutes a flow of 20 mL/min $H_2$/He with a ratio of 3/1 is ran across the catalyst at 180 °C and 20 bar. (a) MCR resolved spectra of the obtained DRIFTS results (b) MCR resolved concentration profiles of the MCR resolved spectra, the concentration profiles correspond to their respective spectra with the same colors (c) normalized response of EtOH, $CH_4$ and MeOH measured by MS in the outlet gas.

**Keywords:** mercury porosimetry, pore size, throat size, cavity volume, catalyst support, pore networks, hierarchical porosity

**Introduction.** The void structure of porous materials used as catalyst supports affects several properties such as permeability to liquids, gas diffusion, access of organic molecules, availability of oxidation/reduction active sites, etc. Mercury intrusion porosimetry has been widely used to investigate the accessible pore volume starting from about 3.6 nm up to more than 600 µm. The main limitation of mercury porosimetry is related to the measure of the access size to the porous network, to which the volume of mercury intruded, thus the pore volume, is associated. This generates an image of a simple bundle of cylindrical capillaries that might jeopardize further calculations that are related to pore size and pore volume, like permeability and diffusion. An advanced technique of differential cycling porosimetry [1] has been applied to several catalyst supports to better describe the porous network distinguishing the access channels' volume and size (pore throats) from the internal junction void volumes (pore cavities).

**Experimental/methodology.** Eight commercially available alumina catalyst supports were analyzed using repeated mercury intrusion cycles. Catalyst supports have been first measured by a classic intrusion/ extrusion mercury porosimetry up to about 400 MPa. The obtained curve is then used to evaluate the required pressure steps to better define the intrusion pressure region. Once the cycling steps are defined, fresh samples are submitted to pressurization up to the first step followed by a depressurization back to about atmospheric pressure, measuring at this point the residual volume of mercury trapped in the cavity. The porosimeter then is going to the next pressure step, as stated by the preliminary evaluation, to go back again to atmospheric. Cycles are repeated up to the maximum pressure of over 400 MPa. The distinction between the pore throats and pore cavity volumes is attainable by subtracting the residual mercury volume from the total intruded volume for each cycle.

**Results and discussion.** The differential cycling porosimetry technique provides additional information on materials with a complex pore structure distinguishing the access volume and size from the cavity volumes. Cavity volumes can then be put in relation to the average access size determined by the intrusion pressures. The method might help to better investigate different catalyst behaviors, despite having similar physical and chemical properties, when diffusion or permeation phenomena are affecting the catalyst efficiency or selectivity. A detailed comparison of cycling porosimetry with more classical mercury porosimetry methods and the Reverberi technique [2] is described in the present work.

**Introduction.** Ammonia is regarded as a promising alternative to hydrogen for renewable energy storage [1]. Ammonia has high energy density and can be easily liquified and transported through the existing well-established infrastructure to a place of energy demand. However, technologies for recovering energy from ammonia, such as combustion or cracking to hydrogen for fuel cells, suffer from incomplete conversion. To remove the residual ammonia, ammonia slip catalysts (ASCs) need to be applied. They are typically based on supported Pt and are used to selectively oxidise ammonia to nitrogen and water. To improve the activity and selectivity of ASCs, it is important to unravel the surface species on Pt participating in the reaction mechanism and their effect on catalytic performance. Most of the studies on the reaction intermediates probe them under vacuum or on unsupported Pt [2,3]. Such model conditions do not allow to account for the role of support and all the moieties present under atmospheric pressure (e.g. $N_2O$ or bulk oxides) [2,4]. Hence, this study focuses on identifying species participating in ammonia oxidation on supported Pt under atmospheric pressure which can be achieved by using *operando* X-ray absorption spectroscopy (XAS) [5].

**Experimental.** *Operando* XAS was used to detect spectral trends reflecting the reaction mechanism on $Pt/Al_2O_3$ catalysts. Further, the species at the origin of these spectral trends were identified with kinetic studies, *operando* diffuse reflectance infrared Fourier transform spectroscopy (DRIFTS), *in situ* XAS in the atmospheres of reaction products/educts. Additionally, the geometries of Pt containing possible reaction intermediates on the surface were optimised with density functional theory (DFT) and used to calculate their Pt $L_3$ edge XAS spectra and to compare them with experimental spectra.

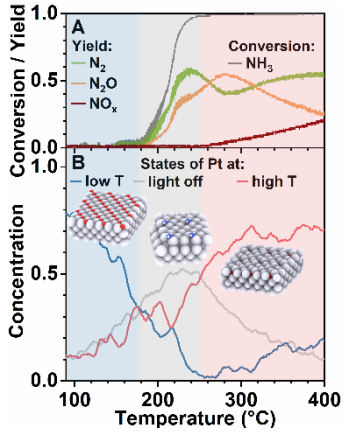

**Figure 1. Species in top layers of Pt governing its catalytic performance.**

**Results and discussion.** Three main states of Pt surface were identified during light offs in reaction mixture. Their evolution correlated with catalytic activity and selectivity (see fig. 1). The first state was predominant at low temperatures. It corresponded to inactive Pt poisoned by O. The second state prevailed at light off temperatures. It was attributed to more reduced Pt surface covered with

$NH_3$ and its dissociation products. This state related to high activity and selectivity to $N_2$. The third state evolved as Pt surface started lacking ammonia due to its high conversion at elevated temperatures. Under these conditions oxygen probably diffuses into the subsurface of Pt. This state did not decrease catalytic activity but could be associated with low selectivity.

**Keywords:** zeolites, iron active centers, Al distribution, $N_2O$ abatement.

**Introduction.** Elimination of greenhouse gases $N_2O$ originating from the production of chemicals (adipic acid and nitric acid plants), the fossil-fuel combustion processes (power plants), and the three-way catalytic converters (TWCs) represent one of the goals of environmental catalysis [1-3]. Iron zeolites are known as effective catalysts for the $N_2O$ abatement process in the presence of NOx. [1]. In this study, we focused on the analysis of the influence of zeolite structure and population of iron active sites controlled by Al atoms organization on the $N_2O$ abatement reactions.

**Experimental/methodology.** Two Fe-MOR and two Fe-FER with similar Fe wt.% ~1 and ~2 were selected as model catalysts for $N_2O$ abatement via decomposition in the absence or presence of NO ($DecN_2O$ or $DecN_2O$+NO), or via reduction with $CH_4$ in the absence or presence of excess $O_2$ ($CRN_2O$ or $SCRN_2O$). The methododlogy of catalytic tests included in-situ UV-Vis, and in-situ opernado FTIR studies.

**Results and discussion.** Catalytic results showed that Fe-FER catalysts were markedly more active than Fe-MOR at similar Fe-loading for the $DecN_2O$ and $DecN_2O$+NO, and slightly more active for the $SCRN_2O$, whereas for the $CRN_2O$ they showed similar activity. This suggests the influence of the reactant mixture on the iron oxidation state during the catalytic cycle. In situ UV–vis DRS experiments performed over Fe-MOR and Fe-FER, in which samples were oxidized by $N_2O$ at 250 °C and reduced by $CH_4$ at 250 °C, showed different mobility of the redox couple $Fe^{3+}/Fe^{2+}$ in the presence of the various reactants in MOR and in FER, which is in agreement with catalytic results. Operando-FTIR experiments on Fe-FER showed (i) the activation of $N_2O$ assisted by Fe-OH species (formation of an intense OH signal at 3644 $cm^{-1}$) in $N_2O$ flow, and (ii) the activation of $CH_4$ via oxidative dehydrogenation (formation of $Fe^{2+}$-CO) in $CH_4$ flow. Methoxy/formaldehyde/formate species formed in $N_2O$+$CH_4$ flow in both Fe-MOR and Fe-FER, that possessed a similar reactivity. After $O_2$ addition to the mixture, in Fe-FER methoxy/formaldehyde/formate species were stable, whereas in Fe-MOR specific formate species decreased while the activity decreased.

All results suggest that $N_2O$ reduction with $CH_4$ required $Fe^{2+}$-containing bifunctional active sites. In the presence of $O_2$ all these sites are stable in FER, whereas a fraction of them is oxidized in MOR. The cation siting affecting iron reactivity toward $N_2O$ abatement is discussed.

**Introduction.** The emission of nitrogen oxides ($NO_x$) from diesel vehicles is a major contributor to air pollution around the world. Cu-exchanged chabazite zeolites (Cu-CHA) are efficient and stable catalysts for the abatement of these $NO_x$ emissions via the selective catalytic reduction of NO by $NH_3$ to $N_2$ and $H_2O$ ($NH_3$-SCR). However, the application of Cu-CHA catalysts for $NH_3$-SCR is limited, because the presence of $SO_2$ can cause significant deactivation of Cu-CHA catalysts below 300 °C [1-3]. The interaction of $SO_2$ with Cu-CHA catalysts depends on the state of the Cu [4]. To obtain further insight in the $SO_2$ deactivation mechanism of the Cu-CHA catalysts for $NH_3$-SCR we identify the Cu-species that react with $SO_2$ using in-situ X-ray absorption spectroscopy (XAS), by carefully preparing well-defined Cu-species and expose these to $SO_2$ at 200 °C.

**Experimental** The XAS measurements were done at the BM23 beamline of the ESRF (European Synchrotron Radiation Facility). A Cu-CHA catalyst (Si/Al=6.7, 3.2 wt% Cu) was pre-treated in six different ways, to form well-defined $Cu^{I}$ or $Cu^{II}$ species with and without $NH_3$. The reactivity of these Cu species with $SO_2$ was monitored by the changes in the XAS spectra during exposure to 400 ppm $SO_2$ at 200 °C. The effect of $O_2$ on this reactivity was determined by exposing the different Cu species to a mixture of 100 ppm $SO_2$ and 10% $O_2$. Furthermore, the $SO_2$-uptake was determined by X-ray adsorbate quantification (XAQ) [5] and temperature programmed desorption of $SO_2$.

**Results and discussion.** While the XAS spectra of the $Cu^{I}$ species and $Cu^{II}$ species in absence of $NH_3$ remain largely unaffected by the $SO_2$ at 200 °C, the XAS spectra of the $[Cu^{II}(NH_3)_4O_2]^{2+}$ and $Cu^{II}$+$NH_3$-states change significantly, indicating that $SO_2$ reacts with $Cu^{II}$ in the presence of $NH_3$. In these cases, the characteristic pre-edge peak at 8983 eV for the $Cu^{I}(NH_3)_2$ complex [6] becomes more pronounced, indicating that the exposure to $SO_2$ leads to some formation of $Cu^{I}$. With the mixture of $O_2$ and $SO_2$, no $Cu^{I}$ is observed, but the local geometry changes upon the interaction with $SO_2$. $SO_2$-TPD on the $SO_2$ exposed samples and XAQ results during the exposure to $SO_2$ also showed the largest uptake of $SO_2$ by $[Cu^{II}(NH_3)_4O_2]^{2+}$ and $Cu^{II}$+$NH_3$-states, corroborating these results, and the presence of $O_2$ leads to a larger uptake of $SO_2$. Because the $[Cu^{II}(NH_3)_4O_2]^{2+}$ complex is a key intermediate in the $NH_3$-SCR reaction cycle, the poisoning of the Cu-CHA catalyst by $SO_2$ seems to be a chemical poisoning caused by the strong interaction of this $[Cu^{II}(NH_3)_4O_2]^{2+}$ comples with $SO_2$, which is further enhanced by $O_2$.

**Introduction.** Supported metal catalysts are known to respond to pretreatment and reaction conditions by restructuring [1]. An example of catalyst restructuring is the embedding of metal nanoparticles (NPs) by overlayers of reducible supports, such as $TiO_2$, following high temperature reduction [2]. Here, we show that $TiO_x$ overlayers formed on $Ni/TiO_2$ catalysts are completely removed or partially restructured under $CO_2$ hydrogenation conditions, depending on the reduction temperature.

**Experimental/methodology.** 6 wt.% Ni/ $TiO_2$ P25 catalysts were prepared by deposition precipitation, and studied by *operando* TEM ($H_2$ or 1:3 $CO_2$:$H_2$, 1 bar, 400–600°C), on an aberration-corrected ThermoFisher Scientific Titan Cubed EM, in a climate G+ nanoreactor (DENS solutions). *Operando* FT-IR spectroscopy was performed on a Bruker Tensor 37 spectrometer, in a HTHP Specac cell ($CO_2$:CO:$H_2$ mixtures, 200–400 °C).

**Results and discussion.** The $Ni/TiO_2$ catalysts were reduced at 400 or 600 °C to induce different degrees of overlayer formation. After 400 °C reduction, a $TiO_x$ overlayer formed selectively over Ni (111) facets, which was completely removed upon exposure to $CO_2$ hydrogenation conditions, leading to NPs restructuring (Figure 1A-D). After 600 °C reduction, a complete encapsulation by $TiO_x$ was shown by both *operando* TEM and $H_2$ chemisorption. Such layer was only partially removed under $CO_2$ hydrogenation conditions, forming a patchy $TiO_x$ overlayer, and exposing about half of the Ni sites to the gas atmosphere (Figure 1E,F). This led to the formation of Ni interfacial sites in contact with $TiO_x$ and resulted in higher TOFs for $CO_2$ methanation and C–C coupling for the 600 °C-reduced catalyst. We propose that the increased Ni–$TiO_x$ interface aided C–C coupling by providing a reservoir of carbon species in close contact with adsorbates on Ni.

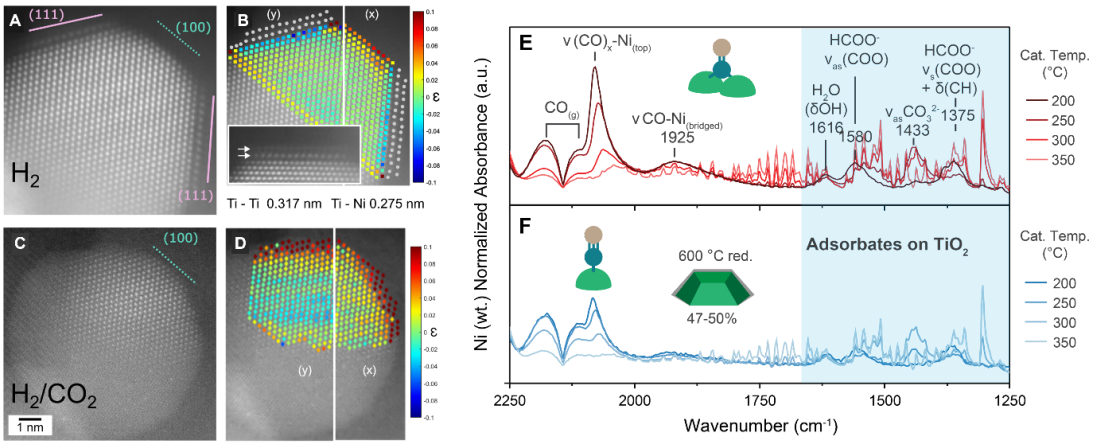

Figure 1. (A) A representative atomic resolution HAADF-STEM image of a Ni nanoparticle (NP) in a $Ni/TiO_2$ catalyst ($H_2$, 400 °C). Solid lines indicate $TiO_x$-covered Ni atomic planes and dashed lines indicate bare facets. (B) Estimated positions of Ti (gray) and Ni atomic columns (color scale for strain). (B insert) Close-up of the $TiO_x$ bilayer, where white arrows highlight each Ti layer. (C) HAADF-STEM image of the same particle as in (A) upon exposure to a $CO_2$:$H_2$ (0.25: 0.75 bar, 400 °C) showing complete re-exposure of Ni and NP restructuring. # Identifying the species producing ethylene and propylene in the methanol-to-olefin reaction by *operando* spectroscopy

J. C. Navarro, S. Chung, T. Li, J. Ruiz-Martínez*

*King Abdullah University of Science and Technology, KAUST Catalysis Center (KCC), Thuwal 23955-6900, Saudi Arabia*

**javier.ruizmartinez@kaust.edu.sa*

**Keywords:** Methanol to olefins, UV-Vis spectroscopy, reaction mechanism.

**Introduction**

Global demand of olefins is based on fossil fuel sources, but they are limited, so the search for new alternatives is required. One of these alternatives is methanol, which can be converted into polymer-grade alkenes over acidic zeolites. Such processes are known as the methanol-to-olefin (MTO) reaction. Although the MTO process is already commercialized, the mechanism of methanol conversion is complex, and it has still not been thoroughly understood. More specifically, the active species governing the selectivity towards ethylene and propylene are not well understood yet [1].

**Results and discussion**

Considering the aspects mentioned, the present work is focused on understanding the species controlling olefin selectivity via *operando* UV-Vis spectroscopy. For that purpose, we have chosen H-Beta as model zeolite as we found that the propylene/ethylene ratios can be easily modified by changing the $SiO_2/Al_2O_3$ ratio (SAR). Six Beta samples with SAR = 25, 38, 75, 100, 150, and 300 (Zeolyst International) were used. Interestingly, propylene/ethylene ratios are increased when the SAR increased, to a level where such ratio is over 60 with the samples with SAR 300 (**Fig. 1a**). Looking at the UV-Vis spectra for the tested zeolites under operando conditions (**Fig. 1b**), we noticed that the band ascribed to alkylated benzene carbocations with low degree of alkylation (≈342 nm) decreases with respect to the band attributed to monoenyl/cyclopentenyl carbocationic species (≈286-299 nm) when SAR increases. A clear correlation was obtained when plotting the ratio of the intensity bands with the propylene/ethylene ratio (**Fig. 1c**), which suggest that low alkylated benzene species are predominantly ethylene makers and monoenyl/cyclopentenyl species are in charge of the production of propylene [2]. A similar trend was also observed in H-ZSM-5 samples.

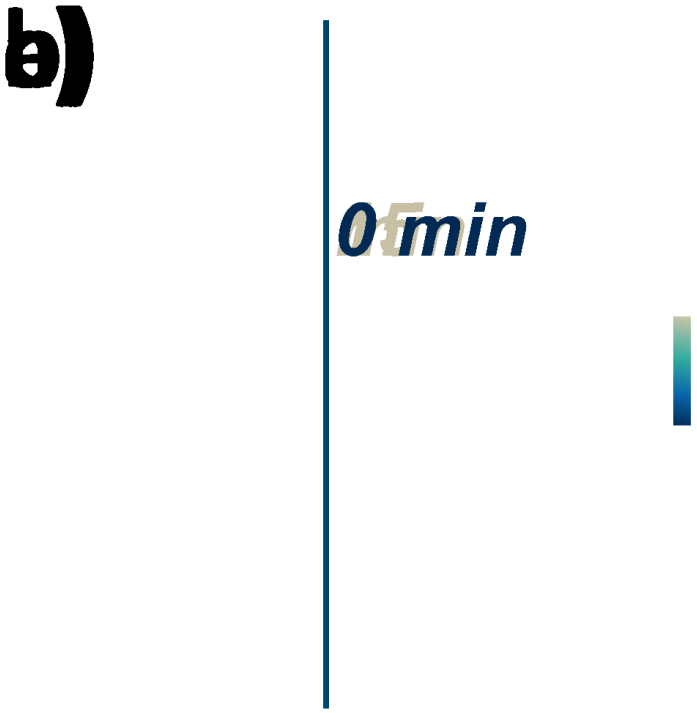

**Figure 1. a)** Catalytic performance for BEA zeolites with different SAR (400°C, 1 atm, WHSV = 4 $h^{-1}$), **b)** UV-Vis spectra for BEA (SAR=25, 150 and 300), and **c)** Bands correlation versus $C_3^=/C_2^=$ ratio for BEA (SAR= 25, 150 and 300)

# Kinetic and operando UV-vis study of $NH_3$-SCR over $V/TiO_2$

A. Lanza[1,2], R. Resmini[1], J. Gopakumar[3], D. Chen[3], K. Rut[3], C. Negri[1], M. Maestri[1], A. Beretta[1*]

[1]*Politecnico di Milano, Milan, Italy;* [2]*Johnson Matthey Technology Centre, Sonning Common, United Kingdon*

[3]*NTNU, Trondheim, Norway ,* [*]*alessandra.beretta@polimi.it*

**Keywords:** $NH_3$-SCR, Operando UV-vis, redox kinetics, HCl promotion, modelling analysis

**Introduction.** $NH_3$-SCR over V-catalysts is known to involve V redox cycle. In [1] dynamic testing and operando FTIR showed a remarkable promoting effect of V-doping with HCl, which was associated to a selective enhancement of NO oxidative activation; this, in turn, supported the identification of V reduction as rate determining step of the process. In this work, operando UV-vis experiments were performed to further investigate the redox kinetics; conversion and d-d transition measurements were acquired simultaneously and their quantitative analysis was based on reactor and kinetic modelling tools, looking for an insight of the dependence of site distribution on operating conditions and HCl addition.

**Experimental.** A 2%$V/TiO_2$ was tested in a operando UV-Vis rig, with a quartz reactor connected to a MS. After preoxidation at 450°C, the catalyst was coold to the desired teperature in the range 150-300°C and the SCR test was performed (NO=$NH_3$=1000 ppm, $O_2$=0.25-10%). A series of tests were also run by adding a chlorination treatment (HCl=100 ppm+$O_2$=10%) prior to the SCR test. The oxidation state of V was monitored by an external UV-vis probe; the fraction of reduced $V^{5+}$ sites was obtained by the d-d transition band at 670 nm (the fingerprint of $V^{+4}$). The maximum fraction of reducible $V^{+5}$ was determined by the extent of the d-d transition at 400°C in a $O_2$-free test with NO+$NH_3$=1000 ppm after preoxidation.

**Results and discussion.** $NH_3$-SCR tests were perfomed at varying temperature and $O_2$ concentration with and without HCl-preadsorption on the catalyst bed. Data were modelled by assuming a 1D plug-flow reactor model and a red-ox rate expression, that combines the single steps of oxidation and reduction; the distribution of reduced and oxidized sites (in terms of $\sigma_{ox}$ / $\sigma_{red}$ ratio and coverage of oxidized sites $\sigma_{ox}$ ) could be obtained as function of gas phase composition and intrinsic rate contants, as shown in the Table.

**Table** – Red-ox rate expression

| | | | |
|---|---|---|---|
| $r = \left(\frac{\sigma_{ox}}{r_{reduction}} + \frac{\sigma_{red}}{r_{oxidation}}\right)^{-1}$ | $r_{reduction} = k_{NO} \cdot P_{NO} \cdot \sigma_{ox} \cdot \theta_{NH_3}$ with $\theta_{NH_3}$ $\theta_{NH_3}$ =1 under large NH3 conc [2] | $r_{oxidation} = k_{ox} \cdot P_{O_2}^{n} \cdot \sigma_{red}$ with n= ¼ [2] | $\frac{k_{NO} \cdot P_{NO}}{k_{ox} \cdot P_{O_2}^{1/4}} = \frac{\sigma_{ox}}{\sigma_{red}} = \frac{\sigma_{ox}}{1-\sigma_{ox}}$ |

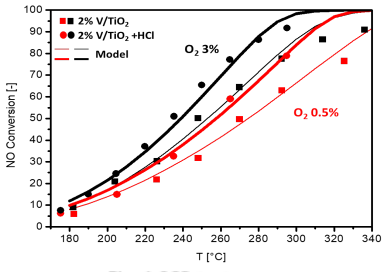

Fig. 1 SCR tests

The rate constants $k_{NO}$ $k_{NO}$ and $k_{ox}$ $k_{ox}$ were estimated from the conversion data with and without HCl doping (Fig. 1). HCl promoted the kinetics and the model analysis confirmed that the rate of reduction grew more importantly than that of oxidation. The model was then applied to predict the site distribution along the reactor, under the conditions explored. The simulated values of $\sigma_{ox}$ at mid bed length were compared with the d-d transition obtained from UV-vis (Fig. 2), taken as representative of the central zone of the bed. The spectroscopic data showed an increasing trend of $\sigma_{ox}$ at increasing T, which is in line with the predicted effect of temperature on site distribution due to the local progressive decrease of NO concentration and extinction of the reduction step. At low T, UV-vis showed a larger extent of reduced V sites after HCl-pretreatment, which well agreed with the estimated promotion of HCl on the rate of the reduction step. While the nature of HCl-V-NO interaction is under investigation, this

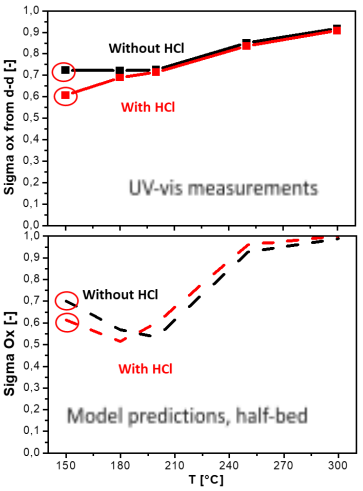

Fig.2 Measured and calculated $s_{ox}$

work demonstrated the potential of a methodology, where the kinetic analysis supports the interpretation of UV-vis data (as herein addressed) and may guide the design of kinetically relevant operando experiments.

# $SiO_2$-Supported $Co_xPt_y$ Nanoalloys for the Dry Reforming of Methane

D. Niedbalka[1], L. Thommen[1], P. M. Abdala[1*], C. R. Müller[1*]

[1]*Department of Mechanical and Process Engineering, ETH Zurich, 8092 Zurich, Switzerland*

**Keywords:** strong electrostatic adsorption, alloys, cobalt, platinum, nanoparticles

**Introduction.** The dry reforming of methane (DRM) allows converting two major greenhouse gases, $CH_4$ and $CO_2$, to produce $H_2$ and CO (syngas). This reaction is catalyzed by noble or transition metals supported on metal oxide supports and requires high temperatures (600 – 1000 °C) to achieve high conversions. However, many catalysts for DRM suffer from deactivation due to carbon deposition, particle growth, and oxidation. Bimetallic nanoparticles offer a versatile strategy to overcome the limitations of monometallic systems via the tuning of the catalysts' electronic and/or geometric structure.[1] Here, we report the development of $SiO_2$-supported $Co_xPt_y$ model catalysts aiming to understand the effect of the ratio of Co : (Co+Pt) on the catalyst's structure and catalytic performance.

**Experimental/methodology.** Mono- and bimetallic $Co_xPt_y/SiO_2$ catalysts were synthesized by strong electrostatic adsorption (SEA).[2] The precursors $[Co(NH_3)_6]Cl_3$ and $Pt(NH_3)_4(OH)_2{\cdot}xH_2O$ were dissolved in DI $H_2O$ and the pH was adjusted to 11. The Co to Pt precursor concentrations were varied to obtain the desired Co to Pt ratio. The catalysts were dried in air and pre-reduced at 800°C in 10 % $H_2/N_2$ for 1 h. The DRM reaction was performed at 800 °C with a space velocity of 75 L $g_{cat}^{-1}$ $h^{-1}$. The catalysts were characterized by a variety of techniques including X-ray powder diffraction, X-ray absorption spectroscopy, $H_2$ temperature-programmed reduction and Raman spectroscopy.

**Results and discussion.** SEA nanoparticles of $Co_xPt_y$ that are highly dispersed on the $SiO_2$ support were obtained (diameter in the range of 1.7 – 3 nm, Figure 1A). We observe that the catalytic activity ($CH_4$ and $CO_2$ conversions) and stability are drastically affected by the ratio Co : (Co+Pt). While $Pt/SiO_2$ deactivates quickly under DRM conditions, $Co/SiO_2$ shows low activities and $H_2/CO$ ratios. The bimetallic $Co_xPt_y/SiO_2$ system increases the stability and/or enhances the $CH_4$ conversion (Figure 1B). Interestingly, we observed a volcano-type $CH_4$ conversion behavior (360 min TOS) with respect to the molar ratio Co : (Co+Pt). Thus, our study demonstrates that fine-tuning the composition of the alloy is a versatile design tool to yield active and stable CoPt-based catalysts for DRM. The formation of a $Co_xPt_y$ nanoalloy with a molar ratio Co : (Co+Pt) = 0.45-0.55 showed the best catalytic performance likely due to a combination of geometrical and electronic effects.

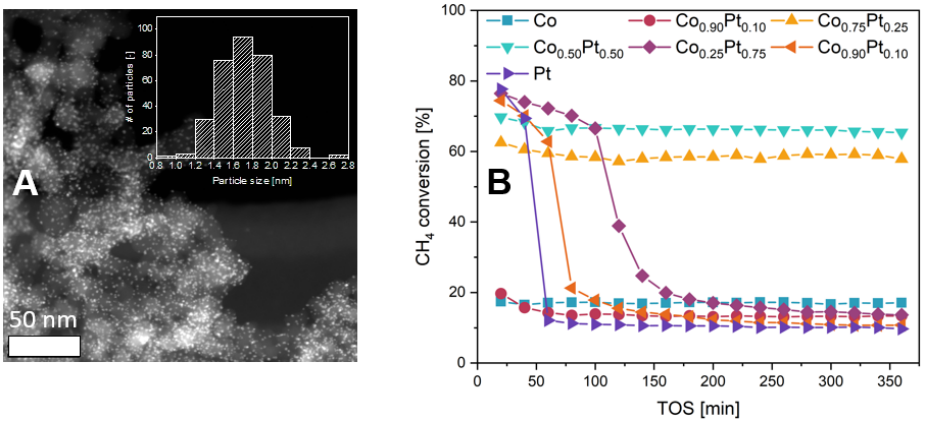

**Figure 1: A) STEM image of $Co_{0.50}Pt_{0.50}/SiO_2$ (reduced at 800 °C in 10 % $H_2/N_2$ for 1 h), $d_{(S)TEM}$ = 1.73 ± 0.23 nm (N = 326). B) $CH_4$ conversion of the series of $Co_xPt_y/SiO_2$ catalysts under DRM conditions (75 L $g_{cat}^{-1}$ $h^{-1}$, 800 °C).**

**Keywords:** lithium-mediated nitrogen reduction, solid-electrolyte interphase, neutron reflectometry

**Introduction.** Ammonia ($NH_3$) is a critical component of fertilizer that sustains the human population of 8 billion [1]. The main method to produce $NH_3$, the Haber-Bosch process, is energy-intensive, centralized, and fossil-fuel powered. An electrochemical method, however, would enable decentralized $NH_3$ production powered by renewables [2]. The most promising electrochemically-driven method, lithium-mediated nitrogen reduction (Li-$N_2$R), involves the electroplating of Li from an organic electrolyte, which subsequently reacts with nitrogen and a proton source to form $NH_3$ [2]. A solid-electrolyte interphase (SEI) layer forms during this process as a result of reduced Li reactivity with the electrolyte and is hypothesized to be critical to dictating system performance [2]. Recent work has demonstrated that using fluorinated salts, e.g., lithium tetrafluoroborate ($LiBF_4$), results in superior performance with respect to the commonly-used lithium perchlorate ($LiClO_4$) [2]. Using *operando* neutron reflectometry, we characterized the structure and composition of the $LiBF_4$ and $LiClO_4$ SEI layers, providing structural insight into improved Li-$N_2$R performance.

**Experimental/methodology.** Copper (Cu) working electrodes were prepared via physical vapor deposition on a silicon (Si) substrate. The electrolyte composition was either 1 M $LiClO_4$ or 1 M $LiBF_4$ tetrahydrofuran (THF) with either 1%v/v ethanol or no ethanol added. Applied current was cycled between 0 and -0.3 mA/cm$^2$ and neutron reflectivity measurements were used to characterize the interface [3]. The observed reflectivity profiles were fit as a function of layer thickness, scattering length density (SLD), and roughness to determine layer structure and composition [3].

**Results and discussion.** Figure 1a-b shows the reflectivity data and fit, and SLD model, respectively, of an experiment on a Cu WE with 1 M $LiBF_4$ and 1 vol% ethanol in THF. A constant current density of -0.3 mA/cm$^2$ was cycled for 4 mins, then 12 mins, and then the reflectivity data was collected at the subsequent open circuit potential. The SLD profile in Figure 1b indicates the formation of two layers on the Cu electrode surface. Previous work describes the first layer to be likely Li-rich [3], and for $LiBF_4$, it likely contains LiF species [2]. The second layer is likely a diffuse layer containing organics interfaced with deuterated THF (SLD = 6.2) [3]. As compared to the $LiClO_4$ equivalent experiment, the structure of these layers is more stable, where reflectivity data before and after cycling show fewer changes. These results confirm that $LiBF_4$ forms a more stable SEI structure, enabling improved Li-$N_2$R performance.

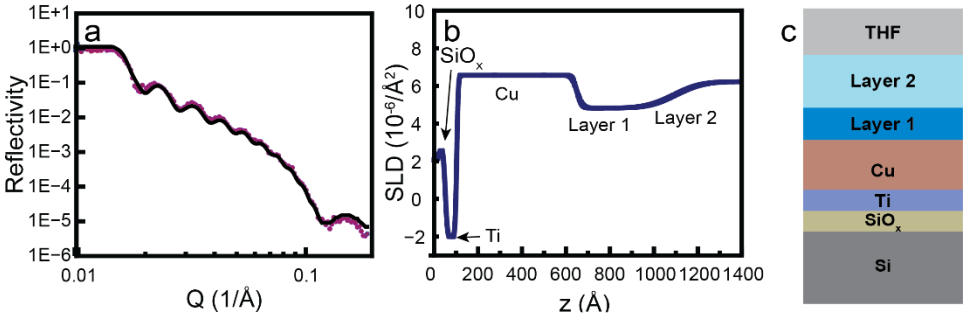

Figure SEQ Figure * ARABIC 1: (a) reflectivity curve after 30 mins constant applied current at -0.3 mA/cm$^2$ to plate Li using 1 M $LiBF_4$ with 1 vol% ethanol and (b) resulting SLD profile where z = distance from the Si substrate (c) schematic of layers indicated in SLD profile

**Keywords:** *Operando* FTIR-DRIFTS-MS, low temperature CDRM, methane, synthesis gas, ruthenium.

**Introduction.** CDRM is a crucial reaction that converts $CH_4$ into synthesis gas utilizing $CO_2$. Two major drawbacks of the reaction are its very strong endothermicity and coke formation. While these acute limitations hinder CDRM to be comfortably utilized, researchers in the last few decades have been studying catalysts which can perform at low CDRM temperatures (T<500 °C). By doing so, coke formation is favored much less and the energy-intensive nature of the reaction is relieved. In this study, a Ru-La/$ZrO_2$ catalyst was prepared and surface of the catalyst was monitored via FTIR-DRIFTS-MS system in *operando* conditions. The targeted information give insight on the surface mechanism during low T CDRM and the extent of its match with the mechanistic results reported in literature for high T CDRM as well.

**Experimental.** A 1% Ru-5% La/$ZrO_2$ catalyst was synthesized by using sequential incipient to wetness impregantion. Reaction temperature was selected as 450 °C for all experiments except room temperature CO adsorption experiments. The study involves characterization experiments with CO at both room temperature and 450 °C, individual $CO_2$ and $CH_4$ adsorption experiments, reaction experiments under ideal feed conditions as well as reaction experiments during sequential adsorption of two reactants. All experiments were performed on $ZrO_2$, La/$ZrO_2$ and Ru-La/$ZrO_2$.

**Results and discussion.** Upon CO adsorption experiments at 450 °C and at room temperature, the most significant differences among DRIFTS spectra of Ru-La/$ZrO_2$, La/$ZrO_2$ and $ZrO_2$ can be seen at carbonyl region. CO failed to adsorb on sole $ZrO_2$ at any of the two temperatures while it adsorbed on La/$ZrO_2$ only at 450 °C. On contrary, CO adsorbed on Ru-La/$ZrO_2$ both at room temperature and at 450 °C. The peak at 1990 $cm^{-1}$ on Ru containing sample is characterized as tricarbonyl species adsorbed on Ru [1] and it is also visible in reaction experiments, confirming the occurrence of CDRM reaction as shown on Figure 1. Simultaneous MS readings made during reaction display presence of water, hence involvement of RWGS reaction (Figure 1, top left). This is expected since RWGS is often reported to be a significant side reaction to CDRM reaction. Results of $CO_2$ adsorption experiments reveal that addition of La increases interaction of $ZrO_2$ support with $CO_2$ which can be traced from elevated intensities of carbonate species (region 1200-1700 $cm^{-1}$) on spectra of La containing samples compared to observations regarding sole $ZrO_2$.

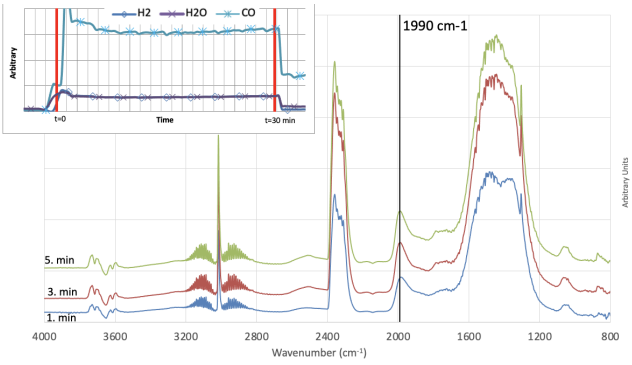

**Figure 1: DRIFTS spectra showing transient behavior of Ru-La/$ZrO_2$ catalyst in reaction conditions with simultaneous MS signals (top left).**

**srbare@slac.stanford.edu*

**Introduction.** Supported gallium oxides have been widely investigated for their ability to catalyze a variety of energy-related chemical transformations, including the dehydrogenation and dehydroaromatization of light alkanes. In particular, their ability to catalyze the selective dehydrogenation of propane has inspired much interest in the catalysis research community. Under the conditions typically used to achieve these reactions, the Ga species proposed to exist or co-exist include $[GaO_4]^-$, $[Ga_2(OH)_4]$, $[GaO]^+$, $[Ga_2O_2]^{2+}$, $[GaH]^{2+}$, $[GaH_2]^+$, and $[Ga]^+$. Identification of Ga(I) sites in catalysts under reaction conditions relies primarily on X-ray absorption spectroscopy (XAS). However, the observation of a low energy absorption edge is necessary but not sufficient evidence for $[Ga]^+$. There are significant variations in edge position for the XANES of Ga(III) compounds.[1-2] We develop a rigorous set of criteria for characterizing the white line behavior, derived from the experimentally observed and computed properties of several Ga(I) molecular complexes and $Ga^+$-β´´-$Al_2O_3$, together with an investigation of the origin of their distinctive features. We report an analysis of the XAS of Ga/HZSM-5 and Ga/γ-$Al_2O_3$, both of which exhibit low edge energy peaks.

**Experimental.** XAS spectra at the Ga K-edge (10,367.0 eV), both traditional and HERFD-XANES, were recorded at the Stanford Synchrotron Radiation Lightsource. Theoretical XANES calculations were performed with StoBe 2011 using the PBE exchange-correlation functional.

**Results and discussion.** To lay a rigorous foundation for characterizing these types of systems and to establish experimental signatures for the elusive Ga(I) oxidation state, Ga K-edge XAS (including HERFD-XANES) were recorded for several well-defined molecular and crystalline Ga(I) compounds. The XANES is essential to establishing the presence of Ga(I), despite the overlap in edge energies with organoGa(III) compounds, because Ga(I)-containing oxide materials show very weak EXAFS scattering. Compared to the XANES of trigonal Ga(III)-containing materials, Ga(I) spectra display a significantly more intense white line feature. Theoretical simulations agree well with this experimental observation, and reveal that the strong XANES intensity originates from the superposition of transitions to several empty, nearly degenerate *p*-like states. These signatures provide compelling evidence for assigning the intense white line in Ga/HZSM-5 and dramatic loss of EXAFS intensity to the near-quantitative reduction of Ga(III) to Ga(I), while the weaker white line and conventional EXAFS signal of Ga/γ-$Al_2O_3$ point to, at most, a minor fraction of Ga(I) sites. This study provides guidelines to ensure that Ga K-edge XAS data of catalysts are interpreted properly.

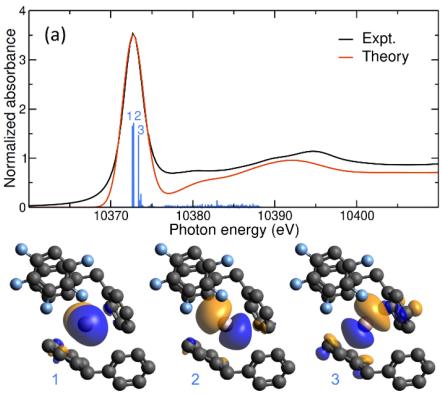

Figure SEQ Figure * ARABIC 1. Comparison of experimental (black) and simulated (red) XANES for [Ga(Ph$_2$CH)$_2$][B(C$_6$F$_5$)$_4$]. The atomically *p*-like molecular orbitals involved in the main transitions that compose the main peak are shown in the computed structures below the spectrum.

**Keywords:** copper-nickel catalysts, anisole, ammonia, TPD

**Introduction.** Catalytic hydrogenation/deoxygenation can be used for selective transformation of biomass-derived feedstocks into sustainable chemicals or biofuels. To understand this catalytic process, it is necessary to understand the catalyst surface properties - acidity and adsorption/desorption behavior of the catalyst with regard to the organic reactant (anisole).

**Experimental/methodology.** $Ni/Al_2O_3$, $Cu/Al_2O_3$ and bimetallic $Ni\text{-}Cu/Al_2O_3$ catalysts varying in Cu and Ni content were prepared using wet impregnation. For catalyst characterization, TPD of anisole and TPD of $NH_3$ was used.

**Results and discussion.** Anisole weakly adsorbed (desorption maxima around 90 °C) on the catalyst surface is adsorbed on the acid sites of the alumina support. The total amount of acid sites decreased with the increasing metal loading, but only in case the metal amount is higher than 5 wt. %. Contradictory to that, the catalyst specific surface area decreased with the increasing metal content only up to 5 wt.% loading. Nickel species in contrast to copper sites have ability to decompose ammonia adsorbed on its surface into hydrogen and nitrogen during TPD $NH_3$ measurement.

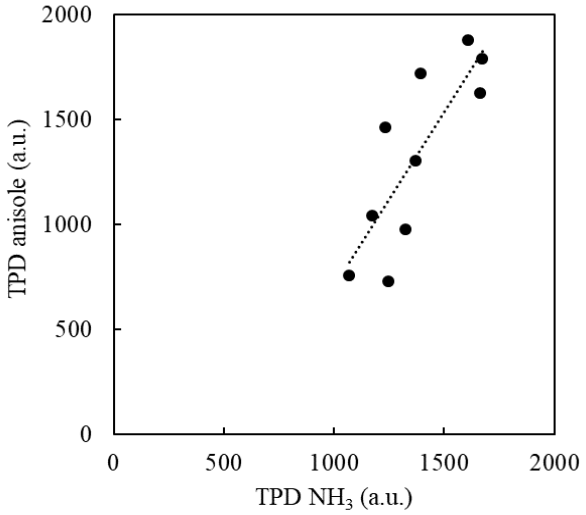

**Fig. 1**: Dependence of the amount of adsorbed anisole (TPD anisole) on the amount of acid sites (TPD $NH_3$).

**Keywords:** methane combustion, ceria, palladium-cobalt, bimetallics.

**Introduction.** There has been an increase in natural-gas-fueled vehicles (NGVs) due to the fact that they represent a cleaner option when compared with other fossil fuels [1]. However, methane is a much more powerful greenhouse gas than $CO_2$, thus it is essential to treat their exhaust gases [2]. Recently, it has been reported that Pd-$CeO_2$ catalysts prepared by mechanochemical synthesis show outstanding activity for methane combustion [3]. On the other hand, it has been reported on conventionally-prepared catalysts that adding Co to Pd helps them to become more water-resistant [4, 5].

**Experimental/methodology.** A set of 1 wt.% Pd and 12 wt.% Co mono- and bimetallic samples were prepared by ball milling (BM) and incipient wetness impregnation (IWI). In order to test the activity temperature-programmed combustion (TPC) cycles were performed: 2 cycles from ambient temperature to 900 °C under lean methane conditions and GHSV of 180,000 $h^{-1}$ (0.5% $CH_4$, 2% $O_2$, balanced with $N_2$) followed by a TPC cycle where 10% $H_2O_{(vap)}$ was added. Samples were characterized by *in situ* XAS, XRD and NAP-XPS at ALBA synchrotron. XAS and XRD were acquired on samples subjected to TPC. AP-XPS was performed at 450 °C at 1 mbar pressure with and without the addition of water (1 mL·$min^{-1}$ $CH_4$, 4 mL·$min^{-1}$ $O_2$, 2.5 mL·$min^{-1}$ $H_2O$ balanced with $N_2$).

**Results and discussion.** The synthesis method does significantly affect the activity of the PdCo system, as represented in Figure 1 (a) by the temperature at which each sample reaches 50% methane conversion. The catalyst prepared by mechanochemical milling is more active than that prepared by IWI. It is accepted that the active phase for methane combustion in Pd-based catalysts is PdO [3]; thus, an increase in the temperature at which the transition of PdO to metallic Pd occurs is desired. From XAS experiments (Figure 1 (b)) it can be seen that the bimetallic sample does not fully convert PdO into metallic Pd, showing the benefits of the addition of Co. Indeed, under reaction conditions $Co_3O_4$ gets reduced and evolves into CoO. It is worth mentioning that this CoO species is amorphously formed since no peaks of CoO are detected by *in situ* XRD. Similarly, the surface (NAP-XPS) follows a similar behaviour, where PdO does not change into metallic Pd, but Co gets reduced, from $Co_3O_4$ to CoO.

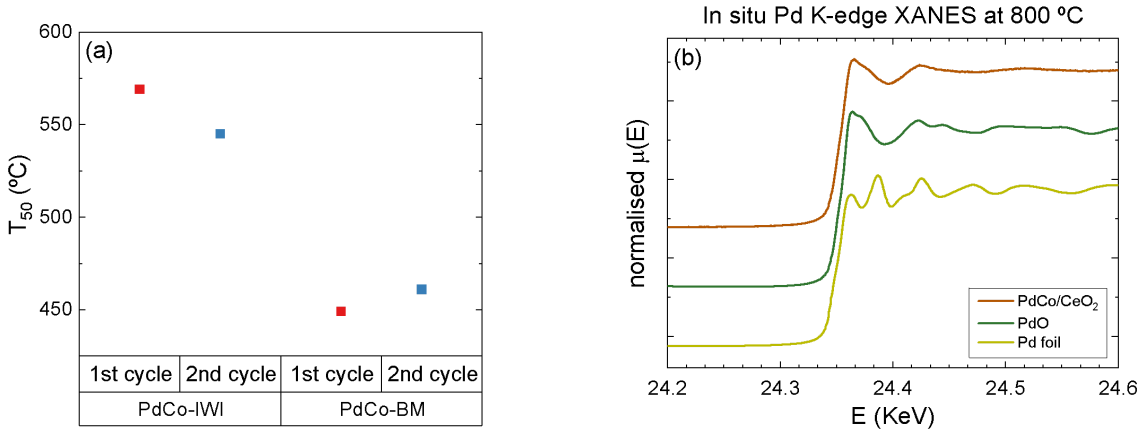

**Figure 1. (a) $T_{50}$ of PdCo-BM and PdCo-IWI of the 2 first cycles, without adding water. (b) In situ Pd K-edge XANES spectra of reference samples and PdCo-BM at 800 °C under methane combustion reaction.**

# Support effects on ammonia decomposition on supported Cu catalysts

Stefan Peters, Anna Kavaklioti, Sebastian Wohlrab, Ali M. Abdel-Mageed*

Leibniz-Institut für Katalyse (LIKAT), Rostock, Germany
*ali.abdelmageed@catalysis.de

**Introduction:** The synthesis and non-oxidative decomposition of $NH_3$ (NOD-$NH_3$) constitute an efficient cycle for the chemical storage and subsequent release of green $H_2$. This approach is motivated by the high gravimetric and volumetric $H_2$ storage capacity of $NH_3$, which is additionally an easily storable and transportable liquid at room temperature when lightly compressed [1]. On top of that, the well-established chemical production of $NH_3$ via Haber-Bosch process would accelerate its immediate introduction into the energy infrastructure [2]. Ru-based catalysts are so far the most efficient reported catalysts for the NOD-$NH_3$ [3]. Cu-based catalysts are promising cost efficient candidates for this reaction, although they do not yet meet the requirements for industrial use [4]. In this work we have systematically investigated the modulation of the electronic and structural properties of Cu nanoparticles, and thus their impact on the catalytic activity for NOD-$NH_3$. This is achieved by controlled variation of Cu loading (i.e., Cu particle size) and support material, whose interplay affects the metal-support interaction and thus activity for NOD-$NH_3$.

**Experimental/methodology:** Catalysts were prepared by wet impregnation of HZSM-5, $\gamma$-$Al_2O_3$ and *m*-$ZrO_2$ supports with aqueous $Cu(NO_3)_2{\cdot}3H_2O$ at 25°C. After the impregnation step, the catalysts were dried and calcined in air at 400 °C for 4 h. Prior to reaction, catalysts were reduced at 600 °C in 5 % $H_2$/Ar for 1 h. Kinetic measurements were done in a quartz tube reactor between 300 and 600 °C using an online FTIR gas cell for continuous quantification of $NH_3$. Catalysts were characterized using *operando* X-ray absorption spectroscopy at Cu K-edge (SOLEIL Synchrotron, *SAMBA* beamline) under conditions identical to that employed in kinetic studies. All samples were additionally characterized before / after reaction using XPS, PXRD, high-resolution STEM/EDS, nitrogen adsorption, and TPX analyses.

**Results and discussion:** Catalytic decomposition of $NH_3$ over Cu loaded on different supports showed superior activity of *m*-$ZrO_2$ supported Cu compared to catalyst based on inert supports such as $\gamma$-$Al_2O_3$ and HZSM-5 at all temperatures between 450 and 600°C. Under steady state conditions at 600 °C Cu/*m*-$ZrO_2$ catalysts showed about 2-3 times and at least 8 times higher Cu-mass normalized activity than Cu/$\gamma$-$Al_2O_3$ and Cu/HZSM-5 catalysts, respectively. Other supports such as $CeO_2$-$ZrO_2$ or graphite were much less active. Optimal catalyst performance was achieved with Cu loadings of 10-15 wt.% but higher intrinsic activity was observed for lower Cu contents. STEM / EDS mapping revealed high dispersion of Cu species on *m*-$ZrO_2$ and $\gamma$-$Al_2O_3$ both after calcination and after reaction at 600°C. Comparison of the Cu 2p XP spectra of both catalysts indicated a core-level shift towards higher binding energy for Cu/$\gamma$-$Al_2O_3$ compared to Cu/*m*-$ZrO_2$. This result was supported by $H_2$-TPR studies which showed the onset reduction of $CuO_x$ species on *m*-$ZrO_2$ at ~100 °C compared to ≥140 °C for $\gamma$-$Al_2O_3$ catalysts, depending on Cu loading. Thus more facile reduction of a part of $CuO_x$ species is evident on *m*-$ZrO_2$, which has been attributed to interaction with oxygen defects before [5]. Primary *operando* Cu K-edge XAS investigations (XANES and EXAFS) under reaction conditions indicated the presence of Cu mainly as metallic clusters, while persisting contribution of oxidic species was also observed (shown by Cu-Cu/Cu-O scattering shells in FT data). This Cu-O interaction may refer to the partial binding of Cu atoms to surface oxo- and hydroxo species. Combined with findings from the O 1s XP spectra it can be concluded that reaction induced oxygen vacancy formation in $ZrO_2$ play a significant role for increasing catalytic activity of Cu. These and other results from several surface and bulk sensitive methods shall be discussed in a bigger picture of the metal-support interactions and its infuence on the performance of Cu species for non-oxidative ammonia decomposition for $CO_x$-free $H_2$ production.

**Keywords:** Gamma-alumina, surface models, edge models, DFT modelling

**Introduction.** γ-alumina is one of the most used catalyst support while the charaterization of its surface active sites still represents a challenge. Thanks to high field nuclear magnetic resonance (NMR), it becomes possible to identify the variety of hydroxyl groups and their proximities through $^{1}$H-$^{1}$H dipolar correlation experiments. Nevertheless many proposed interpretations are still based on the exclusive consideration of ideal alumina surfaces. Thanks to density functional theory (DFT) simulations, we propose to revisit deeply this assignment by considering not only surface models but also edge models.

**Experimental/methodology.** DFT calculations of proton chemical shifts for various γ−alumina facet models ((100), $(110)_l$, $(110)_b$, (111))[1] and edge models ($(110)_l$/$(110)_b$, (100)/$(110)_b$, developped on purpose[2], and (100)/$(110)_l$[3]) were undertaken by using PBE functional with dDsC dispersion correction (VASP software). The gamma alumina samples PuralSB3 from Sasol, with various contents of chlorine, were treated at 500°C under $H_2$ for 2 hours and then conditionned under vacuo. The solid-state NMR spectra ($^{1}$H, $^{1}$H-$^{1}$H 2D and $^{1}$H-$^{27}$Al 2D) were acquired on a Bruker Avance III 18.8T spectrometer using 2.5mm zircone rotors and a magic angle spinning frequency of 30 kHz.

**Results and discussion.** We first show that the δ($^{1}$H) = -0.1 ppm signal is attributed to the H-bond free $\mu_1$-$Al_{IV}$-OH located at alumina edges as highlighted by the DFT models. Indeed, $\mu_1$-$Al_{IV}$-OH species located on facets are systematically involved in H-bonds which deshield these protons to higher chemical shifts. Moreover, the $^{1}$H-$^{1}$H auto-correlation observed at -0.1 ppm is corroborated by the (100)/$(110)_b$ edge model, while the one at 1.7 ppm can be attributed to $\mu_2$-$Al_{VI}Al_{VI}$-OH present on the $(110)_b$ models. The cross correlations at -0.1 – 1.9 ppm and 2.1 – 3.1 ppm are attributed to H-bond free $\mu_1 - \mu_2$ and $\mu_2 - \mu_2$ in the edge vicinity. Adding 1.4 wt% chlorine induces the disappearance of 1D and 2D NMR peaks involving $\mu_1$-$Al_{IV}$-OH species. This observation is explained by DFT calculations revealing a thermodynamically favored exchange of OH groups with chlorine at edges. Hence, this refined understanding provided in the present work will help to make new progress in the design of alumina supported catalysts thanks to a more rational tuning of facets and edges exposed according to the nature of hydroxyl sites targeted.

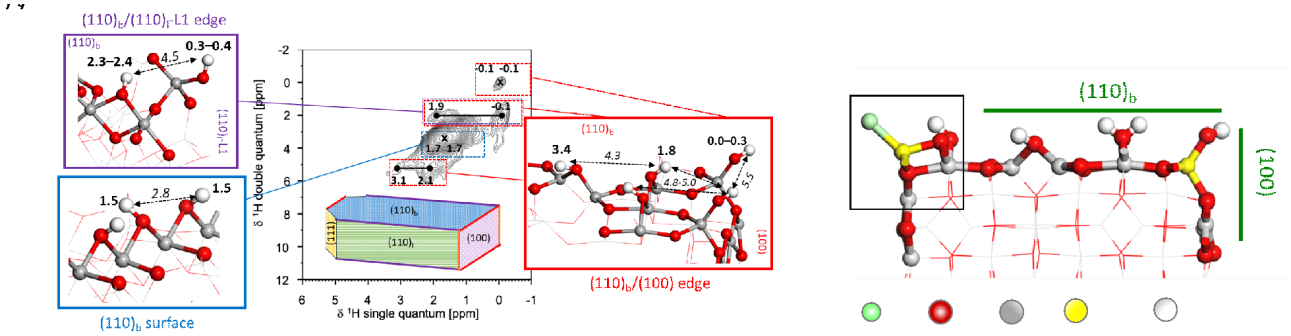

**Figure 1: a)** Most relevant DFT models of hydroxyls corroborating the correlations observed in the $^{1}$H-$^{1}$H double quantum spectrum of γ-$Al_2O_3$. Calculated chemical shifts (in ppm) are reported as bold numbers and distances (in Å) in italic. **b)** DFT (110)/$(110)_b$ edge model exhibiting a $\mu_1$-$Al_{IV}$-OH exchanged with chlorine in the frame.

**Keywords:** spinel ferrites, water gas shift reaction, operando spectroscopy, metal oxides, sol-gel synthesis

**Introduction.**

The water gas shift reaction is part of many industrial processes including steam reforming for adjustment of the ratio of $CO/H_2$ in syngas mixtures such as hydrogen production, synthesis of methanol and hydroformylation. Shifting from fossil syngas sources to renewable ones as well as technological diversity might justify further use of and research on the water gas shift reaction. The catalyst currently in use for high temperature water gas shift reaction (HT-WGS) is chromium-iron oxide doped with copper. Although this system has been optimized for a long time and research is relatively close to understanding the reaction mechanism [1], legislative initiatives require to find chromium-free catalysts for HT-WGS due to toxicity of Cr(VI). $CoFe_2O_4$ and $NiFe_2O_4$ have been chosen as initial candidates to conduct research upon as spinel compounds are reported to offer easy controllability and tunability of composition and chemical stability [2].

**Experimental/methodology.**

$CoFe_2O_4$ and $NiFe_2O_4$ samples have been prepared by a glycine-assisted sol-gel autocombustion process and structurally characterized by XRD and ATR-IR. Chemical reducibility as well as reactivity and possible parallel reactivity in HT-WGS have been investigated by $H_2$- and CO-TPR and temperature programmed reactions and phase changes determined by ex-situ XRD. CO conversion rates have been determined by GC. Insights in the reaction mechanism and the role of phase changes have been obtained by in-situ XRD, operando FTIR spectroscopy and NAP-XPS.

**Results and discussion.**

NAP-XPS revealed carbide-like species to be a relevant part of the reaction mechanism in agreement with the operando FTIR results showing no certain signs of any carbon species engaged in the WGS reaction. The stability of phase composition turned out to be limited in atmospheric pressure experiments as metallic phase formation occurs especially in $NiFe_2O_4$ according to both ex-situ and in-situ XRD results. As different types of carbides have been reported to act as catalysts in WGS [3, 4] and/or to play a role in reverse WGS respectively Fischer-Tropsch process, WGS reactivity of nickel and cobalt carbides has to be considered in future works.

# Spectroscopic Characterisation of Keggin-type Polyoxometalate Catalysts

Maximilian J. Poller[1*], Jan-Christian Raabe[1], Jakob Albert[1]
[1]*Institute for Technical and Macromolecular Chemistry at Hamburg University, Hamburg, Germany*

**Keywords:** polyoxometalates, spectroscopy, transition metals, tailor-made catalysts

**Introduction.** The application of Keggin-type polyoxometalates in catalysis is an intensly researched field. Their high Brönsted acidity makes them excellent acid catalysts, and after introducing RedOx active transition metals into their structure, they can also be applied as oxidation catalysts. A prominent example for such catalysts are vanadium substituted phosphomolybdates, specifically $H_8PV_5Mo_7O_{40}$, which has been successfully applied for the conversion of biomass to formic acid.[1] In order to retain more valuable structures in oxidative biomass valorisation and to enable new processes, it is necessary to tailor the catalysts to the specific application. We have recently shown, that the incorporation of additional transition metals such as Mn(II) can be used to tune the RedOx potential of Keggin-type phosphomolybdates.[2] However, in order to further develop tailor-made catalysts, a more thorough understanding of such compounds is necessary. To this end we have synthesiszed various transition-metal substituted Keggin-type polyoxometalates and characterised them throughly in the solid state and in aqueous solution, with the aim of correlating molecular properties with their catalytic activity.

**Experimental/methodology.** We have investigated various transition metal substituted Keggin-type polyoxometalates in the solid state and in aqueous solution. For this purpose we emplyoed a wide range of analytical methods such as ATR-FT-IR spectroscopy, Raman spectroscopy, UV-Vis spectroscopy, NMR spectroscopy, and single-crystal x-ray diffraction.

**Results and discussion.** Vibrational spectroscopy and x-ray diffraction revealed the strucutral influence of the transition metals on the structure of the catalyst. NMR spectroscopy provided information on the behaviour of polyoxometaltes in solution, such as their dissociation behaviour (Figure 1).

$$[PM_xMo_{12-x}O_{40}]^{y-} + n\ H_2O \rightleftharpoons [PM_{x-1}Mo_{12-x}O_{40}]^{z-} + M_{aq}$$

**Figure 1: Dissociation equilibrium of transition metal substituted Keggin-type polyoxometalate**

UV-Vis spectroscopy showed the influence of the transition metal on the electronic excitation energies (i.e. HOMO-LUMO gap).

Correlation of these results with the catalytic activity of such polyoxometalates[3] will provide useful information for the further development of tailor made catalyst materials based on Keggin-type polyoxometalates.

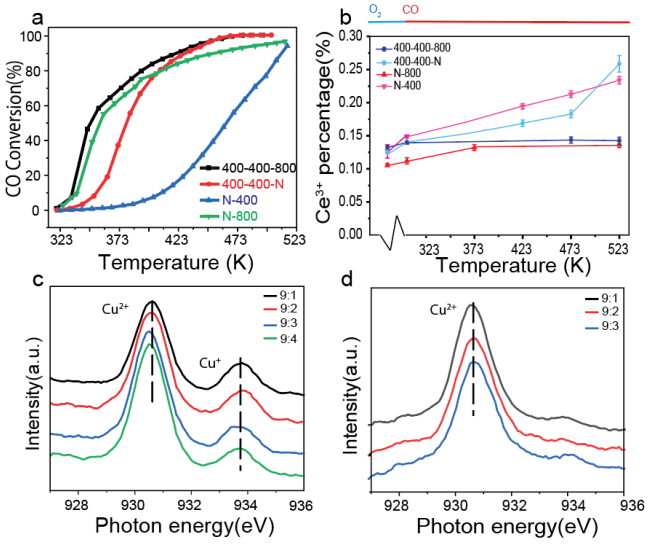
**Introduction.**



In heterogeneous catalysis research, CO oxidation reaction ($2CO+O_2 \square 2CO_2$) is a well-known reaction for fundamental mechanism study, as well as a vital reaction in terms of environmental pollution derived from various of sources, especially from vehicle exhaust. In CO oxidation reaction, it is widely acknowledged that the redox of $Ce^{4+}/Ce^{3+}$ pair and the surface $O_2$- mobility is the key to achieving a high CO conversion. However, we have discovered a Cu-$CeO_2$ system with non-reducible $CeO_2$ surface at 523 K, has an extremely high CO conversion after calcined at 1073 K in air (Fig. 1a). Such massive improvement in catalysis encourages us using various methods to investigate the reason behind it, providing a different point of view towards the electronic metal support interaction (EMSI) theory.

**Experimental/methodology.**

All the chemicals were of analytical grade without further purification. The ceria nanorods were prepared by a hydrothermal method. Then, the catalysts were prepared by a deposition−precipitation method. Catalytic activity tests were performed from room temperature to 250 °C with 1% CO, 10% $O_2$ and balance He. The analysis of the Cu K-edge (8.979 keV) and Ce L3-edge (5.723 keV) was performed at 3.0 GeV with a beam current of 300 mA at the Beamline B18 of the Diamond Light Source (UK). The in-situ measurements were accomplished in the ambient pressure Xray end-station using a Faraday-cup to collect the NEXAFS spectra in the Ce M-edge and Cu L3-edge at different gas compositions at the ISISS beamline of BESSY II in Berlin (Germany), and the beamline B07 of the Diamond Light Source.

**Results and discussion.**

To prevent $Ce^{4+}$ participating the reaction, we have calcined the CuO-$CeO_2$ system at 1073 K, reducing its oxygen vacancy, $Ce^{4+}$ in the calcined sample (400-400-800 and N-800) cannot be reduced to $Ce^{3+}$ even at 523K in pure CO (Fig. 1b). Therefore, we believe that the surface Cu species is the key for high CO conversion at low temperature, which tends to keep $Cu^+$ with O2 existence. This theory is also confirmed by the Cu L-edge spectra for the uncalcined sample(Fig. 1d), which shows the majority of Cu are oxidised when $O_2$ is introduced at 373 K. Cu K-edge spectra also shows a similar result, where the linear combination fitting shows a higher percentage of Cu and $Cu^+$ in the bulk with pure CO and different CO: $O_2$ ratio under 373 K for the calcined sample, comparing with the uncalcined sample in pure CO under the same temperature.

The project will answer what types of Cu-$CeO_2$ interaction leads to such high catalytic performance, and if this interaction is applicable to other metal systems such as Au and Pt.

In the catalytic field, the result will directly challenge the support redox and EMSI theory. It suggests that an efficient catalyst does not require an active support but a unique active site structure, providing a new perspective of catalyst design.

**Figure 1 (a) CO conversion (b) Peak fitting results of $Ce^{3+}$ percentage under $O_2$, 30C and CO in different temperatures (c) Cu L3 edge NEXAFS spectra of 400-400-800 and (d) 400-400-N at 373K with different CO: $O_2$ ratios.**

# Comparative study of the aging time of $Cu/TiO_2$ catalysts: effect of the preparation method

A. J. Reynoso[1,2], L. Djakovitch[1], S. Loridant[1], T. Epicier[1], N. Perret[1]

**Introduction.** Copper-based catalysts are widely used in important industrial applications, such as water-gas shift reaction, synthesis of methanol from $CO_2$, and alcohols production from esters, selective hydrogenation of oils, among many others. The performances of catalysts are closely related to the copper dispersion and particles size [1]. Therefore, preparation method is a crucial step to have active, selective and stable catalyst system. Wet impregnation is a widely employed procedure for preparation of Cu nanoparticles. However, high-temperature $H_2$ reduction process could cause the aggregation of Cu particles. As an alternative, one-pot aqueous reduction method is simple, with limited equipment requirements, ease of control and small nanoparticles size can be obtained [2].

The metallic state of Cu is unstable in air. Depending on the storage conditions the metal will be partly or completely re-oxidized to its stable oxides causing catalyst deactivation. In order to restrain this phenomenon, passivation is commonly carried out. Nevertheless, although reactivation can be conducted in-situ under $H_2$, re-oxidation of the catalyst during storage inevitably occurs over time [3]. In this work, a comparative study on the stability of $Cu/TiO_2$ catalysts synthesized by either aqueous reduction method or wet impregnation followed by $H_2$ reduction was carried out.

**Experimental/methodology.** $Cu/TiO_2$ (10 wt.%) was prepared by either one-pot aqueous reduction method using sodium borohydride as a reducing agent (R-$NaBH_4$) and by wet impregnation method followed by reduction under $H_2$ flow and passivation (R-$H_2$). After synthesis, the samples were stored under air.The catalysts were periodically characterized over several months by ICP, XRD, XPS, $H_2$-TPR, $N_2$ physisorption, $N_2O$ chemisorption, Raman, and TEM-EELS. Catalytic activity was evaluated in 2-octanol acceptor-less dehydrogenation. The reaction was performed in semi-bath reactor with constant flow of inert gas.

**Results and discussion.** Just after synthesis ($t_0$), the sample prepared by $NaBH_4$ reduction process exhibited better dispersion and greater metallic surface than catalyst reduced under $H_2$ flow (25.2 $m^2/g_{Cu}$ for R-$NaBH_4$ vs 13.6 $m^2/g_{Cu}$ for R-$H_2$). By Raman, bands attributable to $Cu_2O$ (216 and 106 $cm^{-1}$) were observed for sample R-$NaBH_4$. After two months ($t_2$), both samples showed bands at 297 $cm^{-1}$, characteristic of CuO. Regarding catalytic activity, R-$NaBH_4$ presented slightly higher conversion and yield than its counterpart (Fig. 1). Results after 4 months will also be presented in detail.

In short, a faster reoxidation process was revealed on R-$NaBH_4$ compared to R-$H_2$ catalysts. Nonetheless, catalytic activity is totally recovered with an in situ $H_2$ pretreatment at low temperature (145 °C).

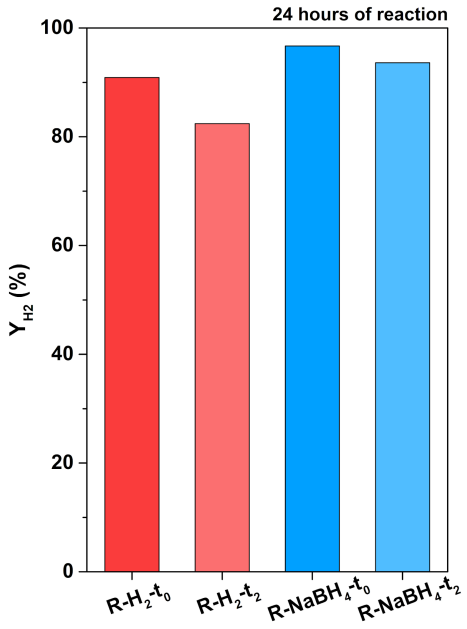

**Fig. 1. $H_2$ yields in 2-octanol dehydrogenation.**

**Introduction.**

The global demand for light olefins, such as propene, is continually increasing as they are critical precursors for chemical manufacturing. Light olefins are mainly produced via steam cracking of naphtha and fluid catalytic cracking of crude oil, but there are several limitations, e.g., high temperature, significant $CO_2$ emission, coke formation, etc. Therefore, discovering new catalysts to increase production efficiency is an essential area of research. Oxidative dehydrogenation (ODH) is one of the promising approaches that has been studied for more than two decades. The advantages of ODH over the non-oxidative method are lower operating temperature, exothermic nature, no equilibrium limit, and no coke formation. But, the challenge is finding a stable catalyst with high activity and selectivity while avoiding overoxidation [1, 2].

**Experimental/methodology.**

In this work, hexagonal boron nitride (hBN), as a recently reported promising nonmetallic catalyst [3], has been studied in the oxidative dehydrogenation of propane (ODHP). The fresh and spent catalysts were characterized by X-ray diffraction (XRD) patterns, energy dispersive spectroscopy (EDS), X-ray photoelectron spectroscopy (XPS), $N_2$ adsorption-desorption isotherms, Raman, and infrared spectroscopy to monitor the chemical changes and the formation of various functional groups in the spent catalysts. DFT calculations were performed on small model clusters of boron-oxide to investigate FT-IR features upon CO adsorption.

**Results and discussion.**

It is widely acknowledged that the $BO_x$ species, which are generated by substituting N with O, are the possible core triggers of the catalytic process. However, views on the actual active sites and the catalytic mechanism are still controversial. In this research, the participation of oxygen within the hBN structure and formation of $BO_x$ were studied as well, but all of the observed phenomena did not influence the catalyst activity, which brings the question of whether the $BO_x$ are truly active sites or not. Impregnation of h-BN with boron oxide proved that the presence of boron oxide on the h-BN surface suppresses the activity of the catalyst, whereas it was recovered by washing the catalyst and removing the boron oxides. Thus the $BO_x$ probably is different from the actual active site. On the other hand, it has already been experimentally and theoretically evidenced that gas-phase reactions play a critical role in this system [4, 5]. Here the experiments show how larger available space can influence radical propagation and productivity. Also, the role of the catalyst surface was investigated with CO adsorption monitored by IR spectroscopy that showed negligible interaction between CO and the BN surface. However, unsaturated boron sites should form a dative bond with CO, as evidenced by model cluster calculations. It disclosed that coordinatively unsaturated boron is not available on the hBN surface or is formed under the elevated temperature of the reaction process (~400 °C). The presented results suggest that the reasons for the unusual activity of h-BN in the ODH of propane should be sought elsewhere than in the presence of boron oxide.

**Keywords:** Pt/$TiO_2$, dynamics, in-situ TEM, strong metal-support interactions

**Introduction**

In the early days of catalysis research, oxide carriers were considered to be mere inert carriers for highly dispersed metal nanoparticles. Forty years ago, experiments with noble metal-TiO2 catalysts demonstrated that oxide supports are far from inert in such catalytic systems and can strongly effect the adsorption behavior and structure of catalysts and the phenomenon was named the strong metal-support interaction (SMSI) [1]. SMSI was observed in noble metal catalysts supported on reducible oxides such as TiO2. This phenomenon is of paramount importance, since it can determine the catalytic activity and stability. The SMSI phenomenon has, for the most part, been characterized ex situ. Such an approach is not able to capture the ongoing dynamics of a working system. The dynamic interactions between noble metal particles and reducible metal-oxide supports can depend on redox reactions with ambient gases.

**Results and Discussion**

In our work [2,3], operando transmission electron microscopy revealed that the SMSI–induced encapsulation of platinum particles on TiO2 observed under reducing conditions is lost once the system is exposed to a redox-reactive environment containing oxygen and hydrogen at a total pressure of ~1 bar. Destabilization of the metal–oxide interface and redox-mediated reconstructions of TiO2 lead to particle dynamics and directed particle migration that depend on nanoparticle orientation (Figure 1). A static encapsulated SMSI state was reestablished when switching back to purely oxidizing conditions.

**Significance**

This work highlights the difference between reactive and nonreactive states and demonstrates that manifestations of the metal-support interaction strongly depend on the chemical environment.

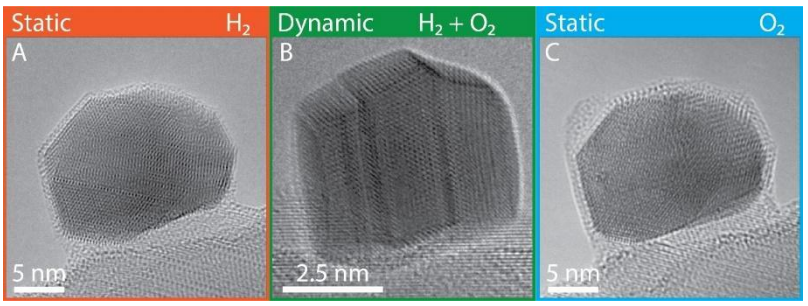

**Figure 1.** In situ TEM micrographs of the platinum titania system at elevated temperature. A under hydrogen atmosphere, B under hydrogen oxygen mixed feed, C under oxygen atmosphere.

**Introduction.** An emerging field in heterogeneous catalysis is to understand the dynamic behavior of atoms and clusters over solid supports. In many catalytic processes that were reported to be catalyzed by nano-particles, recent studies show that single atom or ultra-small clusters are attractive as active species. However, under reaction conditions, stability of single atom is questionable and transformation between atoms and clusters is observed during *in-situ*/operando spectroscopic investigations.[1][2] To unravel the structural evolution of atoms and clusters of late transition metals (Ru, Rh, Pd, Ir and Pt) supported over $CeO_2$, we propose here *in-situ* X-ray Absorption Spectroscopy (XAS) and Diffuse Reflectance Infrared Fourier Transform (DRIFT) Spectroscopy (CO as probe molecule) as powerful tools. In addition, DFT calculations were carried out to accurately predict the CO vibrational frequencies of the species evolved under reaction conditions. This study shows a general trend of late transition metals over $CeO_2$ in CO adsorption energies with CO absorption frequencies over single atom catalysts bearing various charges.[3]

**Experimental/methodology.** All the catalysts were synthesized by wet impregnation and precipitation methods. The catalysts were calcined at 1073 K and 623 K respectively in static air. The synthesized catalysts were characterized by powder XRD, Raman spectroscopy, $N_2$-physisorption, $C_s$-STEM, XAS and DRIFT spectroscopy. *In-situ* XAS and DRIFT spectroscopy were conducted under the gas flow of 1% CO, 1% CO + 1% $O_2$ and 1% CO + 1% $H_2$ balanced with He or Ar.

**Results and discussion.** The *ex-situ* characterization of the synthesized catalysts prepared by the two methods showed that the catalysts are mostly in atomically dispersed state over $CeO_2$. The *in-situ* DRIFT and XAS spectra measured under different reaction conditions showed the species evolved with time and temperature. As an example, the results of the $Rh/CeO_2$ catalysts are shown in figure 1. Two CO vibrational frequencies in the ranges between 2000-2020 $cm^{-1}$ and 2070-2090 $cm^{-1}$ were observed (figure 1(c)) which corresponds to the anti-symmetric and symmetric vibrational frequencies of the geminal dicarbonyl species adsorbed over Rh single atoms. Upon changing the gas mixture to CO + $O_2$, a new CO vibrational frequency at 2107 $cm^{-1}$ appeared which can be assigned to CO adsorbed over $Rh^{3+}$ species. On the other hand, when the gas mixture was switched to CO + $H_2$ at 453 K, a new CO vibrational frequency is observed at 2046 $cm^{-1}$, which can be attributed to CO adsorbed over Rh clusters or nano particles. DFT calculated CO vibrational frequencies match with the experimental results. The temperature programmed XAS spectra collected at the Rh K-edge also show that the Rh single atom catalyst forms clusters at elevated temperature in the presence of CO + $H_2$. These results are highly interesting and will pave the way for future design of new catalysts for industrially relevant reactions such as hydroformylation, higher alcohol synthesis and acetic acid production.

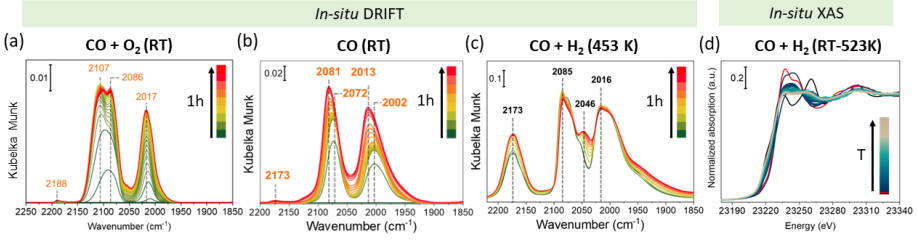

**Figure 1**. *In-situ* DRIFT spectra of $Rh_1/CeO_2$ catalysts measured during (a) CO + $O_2$, (b) CO and (c) CO + $H_2$ reaction conditions. *In-situ* XAS spectra measured at the Rh K-edge under CO + $H_2$ are shown in figure (d). Temperatures are shown within the parentheses. The *in-situ* DRIFT spectra were collected over 1 hour.

# Visualising Sulphur Poisoning in Structured Honeycomb Catalysts with Hard X-ray Nanotomography

S. Sharma[1], T. Delrieux[1], D. Karpov[2], M. Casapu[1], J.-D. Grunwaldt[1], T.L. Sheppard[1]*

**Keywords:** characterisation, spatially-resolved, synchrotron radiation, X-ray tomography

**Introduction.** Technical $CH_4$ oxidation catalysts for removal of unburned hydrocarbons in emissions control applications are usually composed of metal or ceramic substrates with a washcoat of catalytic material. Mass and heat transport limitations in these hierarchical structures bring additional complexity compared to model systems. Depending on feedstock (e.g. diesel, natural gas engines) such catalysts may suffer strong deactivation from sulphur poisoning. This may not only trigger molecular changes in the catalyst, but also affect transport properties by sulphur deposition and blockage of pores and active sites.[1] Moreover, concentration gradients can develop within the washcoat and along the monolith channels. Identifying the location of sulphurous species and the severity of poisoning in structured catalysts is key to understanding the poisoning mechanism and its impact on catalyst performance, later including strategies for catalyst regeneration.[2,3] Hard X-ray nanotomography offers a flexible characterisation toolbox which can be used to observe and quantify local deactivation effects of technical catalysts in 3D space.[4,5]

**Experimental/methodology.** Coated 1.6wt% $Pd/Al_2O_3$ catalyst honeycombs were poisoned in $SO_2$-containing gas feed for various time on stream, and regenerated by short exposure to 2% $H_2$, mimicking fuel-lean operating conditions of $CH_4$ combustion engine followed by fuel-rich catalyst regeneration, similarly as in ref. [3]. Honeycomb catalysts with different degrees of sulphur poisoning and regeneration were then studied by hard X-ray holotomography at ESRF synchrotron, beamline ID16A. Catalyst volumes up to 280x280x100 $\mu m^3$ were studied with spatial resolution estimated at a few hundred nm.

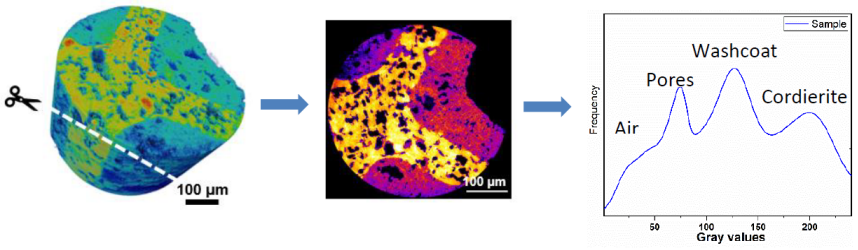

**Figure 1. Volume (l), cross-section (m), and electron density histogram (r).**

**Results and discussion.** Hard X-ray holotomography is shown as a powerful nanoscale imaging method which allows quantitative analysis of the local electron density in the sample,[6] indicating the presence and severity of sulphur deposition. Sufficient contrast allowed to distinguish between alumina honeycomb, open pores, and dense sulphur deposits in the monolith channel and corner sections (Fig. 1). Sulphur deposition was visualised by increased electron density in the washcoat as well as honeycomb support compared to a fresh catalyst. This effect increased together with poisoning duration, and was non-uniform along the monolith channel, with the reactor inlet more severely poisoned than the outlet. Partial structural regeneration was confirmed by loss of electron density (i.e. sulphur deposits) after treatment in $H_2$ feed. The results help to understand the basis of sulphur poisoning and regeneration of technical catalysts, promoted by direct visualisation of such effects with tomography. Only hard X-ray tomography at synchrotron radiation sources is capable of providing 3D spatially-resolved data on extended samples with nm-scale resolution.

# Hard X-ray tomography reveals structural degradation and chemical composition of Pt/Rh gauze catalysts for $NH_3$ oxidation

S. Das[1], M. Stuckelberger[2], J. Pottbacker[3], S. Jakobtorweihen[3], R. Horn[3], T. L. Sheppard[1]*

[*]*Corresponding author: thomas.sheppard@kit.edu*

**Introduction**

Large-scale catalytic production of nitric acid is industrially carried out over smooth Pt-alloy gauze catalysts. During this exothermic process, the surface of catalyst undergoes deformation and reconstructs into cauliflower-like structures[1,2]. This results in material loss, decrease in catalyst activity and reaction selectivity, eventually leading to failure of the catalyst[3]. Despite several decades of industrial operation for Pt/Rh gauze catalysts in $NH_3$ oxidation, the significant potential for wastage of valuable noble metals remains unresolved. In this study, hard X-ray tomography was used to visualise the degradation and quantify the elemental composition of Pt/Rh gauzes, providing a 3D spatially-resolved visualisation of catalyst degradation during $NH_3$ oxidation in a bench-scale setup.

**Experimental/methodology**

Industrial Pt/Rh gauzes of ca. 76 µm diameter were aged under realistic reaction conditions for $NH_3$ oxidation using a bench-scale reactor setup at TUHH Hamburg[4]. To monitor the degradation of catalyst material as a function of reaction time, single wires extracted from aged gauzes were studied to understand the structural and compositional changes using non-invasive *ex situ* 3D scanning transmission X-ray tomography (STXM-CT)[5]. Experiments were performed at P06 beamline of PETRA III synchrotron radiation source (DESY, Hamburg) at resonant energies, i.e. above and below Rh K-edge (23.300 and 23.208 keV).

**Results and discussion**

High resolution STXM-CT performed with a spatial resolution of ca. 2 µm allows for morphological studies extending beyond surface information. Furthermore, on-off resonant energy measurement, via Beer-Lambert's law, provides information regarding the 3D spatial chemical distribution of Pt and Rh in the wires as a function of reaction time. With increasing reaction time, significant loss of bulk catalyst material was observed [Fig. 1a]. This was accompanied by increase in size of porous cauliflower structures. The chemical distribution study shows correlated higher Pt distribution in the wire core compared to the cauliflower-like structures on the outer surface, confirming Pt loss from the surface of the wires. At the same time, Rh enrichment was validated in the outer rim of the wire structure and cauliflowers [Fig. 1b]. Understanding how to mitigate material loss and improve catalyst stability is essential for catalyst development. Advanced catalyst characterization such as tomography with chemical contrast imparts unique insights into the structure and composition of such challenging samples, which are unavailable using contemporary methods.

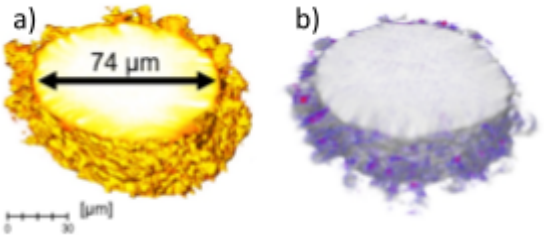

**Figure 1: a) Tomographic reconstruction showing structurally degraded Pt/Rh wire after 24h time on stream for $NH_3$ oxidation, and b) its computed Pt (grayscale) and Rh (color) distribution**

# Elucidating the Role of Bismuth as a Promotor Element on the Pt-Catalyzed CO Oxidation Reaction

J. Siewe[1], E.T.C. Vogt[1], B.M. Weckhuysen[1,*]

[1] Inorganic Chemistry and Catalysis group, *Debye Institute for Nanomaterials Science & Institute for Sustainable & Circular Chemistry, Utrecht University, Utrecht, the Netherlands*
[*] *b.m.weckhuysen@uu.nl*

**Keywords:** *Operando* DRIFTS, CO Oxidation, Bismuth, Promotion Effects, $Pt/Al_2O_3$

**Introduction.** The oxidation of CO is a quintessential system to understand the elementary surface reactions taking place on catalyst materials.[1] Furthermore, since CO is often present as a poisonous impurity in automotive exhaust gases, the catalytic process also has environmental impact. Adding bismuth as a promotor element to supported Pt nanoparticles (NPs) has been found to improve catalyst stability and lowers the temperature at which 50% of CO is converted, $T_{50\%}$, by 20–90 °C.[1,2] The underlying reason for the promoting effect of Bi is not yet well understood. In this work, light has been shed on the promoting effect of Bi by monitoring the surface properties of Pt NPs during catalytic CO oxidation using *operando* diffuse reflectance infrared Fourier transform spectroscopy (DRIFTS).

**Experimental/methodology.** *Operando* DRIFTS CO oxidation was performed in a Harrick cell using a Brüker Tenser II and an online GC. The Pt/(Bi-)$Al_2O_3$ catalyst materials, which were provided by Umicore, were pretreated at 600 °C in $O_2$ atmosphere. The CO oxidation reaction was performed by heating the cell with 1 °C/min up to 400 °C in 1000 ppm CO. X-ray photoelectron (XPS) analysis was performed using a ThermoFischer K-alpha X-ray based XPS system.

**Results and discussion.** In *operando* DRIFTS CO oxidation experiments, a redshift of the linearly bonded CO peak was observed, from 2090 $cm^{-1}$ to 2080 $cm^{-1}$ upon promotion (Figure 1b), which coincided with a 45 °C decrease of the $T_{50\%}$ (Figure 1a). Furthermore, the promoted sample retained a higher CO coverage at the same CO conversion rates, compared to the Pt-only catalyst, as is shown in Figure 1c. There was a notable absence of the bridge bonded CO peak in Figure 1b, which could indicate electronic changes to the Pt NPs. Structural characterization by XPS, as shown in Figure 1d, revealed a shift of the Pt 4d bands of 0.5 eV upon Bi promotion, suggesting that the Pt NPs are in a slightly more oxidized state. Furthermore, Figure 1e shows that Bi is significantly more oxidized in the presence of Pt as $Bi^{3+}$ contributions could be revealed.

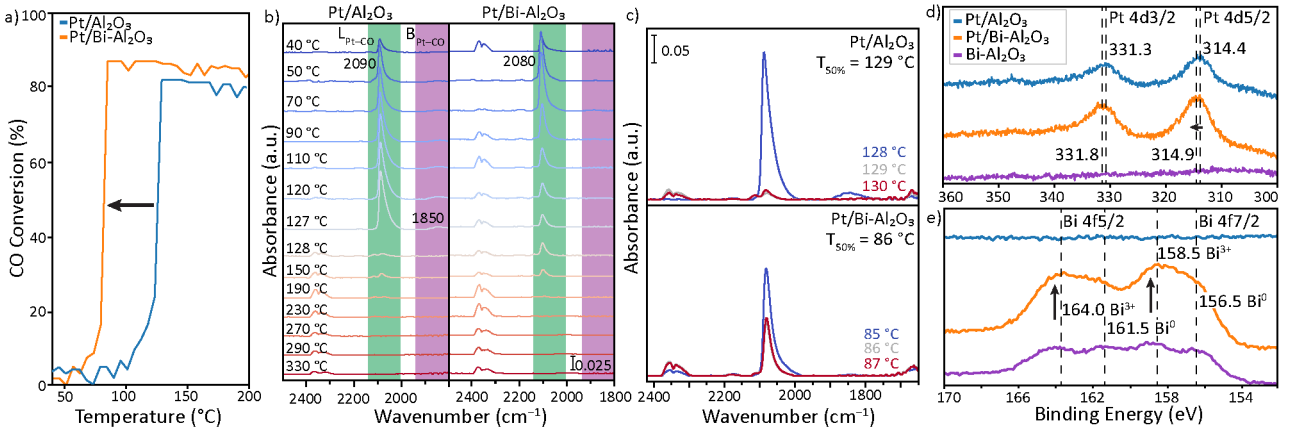

**Fig. 1 a) CO conversion as a function of temperature measured during *operando* CO oxidation, b) DRIFTS spectra at specified temperatures taken during *operando* CO oxidation, c) DRIFTS spectra at $T_{50\%}$ & d-e) XPS spectra of the Pt 4d and Bi 4f.**

**Keywords:** ZnAl reconstructed LDHs, temperature programed techniques, in-situ DRS, structural properties, basic properties, aldol condensation of furfural

**Introduction.** RE-LDHs are characterized by higher activity of the given materials in base-catalysed reactions than original LDHs [1]. The reason for the increased activity could be a change in the basic properties of the RE-LDHs associated with the formation of more Brønsted basic $OH^-$ sites in the interlayer space, instead of the original $CO_3^{2-}$ anions contained in the original LDHs and released from the materials during calcination to mixed oxide [2]. $OH^-$ ions are incorporated into the mixed oxide layers. It changes the Lewis basic sites (medium Zn-O and Al-O sites and strong $O^{2-}$ sites) of the mixed oxide to Brønsted (typically between these include $OH^-$) basic sites of RE-LDHs [3].

**Experimental/methodology.** ZnAl LDHs were prepared by three different methods (coprecipitation method using $Na_2CO_3$ as a buffer, using NaOH as a buffer and using hydrolysing urea), of them the corresponding mixed oxides and RE-LDHs were subsequently prepared. Materials were characterized by XRD, TPD-$CO_2$ and in-situ diffuse reflectance spectroscopy. Their activity was studied in aldol condensation of fufural.

**Results.** The main goal was to describe the so-called memory effect in ZnAl RE-LDHs. The individual preparations differed fundamentally in the ZnAl properties of the RE-LDHs. The most fundamental differences can be seen in content of well-crystalline ZnO phase, ability to reconstruct the LDH structure and content of basic sites. All ZnAl RE-LDHs contained both LDH and ZnO structure. The content of well-crystalline ZnO phase depended on the type of synthesis and it increased with increasing Zn/Al molar ratio. Its content was higher in ZnAl RE-LDHs than in corresponding ZnAl LDHs and it was present even in materials originating from ZnAl LDH with pure LDH structure. The content of well-crystalline ZnO phase was lower in ZnAl RE-LDH originated from coprecipitation method of LDH synthesis using hydrolysing urea than from coprecipitation method of LDH synthesis using NaOH or $Na_2CO_3$ as a buffer. Repeated number of the reconstruction of LDH structure led to the increase content of well-crystalline ZnO phase that possess smaller crystallite size, the increasing width of the space between the layers, decreasing interaction of the interlayer $CO_3^{2-}$ groups with LDH structure and increasing content of weak basic sites. Although LDH structure recovery is slower in gas phase than in liquid phase, the prolong time in gas phase leads to the similar LDH structure recovery as in liquid phase. ZnAl Re-LDHs possed significantly higher furfural conversion than ZnAl mixed oxides.

**Keywords:** photocatalysis, heterojunction, SPV, mechanism

**Introduction.** The design of heterojunctions by coupling two semiconductors together is a promising way to achieve high photocatalytic activity by inducing photogenerated charge separation. The surface photovoltage measurement can be a very efficient tool for the verification of p- or n-type conductivity of separate photocatalysts. Moreover, if the semiconductors are coupled in the form of layers, the direction of the photogenerated charge transfer can be monitored using this technique [1]. Therefore it can be applied to determine a junction's existence and provide tips for photocatalytic mechanism enlightenment.

**Experimental/methodology.** The photocatalysts systems were designed for $CO_2$ reduction and water-splitting/methanol photoreforming. The materials used for measurements were standard photocatalysts (*e.g*. P25, anatase) and as-synthesized by wet methods (precipitation, hydrothermal). After verification of their photocatalytic activity, the mechanism was studied using the Kelvin probe (surface photovoltage as the change of contact potential difference during pulsed irradiation in monochromatic light) and additionally supported by spectroelectrochemical measurements (SE-DRS).

**Results and discussion.** Surface photovoltage was measured for separate materials, mixed together and as layered coatings ("sandwich" type). The efficient junction can be observed as an increased absolute contact potential difference (CPD) after the coupling of both materials. The direction of the charge transfer between them was verified by preparing materials coupled layer by layer in inverse order. For example, an effective heterojunction was found for ZFO-$TiO_2$ ($ZnFe_2O_4$-anatase) tandem, which was designed for photocatalytic $CO_2$ reduction – Figure 1. Moreover, the applied methodology enables us to revise the well-known $TiO_2$-$Ag_2O$ system (used *i.a.* for water-splitting), revealing no junction between both materials [2].

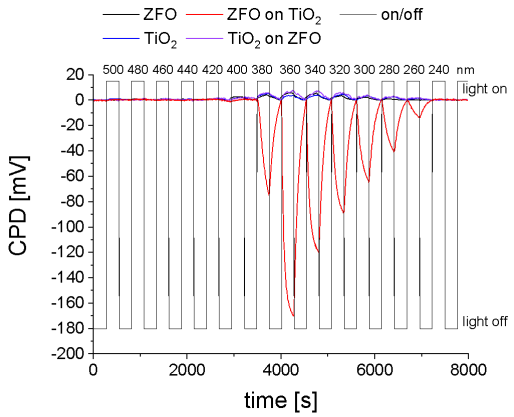

Fig.1. Surface photovoltage for $ZnFe_2O_4$-anatase photocatalytic system.

# Toolkit for the Structural Characterization of Mesoporous Zeolite Catalysts

Katie Cychosz Struckhoff[1*]; Matthias Thommes[2]

[1]*Anton Paar Quantatec, Boynton Beach, FL, USA*
[2]*University of Erlangen-Nuremburg, Erlangen, Germany*

**Introduction.**
Much effort has been devoted to the development of materials which exhibit hierarchical pore structure with advantageous micro- and mesopore connectivity. The network of interconnected pores facilitates efficient transfer of fluids to and from catalytically active sites, leading to benefits in numerous catalytic applications. A large amount of work has been dedicated to their pore structural characterization [1]. Detailed insights into the pore architecture (pore size distribution, pore volume and pore interconnectivity) are important because they control transport phenomena, diffusional rates, and govern selectivity.
Gas sorption is well suited for this because it assesses a wide range of pore sizes [2]. An in-depth characterization of the pore network can also be obtained with a detailed understanding of the adsorption and phase behavior of fluids confined in such complex pore structures. Here, a toolkit of recommended experimental and state-of-the-art data reduction methods for a comprehensive study of the pore architecture is provided.

**Experimental/methodology.**
Adsorption experiments were performed using a Quantachrome autosorb-iQ MP. Prior to the adsorption experiments, samples were degassed for 12 h at 623 K under turbomolecular pump vacuum.

**Results and discussion.**
Each tool for characterization of mesoporous zeolites has been validated using recent examples, which will be discussed in detail. Tools include:
(1) *Argon (87 K) adsorption* is recommend by IUPAC for accurate characterization of polar materials.
(2) *NLDFT methods for pore size* allow one to obtain a complete and accurate micro- and mesopore size distribution. Argon (87 K) adsorption coupled with NLDFT methods have been applied to a series of mesoporous Y zeolites (Figure 1) [3].
(3) *Comparison of isotherms measured using different adsorptives* ($N_2$ and Ar) to obtain pore network information.
(4) *Varying measurement temperature to* change the state of the confined pore fluid. Argon (77 K, 65 K) measurements have been used to determine the % freely accessible vs restricted mesoporosity in mesoporous Y zeolites (Figure 1, right).
(5) *Hysteresis scanning* to elucidate pore connectivity and pore desorption mechanisms and confirmed the presence of cavitation in Figure 1, right.

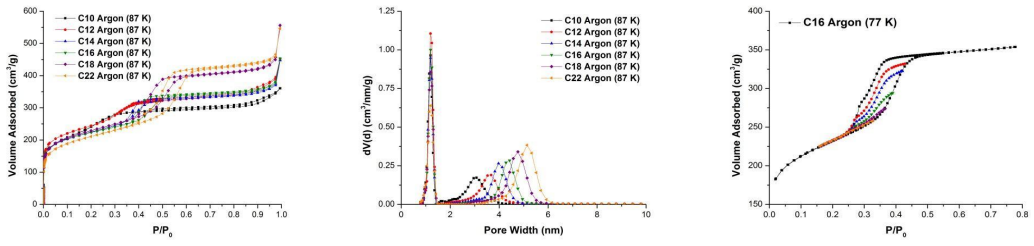

**Figure 1.** Argon (87 K) adsorption isotherms of a series of mesostructured zeolite Y (left), NLDFT pore size distributions from the argon (87 K) isotherms (middle), and hysteresis scanning curves on the argon (77 K) isotherm for one material (right).

# Probing the possibility of cooperativity of two divalent cations in Si-rich zeolites by Zn(II) emission quenching

E. Tabor*, J. E. Olszowka, P. Kubat, J. Dedecek

*J. Heyrovský Institute of Physical Chemistry of the Czech Academy of Sciences, Dolejškova 3, Prague, Czech Republic*

**edyta.tabor@jh-inst.cas.cz*

**Keywords:** binuclear sites, luminescence, ferrierite, Co(II) ions, Zn(II) ions

**Introduction.**

Distant binuclear transition metal (TM) ion sites stabilized in the zeolite matrix represent a new, recently discovered type of redox sites. [1] These sites are formed by two bare M(II) ions capable of the M(II)↔ M(IV) redox cycle, located in two opposite extra-framework cationic sites at a distance of. 7.5 Å. The distance between cations is short enough to allow them to perform the four-electron redox process, which can result in the splitting of two- or three-atom molecules, as was demonstrated for $N_2O$ and $O_2$. Particularly facilitated splitting of $O_2$ is a significant step ahead in oxidation catalysis, as by this process a pair of highly active, so-called α-oxygens is formed. These α-oxygens are so active that they are able to oxidize methane at room temperature [1]. Moreover, the oxidation products formed are released without aid on effluent to the gas phase also at room temperature. However, the formation of distant binuclear TM ion sites in zeolites was up to now only predicted by DFT [2] and confirmed indirectly, by the activity of M(II)-ferrierite in the oxidation of methane at low temperature. Therefore, in this work, the introduction of Zn(II) (emitter) and Co(II) (quencher) to develop the method for studying the intrinsic property of the chosen FER matrix with Al distribution assuring the formation of binuclear catalytic centres with appropriate geometry is presented.

**Experimental/methodology.**

The formation of distant binuclear site formed by Zn(II) and Co(II) ions is evidenced by employing the time-resolved laser-induced emission spectroscopy of Zn(II) ions in the presence of Co(II) ions in ZnCo-ferrierite. Commercially supplied ferrierite (FER) with Si/Al 8.5, Tosoh Corporation Japan was employed for the preparation of ZnCo-ferrierite samples with various Zn and Co loadings. Co(II) ions were characterized by UV-Vis DR spectroscopy of dehydrated samples using Perkin–Elmer Vis spectrometer Lambda 19 equipped with an integrating sphere. Zn(II) ions were characterized using LKS 20 laser kinetic spectrometer (Applied Photophysics) excited by Lambda Physik COMPEX 102 excimer laser (wavelength 308 nm).

**Results and discussion.**

As it was reported previously, bare Zn(II) ions stabilized in extra-framework cationic sites of ferrierite exhibit luminescence with a lifetime varying from 50 to 130 μs in the dependence on the site accommodating Zn(II) ion. In the case of the presence of Co(II) co-cation in the ferrierite matrix, the Zn(II) luminescence lifetime is significantly shortened to only 6 – 11 μs. This indicates quenching of the Zn(II) luminescence by the neighbouring Co(II) ions *via* resonant energy transfer, analogously as it was already reported for Cu(I) ions in Al-rich zeolites.[3]

**Introduction.** Silver ions incorporated to zeolite can serve as active sites in numerous catalytic reactions as the aromatization of alkanes, alkenes and methanol [1]. The reduction process of $Ag^+$ cations to various forms of $Ag^0$, clusters or nanoparticles, can occur upon the thermal treatment with CO, alcohols and alkylobenzenes [2]. Further, the thermal treatment itself plays an important role in the control of Ag species nature in zeolites. An isolated $Ag^+$ cations are the most favored at temperatures below 400 °C while higher temperatures facilitate their aggregation [3].

**Experimental.** The evolution of Ag species in the oxidative and reductive atmosphere was tracked in operando UV-vis studies. The temperature was increased gradually from RT to 500 °C with rate of 10 °C/min. The status of silver sites in zeolites will influence the process of catalytic oligomerization of ethylene and methane activation because of the $Ag^+$ cation itself can serve as the reaction site. Further, the activity of protonic sites present in reduced sample can be moderated by charged silver cluster presence. This aspect of the oligomerization activity influenced by the co-presence of $Ag^+$ cations was studied by means of 2D COS FT-IR spectroscopy of ethylene transformation over Ag-ZSM-5 at 375 °C over 10 h.

**Results and discussion.** It is well known fact that during oxidation at elevated temperatures the reduction of $Ag^+$ to $Ag^0$ can take place even in pure oxygen atmosphere. This is the case as the bands placed at 220-250 and 280 nm ($Ag_m^+$ and $Ag_n^+$ clusters, where m<n<8) increased significantly upon the thermal treatment in synthetic air flow from RT to 500 °C (Fig. 1). On the hand, under $H_2$ atmosphere with gradual increase of temperature to 500 °C leads to the formation of new kind $Ag_x^+$ with lower atomicity degree ( 4<x<8, 310 and 320 nm) accompanied by development of $Ag_{NPs}$ (360 nm) (Fig.1B). The AgZSM-5 zeolite during ethylene oligomerization process is selective to the aromatic compounds, e.g. 1,2,4-trimethylbenzene (1505 $cm^{-1}$) and bulky aromatics seen as 1590 and 1570 $cm^{-1}$ bands. Homogenous nature of the oligomerization products is reflected in the maps as well-resolved high intensity correlation peaks.

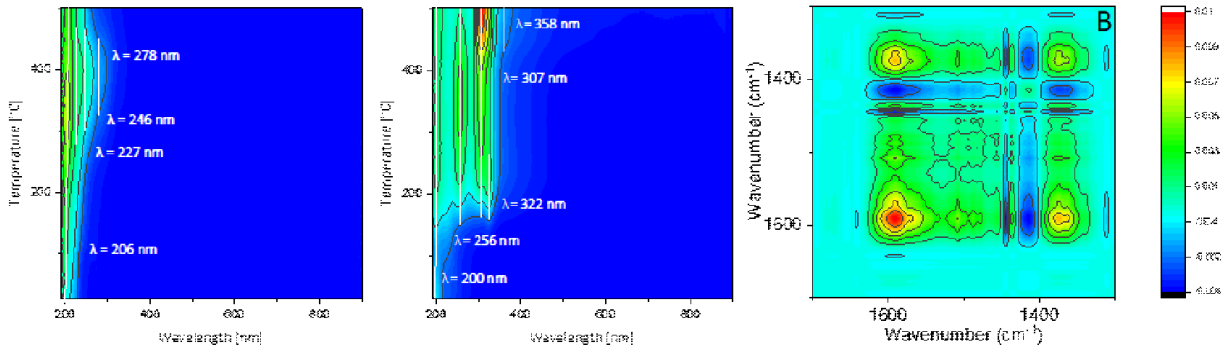

**Figure 1 UV-vis spectra of Ag-ZSM-5 zeolite upon thermal treatment in oxidative (right) and reductive (middle) atmosphere, 2D COS maps of FT-IR spectra registered during ethylene oligomerizaiton over AgZSM-5 (left).**

**Introduction.** The nature of carbonaceous deposits is a crucial issue in catalytic reactions involving hydrocarbons transformations. The carbonaceous species plug the zeolite micropores and inhibit the diffusion of reactants and products. Prior knowledge regarding the paths of catalyst deactivation by means of carbonaceous moiety formation is unequivocally important for designing the zeolitic catalysts with targeted performance. In this respect, defining the relationship between the coke speciation and zeolitic catalysts properties which determines the carbonaceous deposit formation is important research goal.
**Experimental.** Carbonaceous species over the catalysts with acidic property are rapidly formed during the transformation of ethylene into higher hydrocarbons (ZSM-5, CBV2314E, Zeolyst, 325 °C, 5000 ml/(g·h), 15 hours). The thermoprogrammed oxidation experiments supported by mass spectrometry during coke removal from spent catalysts were performed from 200 to 550 °C in flow of synthetic air and additionally the FT-IR and UV-vis spectra were recorded. For quantitative analysis the TG experiments of total coke removal were perfomed. The qualitative analysis was further supported by GC-MS analysis of coke extracted from catalyst (dissolved in HF and extracted with $CH_2Cl_2$).
**Results and discussion.** The complex IR band around 1640-1550 $cm^{-1}$ identifies the coke species formed during the oligomerization of ethylene over a series of ZSM-5. The position of the coke bands are indicative of its nature itself. Thus the bands centered at 1615 and 1575 $cm^{-1}$ suggest are indicative for species formed by condensation reactions producing $C_6H_7^+$ olefinic cations ($CH_2$=CH−CH]CH=CH]$CH^+$ or cyclic alkenyl carbenium ions $C_6H_9^+$ - the 1575 $cm^{-1}$ band) and polymethyl-benzenes as coke forming compounds (e.g. 1,2,4-trimethylbenzene, 1,2,3-trimethyl-benzene – the 1615 $cm^{-1}$ band). The shape of the UV−vis spectra provides information that coke on spent catalyst consists of 1-, 2-, and 3-ring aromatic compounds that are identified by the bands appearing at 220 and 260 nm only. Both neutral and charged aromatics species are identified by a complex band in the 220-620 nm region. More specifically, a complex band at 425 nm is ascribed to 1-methylnaphthalene, in line with its relatively small bandwidth indicative of a narrow distribution of hydrocarbon species contributing to this band. The highest amounts of $CO_2$ are formed by the oxidation of residues in ZSM-5 zeolite at temperatures as high as 500 and 550 °C. This confirms further the aromatic character of coke species formed during ethylene oligomerization.

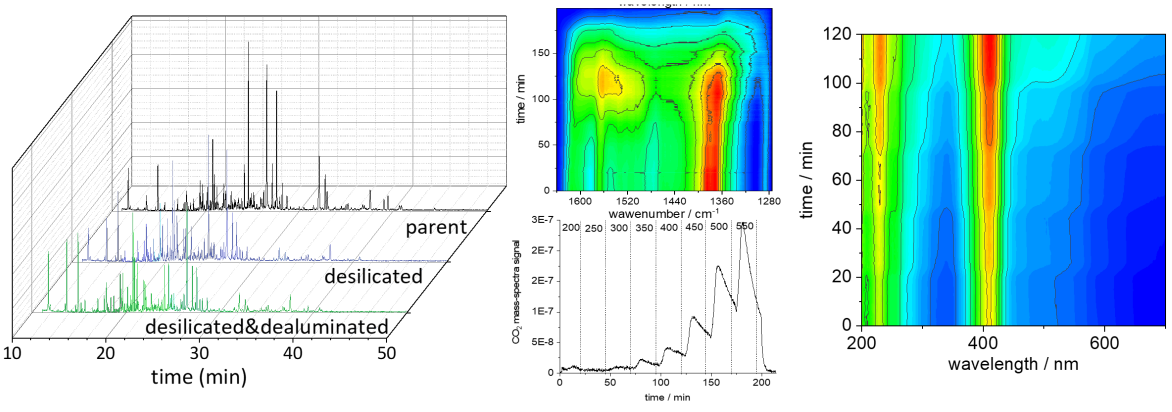

**Figure 1. GC-MS results of coke analsysis (right), IR-MS (middle) and UV-vis (left) results of coke burnign-off**

**Keywords:** silver, oxidation, surface morphology, focused ion beam, electron microscopy, tomography

**Introduction.** Silver is an effective catalyst in the partial oxidation of methanol, and silver particles are used industrially to produce formaldehyde. During interactions with oxygen at high temperatures (≳600 °C), the silver morphology changes drastically following oxygen dissolution and diffusion into silver and subsequent surface reconstruction and pore formation [1]. This restructuring is coupled with questions that have yet to be fully answered, including i) the role of hydrogen and carbon, ii) direct observations of the atomic planes in relation to the surface and pore facets, and iii) how the post-reaction morphology relates to the reaction dynamics. In this study, electron microscopy is employed to characterise annular silver catalysts before and after oxidation in various reaction atmospheres, with the main goal of disclosing the (sub-)surface morphological and microstructural changes occurring in three dimensions.

**Experimental/methodology.** An annular reactor [2] is used with hollow cylindrical silver catalysts (⌀ 10 mm) that are heated in steps up to 700 °C and subsequently cooled. Several samples are studied, including as-received silver (A), silver heated in $N_2$ (B), and silver after oxidation of CO (C), $H_2$ (D), CO and $H_2$ (E), $CH_3OH$ (F) and $CH_3OH$ and $H_2O$ (G). Scanning and transmission electron microscopy (SEM and TEM) techniques are applied to characterise the pores and facets. Focused ion beam (FIB)-SEM is used to obtain three-dimensional tomographic reconstructions [3] of the (sub-)surface region. The grain structure is revealed by electron backscatter diffraction and scanning precession electron diffraction (SPED) [4].

**Results and discussion.** The as-received silver (A) shows small grains and pores within the near surface region (≲1 µm), but no surface facetting. The heated samples display facets mainly corresponding to {111} planes, and the grain structure indicates recrystallisation and twinning. The FIB-SEM tomography discloses smaller rounded (∽10 nm) and larger often facetted pores (∽1 µm). Figure 1 shows selected results from silver after CO oxidation (C). Similarities and differences between the catalysts are shown and discussed.

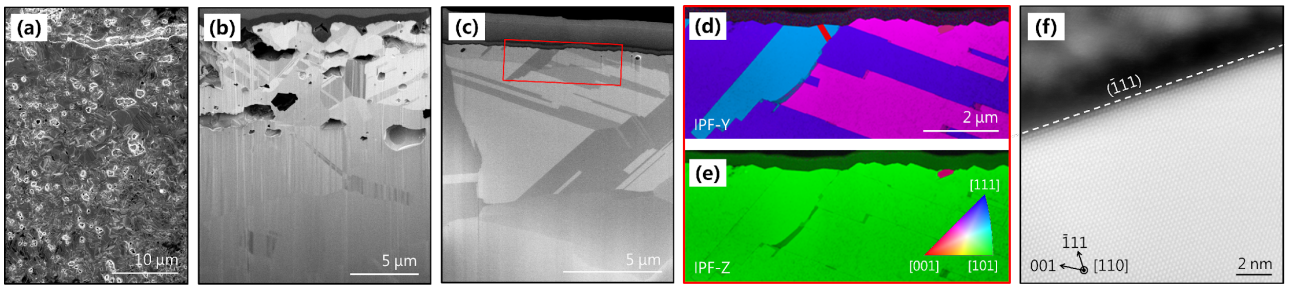

**Figure 1: Silver after CO oxidation (C). SEM images showing (a) top-view, and (b) and (c) cross-sections milled by FIB. (d) and (e) orientation maps obtained from SPED data. (f) high angle annular dark field STEM image.**

**Keywords:** sustainability, decarbonisation, electrification, climate neutrality

**Introduction.**Ethylene epoxidation is an essential selective oxidation process in the industrial production of materials such as glycols, ethers, ethanolamines, and ethoxylates. The process involves the conversion of ethylene to ethylene epoxide (EO) using doped silver catalysts. The silver is doped with various elements, such as antimony, bismuth, caesium, chlorine, copper, or noble metals, to improve selectivity. Despite the effectiveness of silver as a catalyst, there is ongoing debate about the microscopic origins of the beneficial effects of dopants.

**Experimental/methodology.** In this study we synthesized, screened, and characterized catalysts predicted by computational screening to better understand the reaction mechanism, predict more effective catalysts, and explain the favourable effects of known dopants. The formulations were predicted by the use density functional theory (DFT) calculations to examine the reaction mechanism on nine late-transition metals. They then use scaling relations and the Brønsted–Evans–Polanyi (BEP) relations to identify correlations between calculated reaction parameters and a unique descriptor for each catalyst. This screening predicts high-performing alloys, such as silver with copper, cadmium, zinc, and thallium, and provides a framework for future research. The synthesized materials were characterized by XRD, TEM, XPS, and pulse chemisorption of oxygen. Finally, the materials were analysed for their capacity to selectively oxidize ethylene to ethylene oxide in a custom electrified reactor.

**Results and discussion.** The experimental results show that all tested catalysts produced ethylene oxide (EtO), but with CO2 as the majority product. Adding small amounts of Cu to a silver-based catalyst increases EtO selectivity by over 50% (Figure 3). The highest activity and EtO selectivity was found in the Pb and Cu modified catalyst, outperformed by the Cd modified tri-metallic catalyst. The In and Zn modified tri-metallic catalysts were not efficient for ethylene epoxidation. XRD analysis showed that adding metals to silver does not affect the average particle diameter of the catalysts. Pulse oxygen chemisorption showed that adding metals to silver increases oxygen coverage, with a limit before it causes total oxidation of EtO to CO2 and H2O. TEM analysis revealed that the Ag catalyst particles consist of large alumina flakes decorated with Ag nanoparticles.

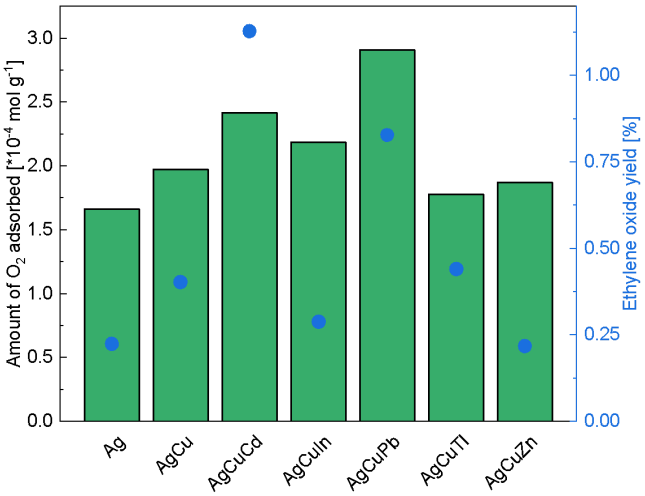

**Figure SEQ Figure * ARABIC 1: The graphs shows the normalized adsorption of $O_2$. It is overlaid with the yield in selective oxidation of ethylene.**

# Combining spectroscopic online monitoring with additive manufacturing in continuous flow liquid phase processes

V. Truttmann[1], M. Kaya[2], C. Klahn[3], B. Häfner[4], C. Jakob[4], D. Doronkin[1,5], E. Saraçi[1,5], J.-D. Grunwaldt[1,5,*]

**vera.truttmann@kit.edu*; *grunwaldt@kit.edu*

**Introduction.** Liquid phase continuous flow synthesis has become an important tool towards a more sustainable production of fine chemicals, often showing better performance and being less hazardous than classical batch processes.[1] Furthermore, improved process control is possible by using spectroscopic online monitoring.[1-3] Typically, spectroscopic probes or flow cells are placed after the respective flow reactor and thus, the data at the point of measurement do not fully represent the actual reaction taking place in the reactor. This not only complicates thorough reaction mechanism studies, but also the establishment of a real-time control loop to achieve reliable process control for increased efficiency.

These problems can be overcome by use of additive manufacturing (AM), which can generate advanced reactor geometries significantly improving e.g. mixing of reactants or heat transfer.[4] Additionally, the versatile features of AM enable the design of tailored solutions for the integration of spectroscopy into a continuous flow (micro)reactor.

**Experimental/methodology/discussion.** A continuous flow set-up including a customized stainless steel 3D-printed reactor was developed in-house and tested for an organometallic model reaction (Grignard reaction). Its performance regarding yield, selectivity, but also temperature management is compared to both a classical batch process as well as a standard continuous flow set-up without additively manufactured parts. Furthermore, online ATR-IR spectroscopic monitoring is implemented, first after the flow reactor and then inside the AM-reactor, and outcomes are compared. Finally, while focused mainly on mid-infrared spectroscopy, also other spectroscopic techniques (e.g. NIR) are evaluated to identify the optimal method in terms of safety aspects, chemical suitability and economic considerations.

With this case study we aim to demonstrate that combining novel manufacturing techniques with advanced *in situ/operando* spectroscopy has the potential to facilitate investigation and understanding of (catalytic) reaction mechanisms as well as to improve process control and automation. These insights provide significant benefits for both academic purposes as well as for industrial applications.

**Introduction**

Fe-based mixed oxide catalysts have been used for over a century to catalyse the high-temperature water-gas shift (HTS) reaction to produce hydrogen from fossil or renewable sources. In this work, Mössbauer spectroscopy (MB) was used to study the incorporation mechanism of the Cr and Cu promoters, which are known to increase catalyst stability and activity of Fe-based HTS catalysts, respectively. MB is a powerful tool to investigate the electronic structure, bonding properties and magnetic behaviour of materials containing nuclei that display the Mössbauer effect, of which $^{57}$Fe is by far the most widely studied.[1] Small changes in MB hyperfine interactions provide insight into the extent and manner of Cr and Cu incorporation into the calcined precursors and the reduced active catalyst phases. Catalyst performance under industrially relevant HTS conditions of a range of catalysts containing alternative promoters to Cr was studied and combined with results from MB spectroscopy to derive structure-performance relations.

**Experimental/methodology**

A range of Fe-Cr, Fe-Cr-Cu and Fe-M(-Cu) mixed oxides (M = Al, Ga, In, Mn, Zn, Nb) was prepared by co-precipitation followed by calcination. The $Fe^{3+}$ catalyst precursors were subjected to industrially relevant HTS conditions (450 °C, 25 bar) for four days. The aged catalysts were analysed by MB, XRD and XPS after reaction.

**Results and discussion**

Small changes in the MB hyperfine interactions revealed that both Cr and Cu are incorporated into the fully oxidised Fe-Cr-Cu catalyst precursor. Upon reduction to the active magnetite phase, Cu is expelled from the mixed oxide lattice whilst Cr is fully incorporated into octahedral sites of the spinel structure, even at the maximum promoter level of 12 at%.[2][3] Substitution of Cr with alternative promoters results in a range of substitution patterns: Al and Zn substitute both tetrahedral and octahdral Fe ions, whilst Ga and Mn exclusively occupy octahedral sites. In and Nb are initially present at octahedral sites; however, these large cations do not remain in the lattice and are expelled from the structure under reaction conditions. Of the alternative promoters, Al displayed highest activity and stability under the applied testing conditions.[4]

**Keywords:** hydrodenitrogenation, sulfide NiMo catalyst , impregnation, citric acid

**Introduction.** The future of fuel supply involve the utilization of feedstock materials from conventional and nonconventional sources and the selective removal of sulfur, oxygen and nitrogen is among the most critical and challenging aspects of the upgrading [1]. Hydrodenitrogenation (HDN) becomes particularly challenging for processing biobased feedstocks since they comprise different nitrogen containing compounds than fossil-based feedstocks [2]. NiMo sulfide supported on alumina is traditionally used as catalyst for HDN [3] and it has been reported that the preparation method influences the properties of the resulting NiMo catalyst which in turn defines the hydrotreating activity [4]. Catalysts with short $MoS_2$ slabs length and large $MoS_2$ stack height resulted in an improved HDN activity [5]. In addition, it was found that the use of citric acid (CA) in the impregnation results in a relatively higher $MoS_2$ stacking number and facilitates the formation of the NiMoS phase [6]. However, the impregnation step at which citric acid is added might also play a role on the resulting catalyst properties [6]. In this work, we explore the effect of the impregnation method and the use of citric acid as additive on the physico-chemical properties of sulfided NiMo catalysts supported on γ-alumina. The impregnation methods studied in this work were wet co-impregnation, and incipient wetness with co- and sequential impregnation of Mo and Ni metal precursors.

**Experimental.** Ammonium heptamolybdate hexahydrate and nickel nitrate tetrahydrate were used as metal precursors for wet and incipient wetness impregnation. Citric acid (with a CA/Ni molar ratio of 1.6) was used optionally as an additive during impregnation. The impregnated supports were calcined at 500 °C for 2 h. Sulfidation of the calcined catalyst precursors was was carried out in batch conditions and it consisted of an initial drying with 10 bar $N_2$ at 180 °C for 1 h followed by sulfidation with 10 vol% $H_2S/H_2$ at 400 °C for 2 h. Characterization techniques included powder X-ray diffraction (XRD), inductively coupled optical emission spectroscopy (ICP-OES), X-ray photoelectron spectroscopy (XPS), transmission electron microscopy (TEM) combined with energy-dispersive X-ray spectroscopy (EDS), and Raman spectroscopy.

**Results and discussion.** Our results show that the use of citric acid during catalyst preparation resulted in a reduced amount of crystalline $MoO_3$ and higher metal loading in the calcined catalyst precursors. The formation of the HDN active NiMoS phase was confirmed in all prepared catalysts by XPS measurements. Additionally, TEM analysis of the sulfided catalysts revealed that the catalysts prepared with citric acid presented shorter $MoS_2$ slabs and a higher stacking number than those prepared without addition of citric acid. In general, comparing the different methods studied in this work, the addition of citric acid during the impregnation steps resulted in catalysts with enhanced physico-chemical properties which can be beneficial for HDN reactions [5, 6].

**Keywords:** Cu-CHA, SCR redox cycle, XAS, TRM, Emission control, $NH_3$-SCR

**Introduction.**

The $NH_3$ Selective Catalytic Reduction ($NH_3$-SCR) is currently considered the leading technology for $NO_x$ abatement from Diesel engines [1-3]. In literature, there is a wide consensus about the redox nature of the Standard SCR chemistry. However, the detailed scheme of the full SCR redox cycle is still debated [3]. In this work, we investigate kinetic features involved in the RHC and OHC of the SCR redox cycle using both Time Resolved X-ray Absorption spectroscopy (XAS) as well as simple Transient Response Methods (TRM).

**Experimental/methodology.**

Kinetic investigations were carried out on 1.7% and 2.1% w/w Cu-CHA (SAR25) model catalyst samples (powders) provided by Johnson Matthey. XAS measurements were performed in a quartz capillary reactor (GHSV = 136500 $cm^3/h/g_{cat}$ (STP)) on the energy dispersive branch of beamline I20 at Diamond Light Source, Didcot, UK. XAS spectra were then analyzed by Multivariate Curve Resolution. TRM experiments were performed in a quartz micro-reactor (GHSV = 450000 $cm^3/h/g_{cat}$ (STP)) and the temporal evolution of the gas phase was monitored by FTR+MS analyzers at Politecnico di Milano. The TRM $Cu^{II}$ reduction data were then fitted according to the transient integral model of the test flow reactor discussed in [4].

**Results and discussion.**

XAS profiles representative of the Cu oxidation state were used to verify the kinetics independently developed over Cu-CHA by gas phase transient response methods. Figure 1a shows that the evolution of $Cu^{II}$ and $Cu^{I}$ ions measured by XAS experiments during the NO+$NH_3$ reduction pulses was well predicted using the same RHC kinetics (2nd order in $Cu^{II}$) that successfully fitted the NO+$NH_3$ TRM experiments. The equivalence of the two techniques further validates a quadratic dependency on $Cu^{II}$ for the reduction half cycle, consistent with a dual site mechanism. The opposite was done in the case of the OHC: transient response experiments were used to further investigate aspects related to the re-oxidation in NO+$O_2$ and $O_2$ only. Combining the two techniques has highlighted that NO is not involved in the re-oxidation of Cu sites. $O_2$ can re-oxidize Cu sites leaving them solvated with $NH_3$. NO presence leads instead to a more complex behaviour and consumption of ammonia prior complete oxidation (Figure 1b,c).

A strong synergy between the two complementary techniques exists: they can be used equivalently to investigate the RHC, but their use in combination has unveiled important mechanistic aspects of the OHC.

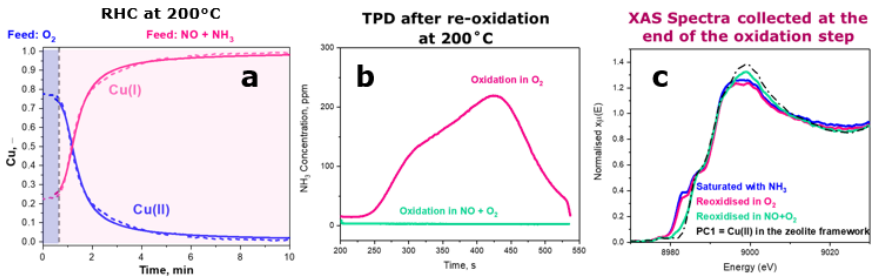

**Figure 1 a) RHC: experimental data (EDE runs) versus kinetic simulations; b) $NH_3$ TPD performed after reoxidation in $O_2$ or NO + $O_2$; c) XAS spectra collected at the end of the oxidation step in $O_2$ vs NO+$O_2$.**

# Operando Luminescence Thermometry of Propane Dehydrogenation Catalysis

R. Vogel[1*], Freddy T. Rabouw[1], Bert M. Weckhuysen[1]

[1]Inorganic Chemistry and Catalysis, Department of Chemistry, Utrecht University, *Utrecht, The Netherlands*
[*]*r.vogel@uu.nl*

**Keywords:** Propane dehydrogenation, luminescence thermometry, in-situ spectroscopy

## Introduction

Catalytic propane dehydrogenation (PDH) is an industrial route towards the production of propylene. Unfortunately, the formation of carbon deposits (coke) on the catalyst material, results in gradual activity loss. Catalytic performance, including activity and selectivity, is often regained in an oxidative regeneration step.[1] In the processes of catalysis and catalyst regeneration, local temperature is expected to influence events on the catalyst surface that affect its overall performance and long-term stability. Figure 1a illustrates how the endothermic dehydrogenation process over a Pt-Sn/$Al_2O_3$ PDH catalyst can result in a locally lower temperature at the catalyst while the exothermic regeneration process can result in strongly increased local temperatures. Potentially, information on the local temperature can be used to adjust the regeneration procedure in order to reduce catalyst degradation. In this work, we have developed a non-invasive thermometry technique based on the temperature-dependent luminescence of $Eu^{3+}$ to gain insight in the local temperature of the catalyst during PDH and regeneration.

## Methodology

Figure 1b shows that $Eu^{3+}$ can serve as a temperature sensor. The luminescence originating from two thermally coupled energy levels, $^5D_1$ and $^5D_1$ changes as a function of temperature.[2] Spectra recorded at a known temperature can be used as a reference to deduce the temperature of a sample containing $Eu^{3+}$ at an unknown temperature.

## Results and discussion

Figure 1c reveals a strong exothermic effect during the regeneration of a coked Pt-Sn/$Al_2O_3$ PDH catalyst. The catalyst was mixed with the temperature sensor and heated in an $O_2$-containing atmosphere. Time-resolved $Eu^{3+}$ emission spectra revealed a fast local temperature rise after the reactor temperature reached 450°C. This observation can be coupled to the combustion of carbon deposits and the regeneration of the catalyst. Combining local temperature information with thermogravimetric analysis and in-situ spectroscopy techniques, such as UV-Vis and Raman spectroscopy, builds a complete picture of the processes occurring on the surface during regeneration.

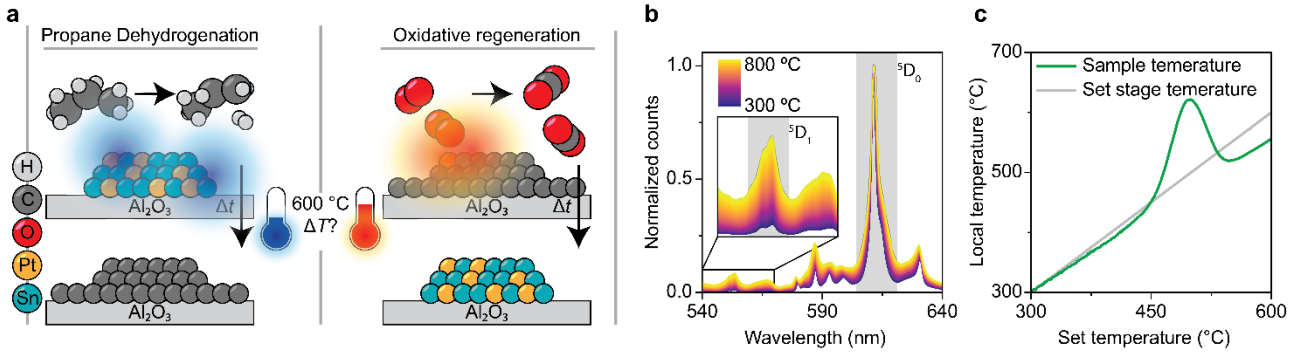

**Figure 1 – (a) Endothermic and exothermic effects during propane dehydrogenation (PDH) and oxidative regeneration over a Pt-Sn/$Al_2O_3$ catalyst; (b) Normalized $Eu^{3+}$ emission spectra between 300 and 800°C. (c) Local temperature during regeneration of a coked PDH catalyst.**

**Keywords:** Catalysis, *in situ*, *Operando*, X-Ray Reflectivity, Grazing Incidence X-Ray Diffraction, Thin-films

**Introduction:** *Operando* Grazing Incidence X-ray Diffraction (GIXD) and X-Ray Reflectivity (XRR) were applied under *in situ* conditions to study 2D model catalysts during activation in $H_2$ and acetylene hydrogenation ($C_2H_2$ + $H_2$). These methods were combined with online mass spectrometry (MS) analysis to determine the relationship between structure and activity. Model 2D catalysts comprised of Pd (mean thickness ~10 nm) and 36 nm of ZnO deposited on single crystal $SiO_2$/Si(100) were studied. Reduction in 2% $H_2$ followed by acetylene hydrogenation was performed as a function of temperature (90 to 350 °C) and 1 barg in order to follow the structure evolution, particularly to determine the role of Pd speciation (Pd metal, PdC, PdH and β-PdZn with the support) on semi-hydrogenated (ethylene) and fully hydrogenated (ethane) product formation. This work also addressed the issue of the reversibility of the Pd-C species that is formed during reaction conditions. The results allowed us to obtain a unique insight into the structural transformations occurring at the metal-support interface and its implications on catalyst performance.

**Experimental/methodology.** The Pd/ZnO_$SiO_2$ samples were prepared at the Helmholtz-Zentrum (HZB) in Berlin as a part of the CatLab project. These samples comprise of Si and Si-200 nm $SiO_2$ substrates which have been sputter coated with Pd and ZnO respectively. In this experiment, samples with the following thickness have been used: 10 nm Pd and 36 nm ZnO layers. The Pd and ZnO is being sputtered on the substrate by DC-sputtering. The grazing incidence measurements were performed using an incident angle of 0.6199°. The detector images were processed to obtain a 2θ projection of the diffracted intensities. The sample was mounted on a stainless-steel plate using silver paste glue and placed inside a sealed reactor complete with an X-ray transparent Beryllium dome with K-type thermocouple attached on the sample plate near the sample. The reactor was connected to a gas delivery system comprising of switching valves and mass flow controllers which enabled complete control of gas mixing and flow rates.

**Results and discussion.** The ratio between $H_2$ & $C_2H_2$ impacts the catalytic activity. The pristine sample comprises crystalline Pd as evidenced by the presence of reflections at 15.88°° (111), 18.38°° (200), 26.02°° (220), 30.52°° (311) and 31.83°° (222). This is accompanied by ZnO reflections at 12.63°° (100) and 14.38°° (101). Reduction at 90 °C displays the same reflections as the initial reading but all at a lower intensity. From 1:1 ($H_2$:$C_2H_2$) at 90 °C onwards, there are only two phases present throughout the remaining data. The positions of these reflections do not change. The PdC phase is shown to form by the presence of reflections at 15.62°° (111), 18.03°° (200), 25.58°° (220), 30.08°° (311) and 31.48°° (222). The ZnO reflection positions remain & are unchanged. XRR data shows changes at the interface of the sample, with changes in roughness affecting the quality/shape of oscillations. The XRR shows the presence of Pd, ZnO and PdZn. The GIXD pattern does not show any presence of PdZn at this stage. It is likely the PdZn alloy formation is in its early stages, thus, the deeper probing from XRR has proven to be beneficial to see these physiochemical changes.

# On the basicity dermination of thermally unstable materials

L. Dolejšová Sekerová[1], I. Paterová[1], E. Vyskočilová[1*]

[1]*Dpt. of organic technology, University of Chemistry and Technology Prague, Prague, Czech Republic*
[*]*eliska.vyskocilova@vscht.cz*

**Keywords:** basicity, sorption, HPLC/MS, UV/Vis, layered double hydroxides

**Introduction.** The basicity of materials designed as catalysts is one of the most important factors in evaluating catalytic activity. Typically, the basicity is determined using the TPD method [e.g., 1] of the preadsorbed gaseous acidic probe – $CO_2$ is used most often. However, this method needs thermal pretreatment of the measured samples necessary that is, of course, problematic for thermally labile samples. Moreover, the $CO_2$ probe is a small molecule that can access even the more hindered basic sites. Thus the results might be misrepresented for reactions with larger molecules as basic catalysts are often used for, e.g., aldol condensation reactions.

**Experimental/methodology.** Mixed Mg-Al oxides (MO) with different ratios Mg:Al (prepared by precipitation–calcination method) were used as model materials for development of new method for basicity evaluation. Two methods – UV/Vis and HPLC/MS - were used. Both methods used anthranilic acid as a probe molecule, and the results were compared with the results obtained by commonly used TPD of $CO_2$. The optimized procedure was applied to the basicity determination of thermally unstable layered double hydroxides (LDH) prepared from model mixed oxides. The basicity values were compared with the results of testing of catalytic activity in aldol condensation reactions [2,3].

**Results and discussion.** The probe molecule was applied from acetonitrile solution by wet sorption. Mixed oxides were calcined prior to the sorption. HPLC/MS served to determine the amount of basic sites. At the same time, UV/Vis confirmed that the probe molecule was attached to the surface by acid-basic interaction, and simple sorption was avoided. The dependence of UV/Vis absorption properties of anthranilic acid under different pH was measured. The significant shift of absorption band was detected in basic as same as an acidic solution. The amount of basic sites measured by HPLC/MS decreased in the row MO2 ≈ MO2.5 > MO3 > MO3.5 (the number was the ratio Mg:Al). The anthranilic acid adsorbed amount ranged from 18.5 to 7.5 mg/g of material. This row was the same as in the determination of the amount of basic acids sites by TPD $CO_2$. The more challenging was the basicity determination of LDHs, which we prepared by rehydration of the tested mixed oxides. Thus we prepared four LDHs denoted as LDH2, LDH2.5, LDH3, and LDH3.5 (the number corresponds to the ratio Mg:Al). LDHs adsorbed a significantly higher amount of the probe molecule as expected. The lowest adsorbed amount was 197.8 mg/g of material, which was ten times higher than the highest amount adsorbed in the case of MO. The basicity of LDHs materials decreased in the row LDH3.5 > LDH2.5 > LDH3 > LDH2. However, the catalytic activity of these materials differed. We have found out that the different textural properties of materials may explain the different behavior of materials after rehydration. As the catalytic activity measurement took only 6 hours while the basicity measurement was performed until the equilibrium was reached, the more precise comparison was the probe molecule's consumption rate. In such a case, the consumption rate decreased in the row LDH2.5 > LDH3.5 > LDH3 > LDH2, which followed the catalytic activity of the materials. We can conclude that we have developed a method for evaluating the basicity of solid materials that is also applicable to the thermally unstable materials of the layered double hydroxide type. This method offers a promising way of further characterization of basic materials.

[*]*anna.wach@uj.edu.pl*

**Keywords:** X-ray spectroscopy, synchrotron, in situ, operando, catalysis

**Introduction.** The SOLARIS National Synchrotron Research Centre is a third-generation light source operating at medium electron energy since 2015 in Krakow, Poland. The storage ring operates at a final energy of 1.5 GeV in a decay mode with a maximum current of 500 mA and a total lifetime of 15 h. As the only synchrotron light source in central and eastern Europe, SOLARIS has the potential to become the leading applied research facility in the region. The presence of bending magnets and insertion devices within the storage ring allows to cover a wide spectrum of emitted photons from VUV to the hard X-ray region. Thanks to its unique properties and excellent parameters, SOLARIS provides different photon- and electron-based techniques for material investigation in various research fields, e.g. catalysis, material and surface science and environmental chemistry. Presently, the synchrotron experiments are possible at five beamlines (overall six end-stations) and a cryo-microscopes facility, while three additional beamlines are under construction and several more are in conceptual preparations.

**Results and discussion.** We will present current studies and future perspectives of in situ/operando project at SOLARIS. In particular, we will present the development of an operando endstation that will allow for synchrotron-based multitechnique studies (combinations of X-ray spectroscopy with complementary techniques) at hard x-ray energies. The endstation will be designed to be used at the two hard X-ray beamlines of SOLARIS, namely ASTRA and PolyX beamlines. The ASTRA beamline is designed for X-ray Absorption spectroscopy (XAS) measurements at tender and higher X-ray energies (from 1 to 15 keV). XAS is element specific, sensitive to the chemical environment of the absorbing atom and together with the high X-ray penetration depth of the X-rays used, uniquely suited for studying catalysts under relevant conditions (in situ/operando). The PolyX beamline is a compact bending magnet beamline in the hard X-ray energy range (4-15 keV). The beamline is based on polycapillary optics, which in conjunction with energy-dispersive X-ray absorption and emission spectroscopy and von Hamos spectrometer will enable time-resolved studies. Microfocus capabilities of the beamline are important for in situ experiments where a local X-ray probe is essential for precise determination of the sample's chemical state.

Further, we will describe the parallel development of the second endstation dedicated to NAP-XPS studies. NAP XPS allows for in situ investigations of catalysts in gaseous environments in the mbar pressure range. These near ambient pressure XPS, have opened up new opportunities to study dynamic modifications at surfaces and correlate them with the catalytic performance. We will discuss the possibility to conduct research with NAP-XPS beamline in soft X-ray energy range, which will be an ideal operando measurement method for investigating the electronic structures of materials at gas/solid interfaces, with simultaneous monitoring of material function.

**Keywords:** Metal oxides, C-H activation, $CO_2$, molybdenum oxide, alkane, oxidative dehydrogenation

**Introduction.** Activation of C-H bond in alkanes and C=O bond in $CO_2$ on transition metal oxides is of industrially importance in shale gas conversion, commodity chemical production, and/or in $CO_2$ utilization. Through kinetic assessments, UV-vis and XPS spectroscopic studies, and density functional theory calculations, we establish the common mechanistic traits and active site requirements for these reactions—when analyzing them at the molecular scale level, the reactions contain several kinetically coupled catalytic cycles that involve the activation of the reductant on metal cation-oxygen anion site pairs and the activation of oxidant on oxide surfaces.

**Experimental/methodology.** Molybdenum catalysts promoted with Co, Fe, and Ni were prepared by wet impregnation methods. Kinetic assessments of alkane-$CO_2$ turnovers were carried out in a microcatalytic fixed bed reactor. UV-vis and XPS spectroscopies were carried out either in-situ or transferred from reactor under controlled environments. Density functional theory calculations were performed using VASP.

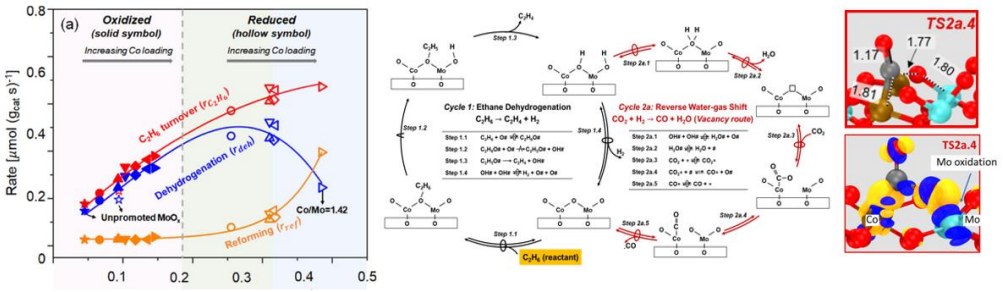

**Figure 1.** (a) Rates (per mass) of total $C_2H_6$ turnover ($r_{C2H6}$), dehydrogenation ($r_{deh}$), and reforming ($r_{ref}$) versus the RWGS rates ($r_{RWGS}$), after $C_2H6$–$CO_2$ catalysis (5 kPa $C_2H_6$, 10 kPa $CO_2$, 6000 $cm^3$ $g_{cat}^{-1}$) for 15 h at 873 K on a series of CoO−$MoO_x$ catalysts [2]; (b) dual catalytic cycles of ethane dehydrogenation and $CO_2$ activation; (c) transition state structure and isosurfaces of charge density of $CO_2$ activation on the oxygen vacancy on $CoMoO_x$ surfaces; orange and blue surfaces show electron accumulation and depletion, respectively.

**Results and Discussion.** Ethane-$CO_2$, ethane-$O_2$, and ethane (without oxidant) reactions on Co, Fe, or Ni promoted $MoO_x$ catalysts start with the kinetically relevant C-H bond scission of $C_2H_6$ on Mo-O site pairs, thus their initial turnovers on fresh catalysts remain identicals (1.4:1.8:1.9 mmol (g-atom Mo s)$^{-1}$, 873 K, 5 kPa $C_2H_6$, 3.2 kPa oxidant). The rates decrease due to the accumulation of the carbonacious species on the surfaces [1]. Coupled together with the alkane activation is the activation of oxidant, where rates vary with the identity of oxidant as well as that of cation (Co, Fe, Ni) in the Mo-O second coordination sphere [2]. Fig. 1 depicts the proposed dual catalytic cycles of ethane and OC=O activation and their coupling, where C-H bond activation, which reduces the oxide surfaces, is kinetically coupled with the OC=O activation, which replenishes the surface oxygen. Due to this kinetic coupling, the ethane turnovers, which equal the sum of the yields to ethene and reforming products, depend strictly on reverse water-gas shift turnovers (Fig. 1). Incorporating Co into the Mo-O-Co coordination sphere promotes the formation of oxygen vacancies that in turn promote $CO_2$ activation, leading to higher ethane turnovers and to selective ethene formation, mediated by the increase in reverse water-gas shift turnovers. This reactivity trend confirms that reverse water-gas shift rates are appropriate kinetic descriptors for ethane activation turnovers and also catalyst stabilities during $C_2H_6$-$CO_2$ catalysis. Both the vacancy and carboxylate routes are facile for $CO_2$ activation, but vacancy route prevails at elevated temperatures (973 K) with the transition state shown in Fig. 1. This mechanistic knowledge further allows us to design active sites with dual functionality to enable effective ethene formation.

# Experiments and Kinetic Model Development on Side Chain Alkylation of Toluene with Methanol: An Industrial Perspective

Shamayita Kanungo[1*], Kartick Mondal[1], Vikram Bhide[1]

[1]*Shell Technology Centre, Bangalore, India*
[*] *shamayita.kanungo@shell.com*

**Keywords:** alkylation, kinetic model, reaction network, industrial processes, technology maturation

**Introduction.** Ethylbenzene (EB) is an important captive intermediate for Shell, which is currently produced by the reaction of benzene and ethylene. An attractive alternative for EB (and styrene) production is by the side chain alkylation of toluene with methanol due to advantaged/cheaper feedstock. For this technology to replace the existing one, it is important to reach the steep performance targets which in turn requires a better understanding of the underlying reaction mechanism and pathways to the main products (both desired and undesired).

This talk will focus on the reaction network development by a dedicated experiemtal program and kinetic model development. It will give a flavour of technology maturation, in particular how industrial scientists use smart experimentation and simple kinetic models to derive important information that drive decisions on the development of future technologies.

**Experimental/methodology.** The experiments were conducted in a fixed bed reactor with gas and liquid feeding sections. Typically ~5g of catalyst was loaded, the liquid feed was diluted with $N_2$ (feed type and dilution depending on the experiment, typical feed partial pressure~1.3 $bar_a$) and reaction temperature range was 375-405°C. The products were either analyzed online in the gas phase or in certain experiments were condensed downstream and analysed offline.

**Results and discussion.** The overall outcome of this work is illustrated in Figure 1.

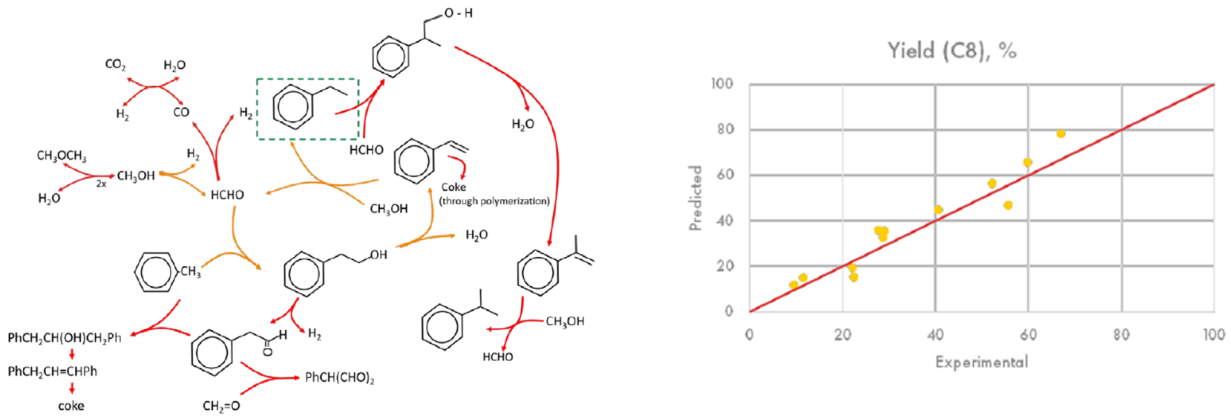

**Figure 1 (a) Derived reaction network showing the formation of all major products (d) Modeling results in form of parity plot showing Styrene+EB ($C_8$) experimental and (model) predicted yield**

- A dedicated experimental study was conducted for deriving the reaction network. The pathways to main products as well as to unwanted products which can be potential showstoppers for this technology, were identified.
- Based on the above study and other experiments, *a fit for purpose power law based kinetic model* was developed. This was used to simulate different process concepts which saved crucial experimental time and resources. The outcome from the model helped to make *crucial decisions* in the technology maturation for this process.

**Keywords:** methanol (MeOH)-to-hydrocarbons (MTH), $^{13}C/^{12}C$ switch, FAst Scanning-Pulse Analysis (FASPA), hydrocarbon pool (HCP) mechanism, isotope labeling

**Introduction.** Monitoring and revealing complex catalytic pathways under industrially relevant conditions is one of the key challenges in catalysis science. As an example, the kinetic study of MeOH transformations into light hydrocarbons is difficult from a purely experimental point of view due to the complex reaction network, dynamic features of active intermediates, and limited spatial and temporal analysis tools to study the ongoing processes within zeolite micropores under operational conditions.

**Experimental/methodology.** The switching sequences $^{13}C$-labeled and unlabeled MeOH pulses over a model H-ZSM-5 catalyst combined with on-line MS analysis and a newly introduced technique called 'fast scanning-pulse GC analysis' (FASPA) are applied to provide a direct and quantitative insight in the MTH reactions under *quasi* steady-state conditions. The product responses were analyzed using Kubin-Kucera model[1, 2].

**Results and discussion.**

**$^{13}C$-/$^{12}C$-MeOH switch pulse experiment procedure (*left*); Comparison of BTX (benzene, toluene, and xylenes) responses in the FASPA test (*bottom, right*) and $C_7$ isotopic compositions in the first $^{12}C$-MeOH pulse after switching from $^{13}C$-MeOH (*top, right*)**

FASPA/switch experiment conditions: injection of either $^{12}C$- or $^{13}C$-MeOH in He, 7.6 μmolC/pulse, T = 400 °C, $m_{cat}$ = 100 mg (H-ZSM-5, Si/Al = 25, 150–212 μm), $P_{reactor}$ = 1 bar, carrier gas He = 20 mLNTP/min, pulse interval = 3.75 min.

This FASPA technique allows (sub-)second resolution of the full temporal products response. Upon a MeOH pulse, a very fast primary product formation in the presence of MeOH in a narrow active MTH reaction zone was first observed (R1 in figure), followed by a slower formation of light aromatics (R2), which is closely related to the decomposition and release of HCP species and secondary reactions in absence of MeOH in the downstream part of the catalyst bed.[3] The following isotopic analysis of typical aliphatic $C_{3+}$ product responses after switching $^{13}C$-MeOH pulses to the unlabeled MeOH pulses showed a fast isotope scrambling in the formation of $C_{3+}$ species. MS analysis of the light aromatics indicates a complete consecutive but slower isotope incorporation process of $^{12}C$ into $^{13}C$-aromatics. Results provide direct experimental confirmation of the kinetically preferred olefin-based cycle over the aromatics-based cycle. The sequential isotopic incorporation strongly suggests that the paring reaction pathway through aromatic ring contraction and re-expansion steps is operative. In the appearance of aromatics upon pulsing MeOH over larger catalyst beds four processes are directly discerned, involving the displacement of adsorbed species by formed water, isotope incorporation yielding directly labelled and unlabeled products through the paring mechanism and direct aromatization, and HCP conversion through secondary reactions.

**Keywords:** ODH of ethane, catalyst development, process development, scale-up, M1 oxide

**Introduction.** Ethylene belongs to the fastest growing chemicals worldwide mainly driven by polyethylene production. Currently, ethylene is manufactured in large-scale, especially in ethane crackers by dehydrogenation in a rather energy demanding endothermic high-temperature process (steam-cracking). Further, acetic acid as another important C2 component is today typically produced by carbonylation of methanol which in turn is produced from natural gas leading to intense CO2 emissions.
Today, the oxidative dehydrogenation of ethane (ODHE) has become a commercially very attractive alternative since the pioneering first investigations by Thorsteinson in the mid 70ties of the last century. In the late 80ties of the last century, Mitsubishi issued a series of ground-breaking patents covering an oxidative dehydrogenation process of ethane utilizing the so-called M1 oxide, which was the starting point for MoVNbTe mixed metal oxides as ODHE catalyst. Since then, many academic and industrial research groups worked on this catalyst material for various alkane oxidation reactions incl. ODHE. But only recently, a collaboration of Linde Engineering and CLARIANT jointly developed an innovative and commercially attractive combination of process, reactor and catalyst design for the ODHE yielding ethylene and acetic acid with very high product selectivities, which is readily available for licensing from Linde (EDHOXTM).

**Results and discussion.** Two main keys to the superior performance are the multi-layer bed with optimized catalyst properties combined with highly advantageous reaction conditions not only ensuring a stable catalyst operation but also allowing a flexible adaption of the ratio between ethylene and the coproduct acetic acid. Next to the higher overall product selectivity, the ODHE is characterized byzero Scope 1 CO2 emissions. moreover, Scope 2 emissions too can be significantly reduced or even avoided. ODHE is therefore an important enabler to achieve the targeted CO2 reductions in the production of very important key chemicals with high market volumes.

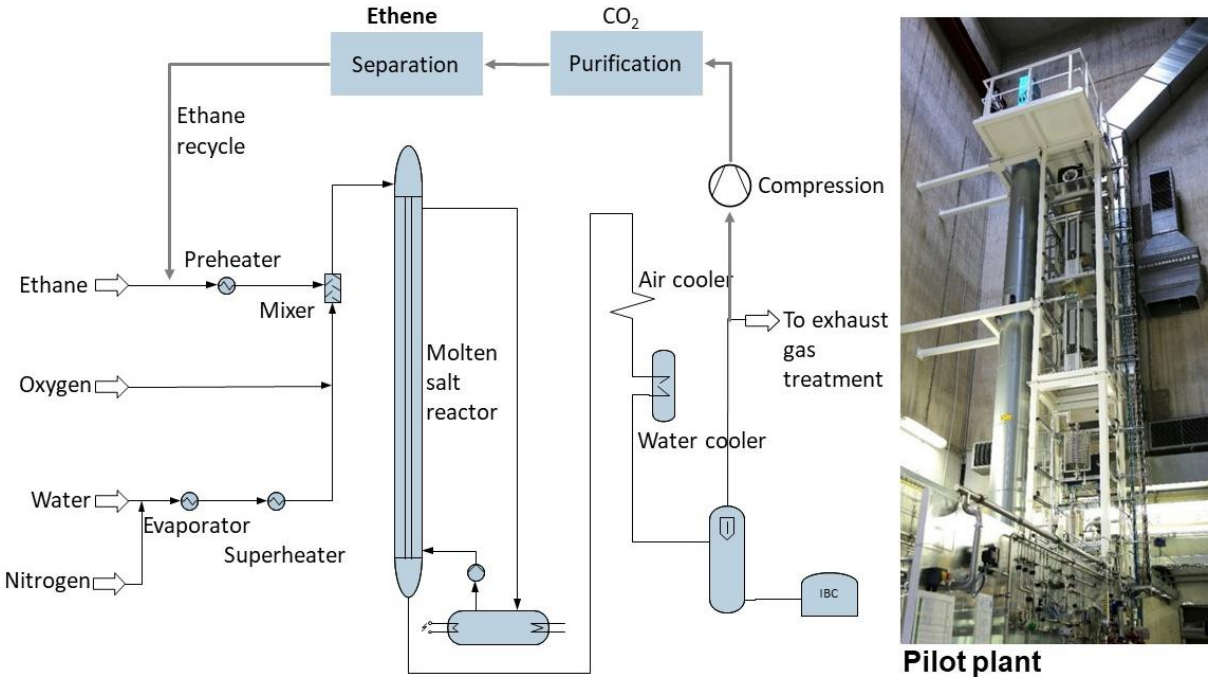

Fig. 1 Scheme of LINDE´s EDHOXTM demo plant

In detail, especially CLARIANT ´sbreakthrough invention of the industrial-scale production of the phase-pure MoVNbTe mixed metal oxide catalyst - exclusively based on cheap, and commercially available raw materials - is an important enabler for the EDHOXTM technology. Eight production unit operations needed to be investigated, scaled-up, and optimized on all equipment scales for guaranteed maximum material yields and minimum raw material losses and waste generation.

Fig. 2 MoVNbTe mixed metal oxide catalyst for the EDHOXTM process

For maximum reactor and process performance, further catalyst properties have been optimized, like the catalyst shape for acceptable pressure drop and optimum filling densities in the saltbath-cooled tube-bundle reactor. In addition, the volume-related catalyst activities were designed such as to achieve the commercially needed one-path ethane conversion levels across the reactor together with the demanded high value-product selectivities to ethylene and acetic acid. It needs to be mentioned here that the ratio between the two value products can be tuned to customer needs by catalyst design and process conditions applied.

Another most important catalyst performance parameter, which had to be tailored, was the required very high oxygen conversion minimizing the remaining oxygen in the reactor effluent still maintaining a minimum concentration required for chemical and mechanical integrity of the catalyst. Further full removal of oxygen can easily be achieved in a separate catalytic downstream step enabling a safe and reliable design of the entire process. All these decisive catalyst parameters for the EDHOXTM process could be successfully developed and proven in a demonstration plant by the joint project team of Linde and CLARIANT researchers.

# Plasma catalytic $N_2$ activation with in-situ product adsorption

Kevin Rouwenhorst, Leon Lefferts*

[1] *Catalytic Processes & Materials, MESA+ Institute for Nanotechnology, University of Twente, P.O. Box 217, 7500 AE Enschede (The Netherlands)*

**Keywords:** plasma catalysis, ammonia, NOx

**Introduction** Although most catalytic conversions studied are thermally activated, alternative excitations methods with photons (photo catalysis) or electrons (electro catalysis) are increasingly importance. A third alternative approach, activation of molecules with electrons in non-thermal plasma, is much less in focus in the catalysis community. However, this approach would enable electrification of the chemical industry, e.g. ammonia and nitric acid production, using processes at mild conditions with operation at flexible scale and with highly flexible load. Besides, non-thermal plasmas excite molecules vibrationally and electronically, without heating all molecules like in thermal activation, which is conceptually very attractive.
This potential has not really materialized at the time, at one hand caused the enormous complexity of physical and chemical effects when combining a non-thermal plasma with a catalytic material [1]. A second reason is that in most cases the energy efficiency is disappointing low because of non-productive relaxation processes in the plasma.
This contribution will show that the presence of catalytic materials in a non-thermal plasma can lead to significant efficiency improvement in plasma catalytic synthesis of $NH_3$ from $N_2$ and $H_2$, as well as plasma-catalytic synthesis of $NO_x$ from $N_2$ and $O_2$.

**Experimental/methodology** All experiments were performed in a quartz tubular reactor with an inner diameter of 4 mm and an outer diameter of 6 mm, at atmospheric pressure. A stainless-steel rod of 1 mm diameter is placed inside the reactor as the high voltage electrode. A metal tube at the outside of the 6mm quartz tube acts as the ground electrode. The temperature was controlled with a thermocouple connected to a heating block around the ground electrode. The product gases were analyzed using an on-line mass spectrometer.

**Results and discussion** Experiments with $H_2/N_2$ mixtures in presence of catalysts revealed that the efficiency of ammonia formation was increased with a factor 2 when using zeolite 4A as a catalyst[2], whereas new data show that the efficiency of formation of $NO_x$ from $N_2/O_2$ mixtures can be improved more than an order of magnitude. The catalyst adsorbs the product ($NH_3$ or $NO_x$) and the improved efficiencies are obtained in cyclic experiments: first product is formed and absorbed in presence of plasma, followed by thermal desorption of the produced molecules, i.e. $NH_3$ or $NO_x$, in absence of plasma. The improved efficiency is assigned to adsorption of product molecules in the internal surface in the porous catalyst particles, protecting them from decomposition in the plasma.

Our results demonstrate that efficiency of plasma-catalytic conversion can be significantly improved by preventing plasma enhanced decomposition of the product. The main function of the catalyst is in fact protective adsorption. The implications of this with respect to selection of catalysts for plasma catalysis will be further discussed, resulting in the conclusion that in general catalysts active for the same reaction with thermal catalysis, are not preferred.

**Introduction.**

Over the last two decades, significant progress has been witnessed towards the consolidation of carbon and nitrogen renewable cycles, disconnected from resources and energy forms of fossil origin. Coupling these independent chemical cycles via the development of versatile catalytic routes for the formation of C-N bonds from unconventional, e.g. $C_1$ and $N_1$ feedstocks, is an attractive strategy towards the sustainable production of nitrogen-containing commodity chemicals. Nitrile synthesis from the direct conversion of ammonia and syngas reaction ($CO+H_2$) mixtures has been reported.[1] However, fundamental knowledge on the true catalyst species and reaction mechanism is required to progress to higher selectivities and catalyst lifetimes. Herein, we present a bimetallic catalyst derived from a crystalline $(NH_4)[Mn_2Mo_2O_8(OH)]$ manganomolybdate precursor which delivers excellent selectivity to acetonitrile (AcCN) alongside remarkable stability. Multi-modal, temperature- and time-resolved characterizations and DFT modelling provide insights into the structure of the catalyst at work and the acetonitrile synthesis mechanism.

**Experimental/methodology**

A series of ex-ammonium metal (Mn, Co, Ni, Cu, Zn) molybdate catalysts were tested in the conversion of $NH_3$:$H_2$:CO mixtures with 2:1:1 (vol) at 3 bar and 723 K. Dynamics in the short- and long-range atomic ordering and near-surface composition of the catalyst during activation and catalysis were studied with T-resolved XANES/EXAFS and HRXRD; and depth-profiling XPS, respectively.

**Results and discussion**

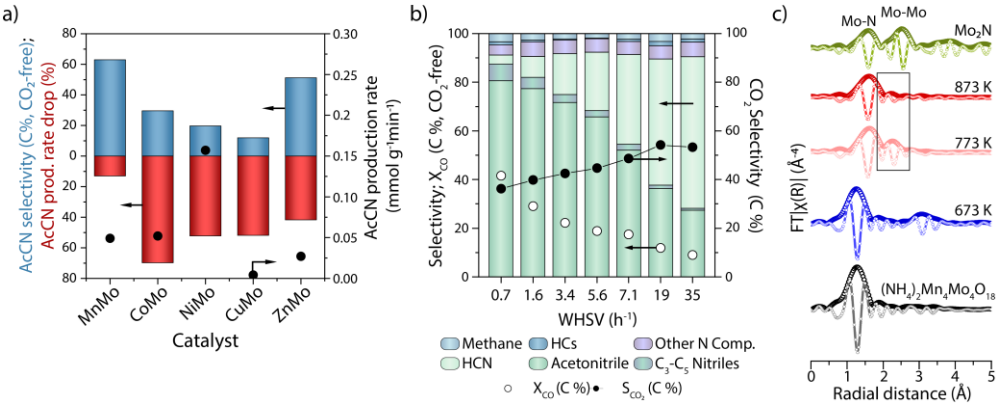

**Figure 1 a) AcCN selectivity, production rate and rate drop (after 3h) with MMo catalysts (M=Mn, Co, Ni, Cu, Zn; $X_{CO}$<18 %); b) Dependence of CO conversion and product selectivity with WHSV for MnMo catalyst; c) T-resolved FT-EXAFS (Mo-K) for the MnMo catalyst precursor exposed to the $NH_3$/syngas atmosphere ($Mo_2N$ as reference).**

Screening of MMo catalysts revealed the superiority of the MnMo bimetallic for a selective and stable production of AcCN (Fig. 1a), achieving a ($CO_2$-free) selectivity to AcCN >80 % at a CO conversion of 42 % (Fig. 1b). T-resolved XRD showed that the MnMo precursor decomposed into $MnMoO_4$ at 723 K under the reaction atmosphere and swiftly took N up to transform into a cubic metal oxynitride within ca. 1 h at reaction conditions. T-resolved EXAFS revealed that Mn inhibits the growth of $MoN_x$ domains (Fig. 1c) which accounts for the superior catalytic performance with respect to a monometallic $Mo_2N$ benchmark. Our work illustrates how multi-technique studies are essential to identify catalysts which develop only once exposed to process conditions, as well as to rationalize and exploit complex bimetallic effects.

# Zeolite-Catalyzed Cracking of Polyethylene in n-Cetane

M. Matsukata*, Eri Miura, M. Sakai, T. Kamo

[1]*Waseda University, Tokyo, Japan*

**Keywords:** Plastics, Chemical Recycling, Zeolite, Decomposition, Polyethylene

**Introduction.**

Currently, ca. 8.2 million tons of waste plastics are discharged annually in Japan, and chemical recycling (CR) is attracting attention as a way to a sustainable society, though the current fraction of chemical recycling has been very low (4%). Due to the mixing of repellent substances in waste plastics, dissolving waste plastics in hydrocarbon solvents and successive separation and removal of repellent substances would improve chemical recycling. The objective of this study was to decompose plastics in hydrocarbon solvent with zeolite catalytically. In this communication, we present our recent results of the decomposition of polyethylene (PE) with Beta zeolite in n-cetane (*n*-C16).

**Experimental.**

Using a 100 cc batch reactor, 5 g of PE (Mw 35,000), 20 g of *n*-C16, and 50 mg of Beta were placed in the reactor. The reactor was heated to 400°C at a hreating rate of 10°C/min, held for 1 h, and then cooled to room temperature. For comparison, we carried out the experiments without use of Beta and/or PE. The conversion of PE was determined from the weight change of solids. Products were analyzed for their composition using GC-FID, GC-GC, distillation GC, and GPC.

**Results and discussion.**

Fig. 1 shows the comparison of yields (wt%) obtained with and without PE. Since *n*-C16 was also decomposed with Beta, to clarify the PE-derived products, the denominator was calculated as the sum of the weight of *n*-C16 and Beta. In the presence of PE, the total yield was 120%. The levels of PE and *n*-C16 conversion were 94.1% and 97.9%, respectively. PE was effectively decomposed with Beta at 400°C, while the PE pyrolysis starting temperature is 439°C. It should be noteworthy that Beta directly decomposed PE. The degradation products are mostly aliphatic with aliphatic/aromatics ratio = 5.27 in the presence of PE. More than 90% of *n*-C16 was decomposed in the presence or absence of PE, and the C5-C9 fraction accounted for 56.9% in the absence of PE.

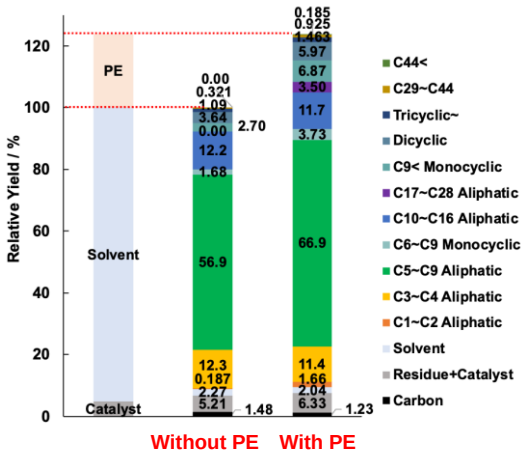

**Fig. 1 Comparison of product yields with and without PE.**

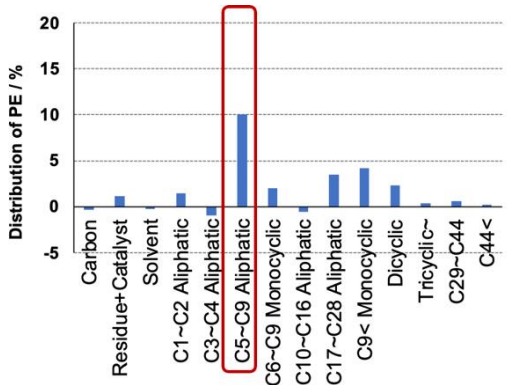

**Fig. 2 Relative distribution of decomposition products from PE.**

Fig. 2 shows the relative yields of PE-derived products extracted from the difference between the results obtained with and without PE. Among PE-derived products, the C5-C9 fraction was the largest at ca. 10%. The decomposition of PE progressed to lower hydrocarbons equivalent to naphtha fractions, even in the presence of solvents. Other products were mainly straight chain C17-C28 (3.50%), monocyclic aromatics (4.16%), and bicyclic aromatics (2.33%). As for the aromatic products, the primary decomposition product of the linear chains would be aromatized and formed.

**Keywords:** selective oxidation, isoparaffin, pure oxide catalyst

**Introduction.** For *t*-Butyl alcohol (TBA) synthesis, one of the industrial processes is the radical oxidation of isobutane under high pressure without a catalyst[1]. This process still has problems of high energy load and low selectivity. As a solution, selective oxidation using Au nanoparticle catalysts at ambient pressure has been reported[2]. In this catalytic reaction, co-existence conditions of $H_2$ and $O_2$ are required to generate reactive oxygen species which are effective for selective oxidation, but there are concerns about the risk of explosion. In our laboratory, we have investigated mild selective oxidation using $H_2O$ instead of $H_2$, and found that mild selective TBA synthesis proceeds under ambient pressure using $Au/Co_3O_4$ and its rate on only $Co_3O_4$ support was faster than that on $Au/Co_3O_4$[3]. The development of this method will lead to economical green conversion of saturated hydrocarbons. In this study, isobutane oxidation experiments were conducted using pure $Co_3O_4$ under various reaction temperature conditions to investigate the mechanism of selective TBA synthesis.

**Experimental/methodology.** Commercial $Co_3O_4$ was used as the catalyst. In oxidation experiments, $H_2O$ (20%) was vaporized and thoroughly mixed with $O_2$ (10%) + isobutane (10%) + $N_2$ gas and fed into a packed bed reactor. The reaction temperature was varied at each experiment in the range of 100-200°C as the operating factor. In the analysis, the concentration of products in the effluent was measured by online GC-FID/TCD to determine the formation rate $r_i$. The selectivity $S_{TBA}$ was calculated based on the total amount of products identified. The adsorbed state of water on the catalyst was evaluated using a temperature programmed desorption with $H_2O$ ($H_2O$-TPD).

**Results and discussion.** Figure 1 shows the effect of reaction temperature on the reaction rate for the target TBA and byproducts $CO_2$. No other products were observed. With increasing temperature up to 140°C, $r_{TBA}$ increased greatly, whereas little $CO_2$ formation was observed. $S_{TBA}$ reached 83% at 130°C. On the other hand, at higher temperatures above 140°C, only $CO_2$ production was observed. On the basis of these results, selective oxidation and complete oxidation are considered to be dramatically switched depending on the reaction temperature. Accordingly, $Co_3O_4$ shows high selective oxidation activity in the specific temperature range, and this is the first report in the world that selective oxidation of hydrocarbons proceeds on pure $Co_3O_4$ without doping any metals.

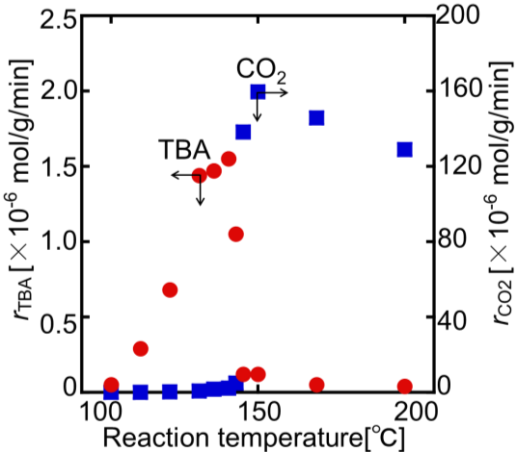

**Fig.1 Effect of reaction temperature on $r_{TBA}$ and $r_{CO2}$ using $Co_3O_4$ catalyst**

Now, we focus on the role of water on the catalyst surface. Figure 2 shows the results of $H_2O$-TPD measurement on $Co_3O_4$, two peaks were observed. Peak 1 on the low-temperature side is due to physisorption, and peak 2 on the high-temperature side is due to chemisorption. Peak 2 has its top at around 140°C. This indicate that chemisorbed water adsorption/desorption has a significant effect on TBA synthesis. In other words, the role of water on the $Co_3O_4$ surface is thought to enable TBA selective synthesis.

# Investigation of Mo-based dispersed catalysts for the upgrading of heavy oils in slurry reactor

F. Papadopoulou[1,2*], A.A. Lappas[1], E. Heracleous[1,2]

[1]*Chemical Process & Energy Resources Institute CPERI/CERTH, Thessaloniki, Greece*
[2]*School of Science & Technology, International Hellenic University, Thessaloniki, Greece*

**Keywords:** Dispersed Catalyst, Mo-octoate, Hydroprocessing, Heavy Oils, Slurry Reactor

**Introduction.** Due to the increasing global demand for energy, the interest in upgrading heavy oils of bio-, waste-, and fossil-origin by means of hydroprocessing has increased [1]. Heavy oils, depending on the feedstock, are characterized by high content of metals, heteroatoms and impurities, as well as low yields of valuable products. Slurry phase hydrocracking processes, employing transition metal-based dispersed catalysts, can successfully upgrade such difficult feedstocks to lower boiling point fuel fractions and overcome the coking and plugging issues often encountered with fixed-bed reactors [1,2]. In particular, Mo-based catalysts proved to be suitable for cracking and hydrogenation and have been studied under different reaction conditions [2]. In this study, we investigate the hydrotreatment of heavy oil in the presence of Mo-based dispersed and conventional solid catalysts in slurry-type reactor.

**Experimental/methodology.** The slurry phase hydrocracking of Vacuum Gas Oil (VGO), selected as model feedstock, was conducted in a stirred semi-batch autoclave reactor at 400 °C under constant $H_2$ pressure (100 bar) for 4 h reaction time. Non-catalytic and catalytic tests were performed with oil-soluble Mo-octoate (15 wt.% Mo) and commercial ex-situ presulfided NiMo-based solid hydrocracking catalyst, at different Mo concentrations (4000 – 12500 wppm Mo). After reaction, the products were separated into gas, liquid, and solid fractions. The gas products were analyzed with GC. The solid was washed with toluene, dried and analyzed (elemental analysis, X-ray diffraction, transmission electron microscopy (TEM)). The liquid product was extensively analyzed (elemental analysis, density, SimDis etc.) to determine the produced fuel properties.

**Results and discussion.** Figure 1a shows the hydrodesulfurization degree achieved in thermal and catalytic tests with liquid and solid Mo-catalysts at similar Mo concentration. The liquid dispersed catalyst reduces sulfur by ~ 50%, while the conventional solid catalyst achieves higher HDS degree (~ 90%). In terms of hydrocracking, the residue, diesel, and gasoline fractions are similar in all cases (Figure 1b), suggesting that cracking mainly occurs thermally in agreement with literature [2]. In the catalytic tests, high organic oil yields are measured (in the range of ~ 85 wt.%), with no significant difference between tests with solid and liquid Mo-based catalyst. Finally, analysis of the solid product from the tests with liquid Mo-catalyst evidenced the formation of $MoS_2$ nanoparticles, responsible for the hydrosulfurization activity of the dispersed catalyst.

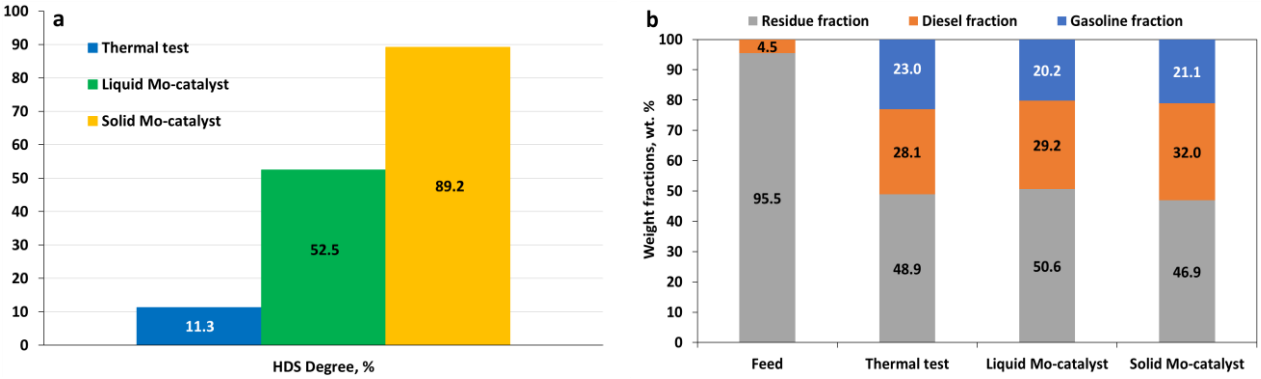

**Figure 1. Effect of catalyst on (a) Hydrosulfurization degree (b) Hydrocracking degree**

# Overcoming the performance limits of commercial benzyltoluene as liquid organic hydrogen carrier by tuning the isomer composition

T.W. Kim[1], Y. Jo[1], Young-Woong Suh[1*]

[1]*Department of Chemical Engineering, Hanyang University, Seoul 04763, Republic of Korea*
[*]*E-mail: ywsuh@hanyang.ac.kr*

**Keywords:** liquid organic hydrogen carrier; benzyltoluene; regioisomer; hydrogenation; dehydrogenation

**Introduction.** The state-of-the-art liquid organic hydrogen carrier (LOHC) molecules, benzyltoluene ($H_0$-BT) and dibenzyltoluene ($H_0$-DBT) are available in the market as heat transfer fluids and dielectric media, which are commercially produced in the same process by Friedel–Crafts alkylation of benzyl chloride and toluene over Lewis acids (typically, $FeCl_3$) [1]. This homogeneous catalysis process affords isomeric mixtures of $H_0$-BT (three regioisomers with *ortho*, *meta*, and *para* linkages [2]) and $H_0$-DBT (at least eight isomers [3]). Leinweber and Müller reported the different hydrogenation kinetics of *ortho*- and *para*-dominated $H_0$-BT mixtures [2]. We also found that the isomers of commercial $H_0$-BT exhibit different hydrogenation rates [4]. This suggests that the isomer structure of $H_0$-BT can affect its conversion efficiency. Moreover, as each isomer of $H_0$-(D)BT is not readily available in pure form, one cannot address the effect of the isomer composition on the (de)hydrogenation performance of the isomeric mixtures.

**Results and discussion.** The study outlines a straightforward strategy to improve the LOHC performance of commercial Marlotherm LH (MLH) [5]. The process started with the synthesis of three $H_0$-BT regioisomers *via* Friedel–Crafts alkylation of methylbenzyl chloride with benzene, where the dechlorination step is of great importance to obtain a high-purity product. Next, the $H_2$ storage and release tests demonstrated the superior LOHC performance of the *para* isomer compared to the other isomers. The importance of the *para* isomer was further confirmed using binary and ternary $H_0$-/$H_{12}$-BT physical isomer mixtures. Therefore, increasing the fraction of *para* isomer in $H_0$-BT is the key strategy for improving the LOHC performance. We attempted to meet this requirement by carrying out a one-pot synthesis from benzyl chloride and toluene. Under optimized synthesis conditions, the H-Beta zeolite ($SiO_2/Al_2O_3$ = 25) afforded the $H_0$-BT-*p*72 product with a 72% fraction of *para* isomer. This product exhibited superior performance in both hydrogenation and dehydrogenation reactions compared to the MLH-simulated mixture having identical isomer composition to MLH. However, unexpected problems emerged during cycling tests; methylfluorene (MF), formed as dehydrogenation byproduct, significantly reduced the rate of the subsequent hydrogenation. This detrimental issue was overcome by using a Pt–S/$Al_2O_3$ catalyst, which reduced the fraction of MF to 3%. By adjusting the reaction conditions for $H_2$ storage over Ru/$Al_2O_3$ and $H_2$ release over Pt–S/$Al_2O_3$, at least 10 interconversions between $H_0$-BT-*p*72 and $H_{12}$-BT-*p*72 could be performed continuously at the $H_2$ storage density level of 6 wt%. Finally, a cost analysis taking into account the material costs along with the LOHC performances demonstrated that $H_0$-BT-*p*72 is a more suitable option than MLH and *para*-$H_0$-BT. Therefore, the sequence of investigations discussed above suggests that it may be worth performing further tests on $H_0$-BT-*p*72 in future process development studies.

**Introduction**

While pure binary bismuth molybdates can perform selective propene oxidation to form acrolein, industrial acrolein catalysts with far higher (factor of > 20) activity are multicomponent molybdate (MCM) system containing at least three promoter elements, namely Fe, Co, and K. Omitting any of them drastically reduces the performance. Here, we reveal the structure of the MCM catalyst and provide mechanistic explanation about how complex structural features are linked to the performance [1].

**Experimental/methodology**

MCM catalysts with various compositions were prepared via coprecipitation, drying and calcination. Kinetic behavior in propene oxidation was studied in conjunction with structural analysis employing STEM-EDX, XRD, XAS (at Mo, Bi, Fe, and Co edges), XPS, UV-vis, Raman, $NH_3$-TPD, Propene-TPR, Pyridine-IR, Hg-porosimetry and $N_2$-physisorption.

**Results and discussion**

High performance catalyst $Bi_{0.6}Mo_{12}Co_7Fe_3K_{0.1}O_x$, which features a low Bi content compared to binary bismuth molybdates, consists of mixed aggregates of cobalt molybdates, iron molybdate and bismuth molybdate particles (Fig. A). STEM-EDX analysis showed the presence of highly dispersed Bi species besides the bulk α-$Bi_2Mo_3O_{12}$ particles (Fig. B, C). To study the relevance of the highly dispersed surface Bi species, we prepared a catalyst by impregnation of Bi on a Bi-free analog $Mo_{12}Co_7Fe_3K_{0.08}Si_{1.6}O_x$. The Bi-free support material showed low conversion even at temperature of 350°C, whereas the catalyst impregnated with Bi showed the same activity as the reference though it contained 90% less Bi (Fig. D). The result strongly indicates that the highly dispersed surface Bi species formed the relevant BiMoO sites, and in turn, suggests minor role of α-$Bi_2Mo_3O_{12}$ which did not exist in the impregnated sample.
In the presentation, detailed structure-performance relationships regarding the roles of molybdate phases, ion vacancies, and K-promoter will be discussed.

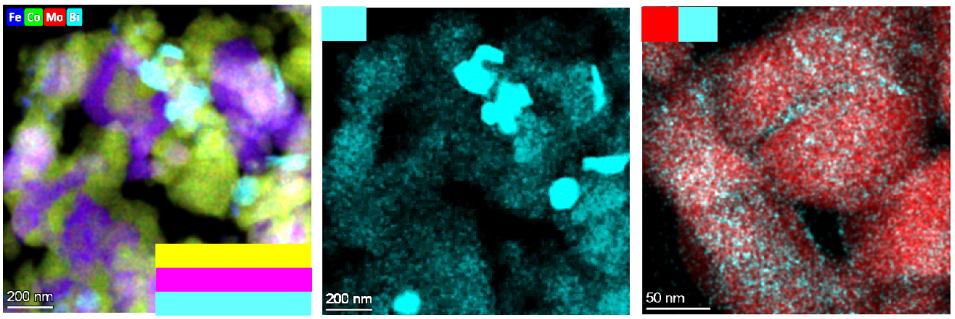

**Fig. Analysis and propene oxidation performance of Bi-Mo-Co-Fe-K-O catalysts. (A-C)** STEM-EDX images of $Bi_{0.6}Mo_{12}Co_7Fe_3K_{0.1}O_x$. **(D)** Propene oxidation performance of reference catalyst $Bi_{0.6}Mo_{12}Co_7Fe_3K_{0.08}Si_{1.6}O_x$ (ref. # Improved heterogeneous Brønsted acid catalysts for cyclic acetal synthesis

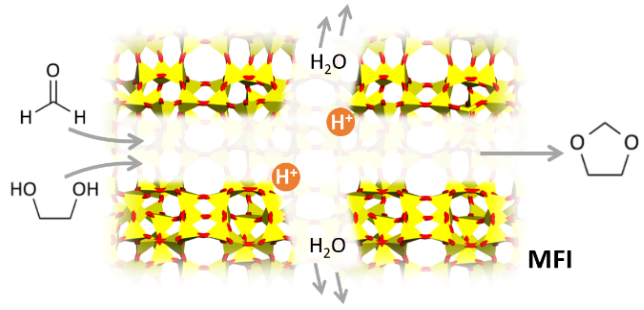
M. Houbrechts[1*], W. Stuyck[1], D. De Vos[1]



[1]*cMACS, Katholieke Universiteit Leuven, Leuven, Belgium*
[*]*margot.houbrechts@kuleuven.be*

**Keywords:** Cyclic acetals, Heterogeneous catalysis, Recyclable polymers, Dean-Stark apparatus, Acid zeolite

**Introduction.**
In recent years, cyclic acetals have been receiving increasing attention as a result of different benefits they can provide. For instance, 1,3-dioxolane (DXL), can be used as a green solvent and as an alternative to more hazardous solvents like THF. In addition, DXL and larger acetals have the potential to be used as monomer for chemically recyclable polymers or as co-monomer in engineering plastics.[1,2] Their performance and use are similar to those of polyolefins, but with the invaluable asset of recyclablility through ring closing depolymerization back to their monomers. Currently, DXL is produced from ethylene glycol using paraformaldehyde or a concentrated solution of aqueous formaldehyde using homogeneous Brønsted acids (e.g., $H_2SO_4$) or acid resins.[3] We propose that their production can be significantly improved by the use of acid zeolites; the hydrophobic properties can expel the generated water from the active sites while their shape selective properties can steer the reaction selectively to the cyclic acetals instead of undesired oligomer byproducts.[4] In addition, these heterogeneous catalysts ensure easy catalyst recovery. In this work we present the acid catalyzed syntesis of cyclic acetals starting from a diol and aqueous formaldehyde, both abundant and cheap building blocks which can be obtained from renewable resources.

**Experimental/methodology.**
For the production of 1,3-dioxepane (DXP) from 1,4-butanediol and $HCHO_{aq}$, a Dean-Stark reaction setup was used. For the synthesis of DXL, a water-DXL azeotrope was collected at the top of a distillation.

**Results and discussion.**
Several commercial zeolites show promising activity towards the conversion of diols and formaldehyde to acetals. For the formation of 1,3-dioxepane (DXP), 12-MR zeolites performed best with a monomer yield of 14% for H-**β** after just 1 hour. This shows a clear increase in monomer yield compared to the commercial Amberlyst-15 acid resin (8% monomer yield). DXL formation is best catalyzed by the 10-MR ZSM-5 zeolite; larger pore zeolites give rise to the formation of larger side products such as 1,3-trioxepane. The optimal Si/Al ratio lies around 25; lower Si/Al ratio renders the zeolite less hydrophobic while at higher ratios the number of Brønsted acid sites decreases. During the recycling test, no significant loss in activity or selectivity was measured.

**Introduction.**

Plasma-induced catalysis is an exciting new possibility for producing chemicals at significantly milder conditions than traditional thermal catalysis [1]. As a model reaction, the synthesis of ammonia is typically chosen. Ammonia is an important bulk chemical, representing some 2% of the world energy consumption, mainly fossil fuel-based, and the synthesis is strongly limited by chemical equilibrium [2]. The catalysts traditionally used in ammonia synthesis are iron-based, but also ruthenium has been found to be very active in the reaction. The cost of the precious metal is, however, prohibiting [3]. The plasma synthesis requires slightly different catalyst material, with Ru, Rh, Co and Ni being more active than iron [4]. Based on the reversibility of the plasma reaction, it has been shown that when ammonia is shielded from additional plasma inside a catalyst support structure, the overall ammonia yield increases [1]. However, since the catalyst support adsorption capacity of the ammonia is limited, there is a need for an optimized ammonia adsorbent to shield the product. The ammonia adsorbent should preferably have:

- A high adsorption capacity for ammonia
- A distinct desorption temperature to allow for a controlled release of the ammonia
- A low desorption temperature to avoid too high a temperature that may damage the catalyst

**Experimental/methodology.**

A number of different adsorbents from the zeolite range are screened for their static adsorption capacity at different temperatures, including room temperature and above the desorption temperature. The static, isothermal adsorption capacity is measured using ammonia in 50 points, ranging from 0.01 mmHg to 500 mmHg. The analysis is performed in a Micromeritics 3-flex unit, and by doing multiple analyses, the chemisorption and physisorption can be separated. The desorption temperature is determined using temperature-programmed ammonia desorption on the same machine. The zeolites are chosen with different pore structures and Si/Al ratios to tune the adsorption capacities.

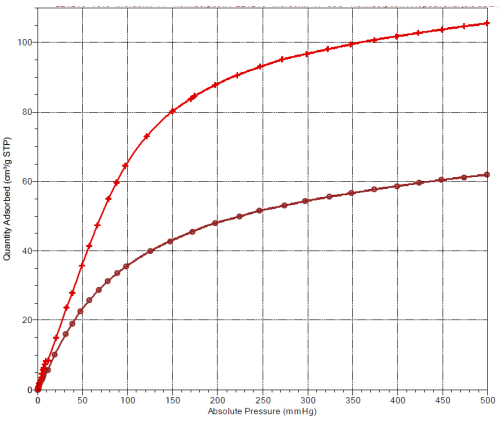

Fig. SEQ Figure * ARABIC 1. Adsorption isotherm

**Results and discussion.**

Multiple adsorbents have been screened, and the overall adsorption capacity ranges from 0.29-0.76 mmol of ammonia per gram of adsorbent. The more acidic materials typically have wider desorption peaks and thus require higher regeneration temperatures. To avoid broad desorption peaks, an adsorbent with mainly physisorption functionality is preferred.

**Keywords:** double metal cyanide, hydrothermal treatment, polyether, polycarbonate, polyols

**Introduction.** A series of Zn-Co double metal cyanide (DMC) catalysts have been prepared in the present of various polymeric templates using hydrothermal treatment method. Their activities were evaluated via ring-opening polymerization of epoxides and copolymerization of epoxides and $CO_2$, which are among the most important processes of DMC catalysis [1-3]. The influence of catalyst preparation parameters such as pH and time of the hydrothermal treatment on the catalytic activity were also investigated.

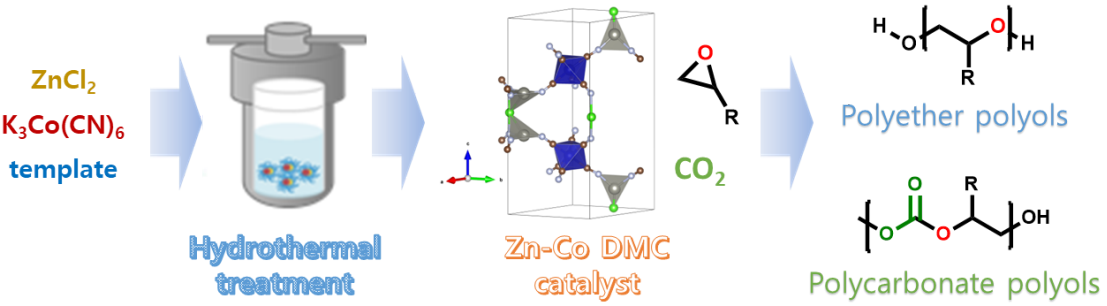

Figure 1. Illustration of the hydrothermal synthesis of DMC catalysts.

**Experimental/methodology.** Double metal cyanide catalysts were synthesized by hydrothermal treatment using different polymer templates. The chemical structure of the resultant heterogeneous catalysts are characterized by infrared and X-ray photoelectron spectroscopies while their compositions were quantitated by elemental analysis. The catalyst morphology was investigated by X-ray powder diffraction and scanning electronic microscopy. The conversion and carbonate content of the resultant polyols were determined by nuclear magnetic resonance. The thermal properties of the produced polyols were also investigated by differential scanning calorimetry and thermogravimetric analysis.

**Results and discussion.** The as-prepared DMC catalysts showed relatively high activities for both ring-opening polymerization and copolymerization of propylene oxide and $CO_2$, producing polyether polyols of very low unsaturation level and narrow dispersity, and polycarbonate polyols with high yield and reasonable carboante content. The polycarbonate properties were also monitored under various conditions such as initial $CO_2$ pressure, reaction temperature, and amount of initiator.

Table 1. Results for the PO/$CO_2$ copolymerization acquired by DMC catalysts

**Keywords:** medium-temperature shift, hydrogen, carbon dioxide, membrane contactor

**Introduction.** There are lots of hydrogen production technologies under research such as steam methane reforming, dry reforming and electrolysis etc. Among these technologies, water-gas shift reaction is one of the most feasible one for hydrogen production. The catalyst categorizes into two types depending on working temperature as low-temperature shift and high-temperature shift. Usually each catalyst is packed in two different reactor with heat exchanger resulting in the complexity of process. Thus, the catalyst working in medium temperature was studied in this work. Furthermore, $CO_2$ is inevitably generated from catalytic reaction. This should be removed from stream, therefore, membrane contactor has studied.

**Experimental/methodology.** Medium-temperature shift catalyst was prepared in precipitation method. In conventional precipitation(CP), metal ions($Cu^{2+}$, $Zn^{2+}$ and $Al^{3+}$) were precipitated together. After ageing, filter cake was washed and calcined. Before testing performance, catalyst was reduced in reactor. In sequential precipitation(SP), $Cu^{2+}$ and $Zn^{2+}$ were precipitated at first and $Al^{3+}$ was added after 1 h. In order to remove $CO_2$ in the mixed gas, membrane contactor module was used. In one-side, gas was passed through membrane and deionized water passed through other side. After membrane module, mixture gas was analyzed by gas chromatography and $CO_2$ removal was calculated.

**Results and discussion.** SP-CZA was shown better performance compared to CP one. CO conversion of SP-CZA is above 90% from 250 to 450 °C which is known as medium temperature range of WGS reaction. SP catalyst displayed more crystalline structure as zincian malachite than conventional catalyst. Furthermore BET surface area of SP-CZA (44 $m^2/g$) is larger than CP oxide (33 $m^2/g$). In $CO_2$ separation, membrane contactor was tested by using $H_2$, $N_2$, $CO_2$ mixture gas. When injecting more gas in module, contact time between gas and liquid decreases resulting that $CO_2$ is less removed. Furthermore, in high pressure, $CO_2$ solubility in water is linearly increased based on Henry's law.

**Effect of Gas flowrate and Pressure**

- As increasing gas flowrate, less $CO_2$ and $H_2$ removed. (More $H_2$ was recovered)
  → Flowing gas through porous membrane, two gases were not reached to gas and liquid equilibrium.
- As increasing pressure, more $CO_2$ was removed and less $H_2$ was recovered.
  → Gas solubility can be increased by Henry's law.
  → Depending on solubility property, gas are solved into water through porous membrane.

Experimental condition
Gas concentration: $H_2$ 43.6%, $N_2$ 12.8%, $CO_2$ 43.6%, Gas flowrate: 5.5–16.5 L/min, Liquid flowrate: 3 L/min,
Pressure: 4.5–8.0 barg, Δ Pressure between gas and liquid: 1.5 bar

# Effect of the vanadia structure on the kinetics of methanol oxidative dehydrogenation

G. Galdames[1*], C. Fuenzalida[1], C. Lillo[1], P. Santander[1], R. Jimenez[1], A. Karelovic[1*]

[1]*Carbon and Catalysis Laboratory (CarboCat), Universidad de Concepción, Concepción, Chile*
[*]*ggaldames@udec.cl, akarelovic@udec.cl*

**Keywords:** Kinetic modeling, methanol, partial oxidation, redox catalysis, acid catalysis.

**Introduction.** Methanol oxidative dehydrogenation (ODH) products: formaldehyde (FA), methyl formate (MF) and dimethoxymethane (DMM) are interesting as chemical intermediates. This ODH reaction follows a Mars-van Krevelen redox cycle, with the dehydrogenation of a methanol molecule to form adsorbed FA as the rate-determining step (RDS)[1]. It has been suggested that the reaction requires acid sites for the dehydration reactions besides the redox sites for the dehydrogenation reactions [2]. However, there is still lack of clarity on the effect of the physicochemical or structural properties of the catalyst on the reaction kinetics [2,3]. In this work, kinetic models for the formation of the main reaction products are developed for $V_2O5/TiO_2$ catalysts, to understand the effect of the vanadia surface density on the kinetic parameters.

**Experimental/methodology.** $V_2O_5/TiO_2$ catalysts were prepared by wet impregnation varying the vanadia surface density (0.5 to 25 V/nm$^2$). The catalysts were characterized by XRD and Raman. The reaction was carried out in a packed bed reactor, evaporating $CH_3OH$ into flowing $N_2$ and air, varying the temperature, residence time and partial pressure of reactants. The effect of water addition to the reactor feed was also studied. The products were detected by gas chromatography. The integral form of the rate equations were solved modeling a 1-D pseudo-homogeneous reactor.

**Results and discussion.** Based on the mechanism proposed by Iglesia et al. [2], the kinetic models shown on figure 1.a were developed and fitted for the net formation of FA, MF and DMM, on 2.5 and 15 V/nm$^2$. A parity plot and an example of experimental vs simulated data are shown in figure 1.b and 1.c, respectively.

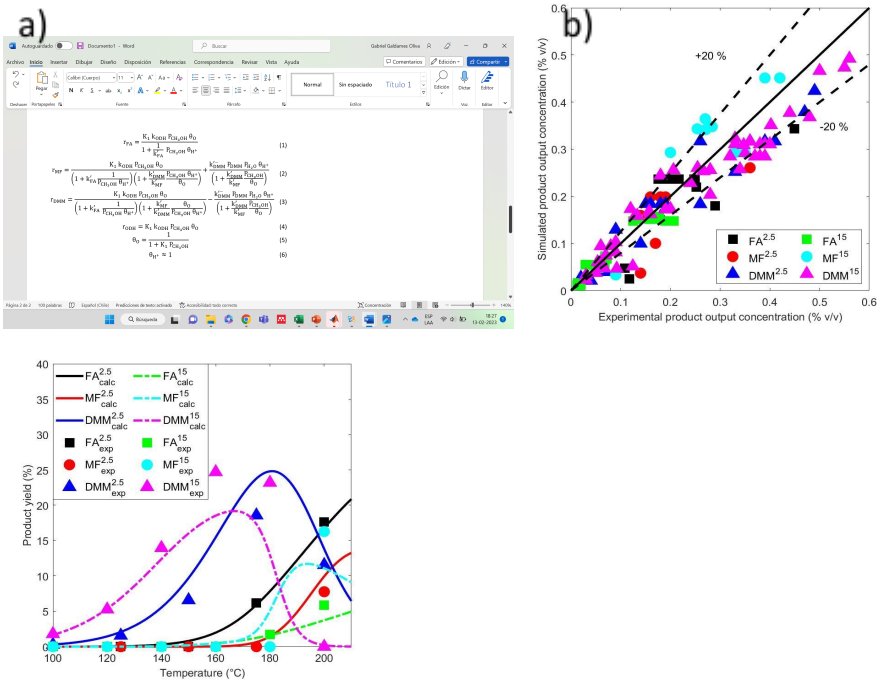

**Figura 1. a) Kinetic models for the formation of ODH products, b) Parity plot for measured and predicted FA (squares), MF (circles) and DMM (triangles) concentration in the product stream and c) Simulated vs experimental FA (squares), MF (circles) and DMM (triangles) yields (GHSV = 20 L/(h gcat), $CH_3OH/O_2/N_2$ = 4/4/92% v/v)**

The $K_1k_{ODH}$ apparent activation energy is similar for both catalysts (-8 and -7 kJ/mol). The difference of activity its attributed to the higher enthalpy of $CH_3OH$ adsorption at 15 V/nm$^2$ (-103 kJ/mol) compared to 2.5 V/nm$^2$ (-82 kJ/mol): 15 V/nm$^2$ has a stronger interaction with the redox sites, attributed to the different

type of lattice oxygen atoms in the multilayer crystalline VOx domains observed at surface densities larger than 8 V/nm$^2$, by XRD and Raman. The model adequately simulates the reaction, with mean errors around the 20% (Figure 1.b) and accurately predicts the trends of product yield at the studied reaction conditions, with DMM as the main product at lower temperatures and higher FA and MF yield as the temperature rises (Figure 1.c). At higher temperatures, the total oxidation of $CH_3OH$ leads to CO and $CO_2$ as the main products.

# Green hydroxylation and ketonization of polyethylene using titanosilicate catalysts

R. Lemmens[1*], J. Vercammen[1], D. De Vos[1]

[1] *cMACS, KU Leuven, Belgium*
[*] *robin.lemmens1@kuleuven.be*

Although polyethylene (PE) is the most common plastic in the world, its applications are limited by the lack of functional groups. The introduction of hydroxyl and carbonyl groups through a post-polymerization C-H bond oxidation step can impart desirable properties, such as paintability and adhesion. Provided that the level of functionalization is sufficiently low, the favorable properties of the virgin PE (*e.g.,* mechanical strength) are perfectly retained, thus rendering the functionalized polymer potentially more valuable [1,2].

Recently, the research group of John F. Hartwig reported an efficient catalytic system for the oxidation of PE, nicely showing the improved applicability of the functionalized polymer, while retaining the beneficial properties of the virgin PE. However, a homogeneous ruthenium catalyst with a perfluorinated porphyrin ligand are employed, along with an atom-inefficient oxidant, in a chlorinated solvent [1].

In this work, PE oxidation was attempted with environmentally benign peroxides, using titanosilicate catalysts in a non-chlorinated solvent. Although titanosilicates are mostly known for epoxidation, also the oxidation of alkanes, yielding alcohols and ketones, has been known for decades [3,4]. For this conversion, an oxygen rebound mechanism (see figure) was hypothesized, involving a rapid recombination between the formed alkyl radical, and the peroxide molecule activated by a Ti-center, yielding an alcohol (a). In the following step (b), the alcohol can similarly be converted into a ketone. Owing to the rapid transfer step, no radicals are set free, thereby providing a highly selective route towards secondary alcohols and ketones [3].

Since the interaction of a polymer with Ti-centers inside a microporous framework represents a challenging task, this research focused on titanosilicates with large external surface areas, to render a large fraction of the Ti-centers accessible for the polymer [5,6]. First, various titanosilicates were screened in the oxidation of alkanes, to optimize the reaction conditions in terms of yield and selectivity. The optimal conditions were then applied in the oxidation of LDPE, MDPE and HDPE. For each type of PE, at least 2 % functionalization (1 C=O group per 50 C atoms) could obtained, with peroxide efficiencies up to 25 %. It was shown that the crystallinity of the virgin PE is retained in the functionalized PE, while thermal stability is slightly increased.

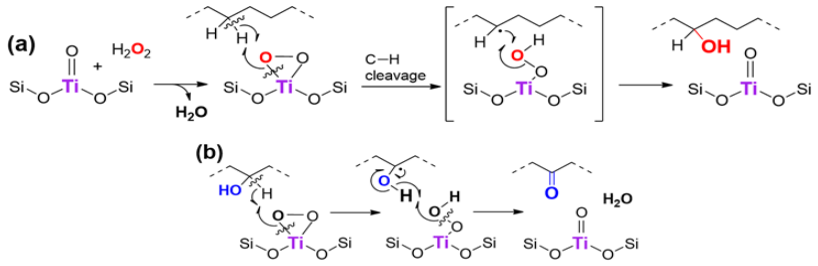

**Figure: Oxygen rebound mechanism for the oxidation of C-H bonds employing $H_2O_2$ and a titanosilicate catalyst.**

**Keywords:** Plastic Recycling, Propylene Production, Cross-Metathesis Reaction, Tungsten Oxide, Catalysis.

**Introduction.**

Plastic waste, instead of traditional landfill and incineration can be converted to valuable chemicals and fuels. Pyrolysis is a promising method for converting plastic waste to value-added products and has advantages, such as simple operation and low-cost technology, enabling the processing of a wide range of feedstocks. Pyrolysis is a thermal decomposition method at high temperatures (300-1000°C) in an inert atmosphere. The three main products of pyrolysis are: solids (char), liquids (pyrolysis oil) and gases (non-condensable gases, NCGs). NCGs mainly contain light olefins such as ethylene, propylene, and butenes. Propylene is a major commodity chemical playing a leading role in the market. However, the disparity between supply and demand created the so-called propylene gap, which highlights the necessity for on-purpose propylene production[1, 2]. The propylene gap in Europe has been estimated at 347 kt in 2021. Consequently, this work aims at valorizing the NCGs, produced via plastic waste pyrolysis, through the cross-metathesis reaction of butenes and ethylene to propylene.

**Experimental/methodology.**

A thermodynamic analysis was performed using Aspen Plus® V9 software. Catalyst synthesis: x-$WO_3$ catalysts were synthesized via the wet impregnation method (x=10, 15, 20, and 25 wt%) on Al-MCM-41. The samples were calcined at 600°C under airflow for 4 hours, labeled as "x-$WO_3$-Al-MCM-41". Catalytic tests: A parametric study was performed in a fixed bed reactor at $P_{tot}$=1 bar, investigating the effect of temperature (450-600°C), $W_{Cat}/F^0$(1.3-5.3 $kg_{Cat}\cdot s\cdot mol^{-1}$), ethylene/1-butene molar ratio (0-4.5).

**Results and discussion.**

To maximize the propylene yield, the optimum cross-metathesis reaction conditions were determined, based on thermodynamic calculations. Pressure and ethylene/1-butene feed ratio showed minimal to no effect on propylene yield, whereas a peak maximum was shown in the case of temperature at 540°C. The support Al-MCM-41 is active, converting 1-butene up to 90%; nevertheless, the selectivity towards propylene was very low, with major products being 2-butene and isobutylene, suggesting isomerization activity. The addition of $WO_3$ further improved the catalytic activity and selectivity towards propylene. The best candidate, 20%$WO_3$-Al-MCM-41 reached propylene selectivity of 32% at a conversion of 88% and 8% for 1-butene and ethylene, respectively, during the metathesis reaction at 550°C, $P_{tot}$ =1bar, $W_{Cat}/F^0$=2.6 $kg_{Cat}.s.mol^{-1}$ and ethylene/1-butene ratio = 4.5. Furthermore, results over the latter catalyst highlighted that after 4 hours of reaction, there was no evidence of catalyst decay. Oxygen temperature programmed oxidation of the used catalyst revealed coke deposition equal to 0.37 wt% ($C_{deposited}$/ $g_{Cat}$ %).

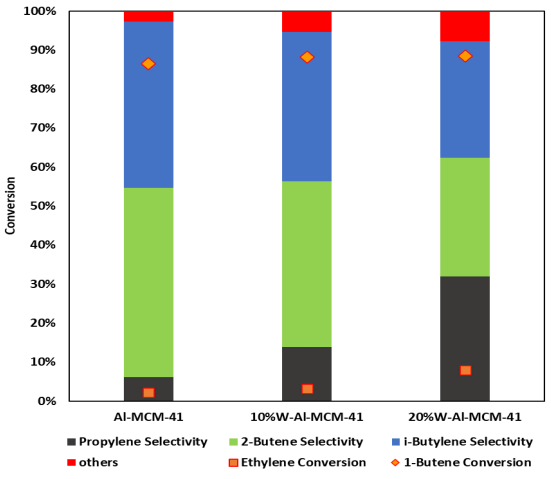

Fig1: 1-Butene, Ethylene conversion and product selectivity, during metathesis at 550°C, $W_{Cat}/F^0$=2.6$kg_{Cat}$.s.$mol^{-1}$, C2$^=$/1-C4$^=$=4.5.

**Keywords:** Recycling, alcoholysis, chemical recycling, catalysis

**Introduction.**

Poly(ethylene terephthalate) is one of the most widely used polymers worldwide. Its annual production have reached over 50 MT in 2016 and it is estimated that 32 MT of PET waste was generated in 2015 worldwide [1,2]. Despite of increased regulatory pressure aimed at increasing recycling of waste plastics most of produced PET waste remains unrecycled or it is used for energy generation. Chemical recycling of PET is usually carried out via hydrolysis or glycolysis of waste polymer to obtain terephthalic acid or PET oligomers which can be used in further synthesis of PET. PET alcoholysis with 2-EH is a process that is not widely described in scientific literature although reaction using organotin catalyst has been known using organotin catalyst [3], zinc and titanium compounds in the presence of ionic liquids [4].

**Experimental/methodology.** The text should be 11-point Calibri.

Catalyst screening tests were conducted in glass reactor equipped with a temperature control system, a mechanical stirrer, an azeotropic cap and a reflux condenser. The azeotropic cap was filled with about 75% distilled water, and the rest was supplemented with 2ethylhexanol (2-EH). The presence of water allows for the effective removal of ethylene glycol (EG) formed as a result of the reaction and separation and the return of 2-ethylhexanol. Post-reaction mixture was purified by washing to remove catalyst and ~~by~~ obtained crude product was distilled in reduced pressure to remove excess of alcohol. Product obtained this way was used as a PVC plasticizer. Another sample was additionally purified by further distillation in reduced pressure to obtain clear TFDO free of pigments that were present in undistilled product. Plasticization properties of obtained samples were tested using standard PVC mixtures.

**Results and discussion.**

Tests were performed using two application samples obtained from depolymerization of waste PET and results were compared commercially available *bis*(2-ethylhexyl terephthalate). All of tested samples had similar hardness and only sample obtained using colour TFDO showed only slightly higher density. Tensile strength and elongation were at similar levels with compared to sample containing pigments and higher boiling byproducts and exhibiting slightly higher plasticizing properties regarding elongation at break. This might be caused by the presence of PET oligomers in undistilled plasticizer. Sample obtained with the use of unpurified plasticizer also exhibits noticeably lower plasticizer migration which can also be attributed to the presence of PET oligomers which did not undergo full depolymerization and therefore are less prone to migration from the PVC mixture. The obtained results show that plasticizers synthesized with the use of waste PET are characterized by good plasticizing properties.

**Introduction.**

Poly(lactic acid) (PLA) is one of the most prominent biobased and biodegradable polyesters (PEs). PLA is currently made by ring-opening polymerization of lactide (LD), which is industrially made by backbiting depolymerization of polycondensed lactic acid (LA), a time- and energy intensive process. Novel routes to LD have been reported recently.[1] For one, our lab developed a shape-selective zeolite-based catalytic process, enabling the one-step conversion of LA to LD in high yield and preserving the stereochemistry of LA.[2,3] While PLA is widely studied, research on its sulfur containing analog, poly(thiolactic acid) (PTLA), is only just starting. Polythiolesters (PTEs), such as PTLA, are known to often show enhanced thermal, mechanical, electrochemical, and optical properties compared to PEs. Moreover, they regularly show enhanced depolymerizability (e.g. chemical recycling, alkaline hydrolysis, photolysis)[4]. Despite these promising features, no industrial syntheses currently exist. One possible reason is the limited amount of efficient and sustainable synthesis methods for thiodilactones. Synthesis routes toward thiolactide (TLD), the sulfur analog of LD, directly from TLA have only been published very recently (2021).[5,6] However, these methods use coupling agents in stoichiometric or excessive amounts, reducing atom efficiency and resulting in waste products. In addition, the reactions are stoichiometric or homogeneously catalyzed and some very toxic compounds are used and formed. Here, we describe a novel one-step synthesis route to TLD from TLA in high yields and in the absence of toxic sacrificial reagents by Brønsted acid catalysis.

**Experimental/methodology.**

In a typical reaction 0.5 g of TLA is added to a 10 mL round bottom flask, together with 0.2825 mmol $H^+$ (i.e. zeolite, ion exchange resin or p-toluenesulfonic acid (p-TSA)). 5 mL of solvent is added (toluene or o-xylene) and the mixture is heated till reflux for 24-72h. A Dean-Stark trap, filled with the same solvent, is used to remove water. The crude reaction mixture is analyzed by $^1$H-NMR (400 MHz, dmso-d6), HPLC, and chiral GC.[7]

**Results and discussion.**

A novel synthesis route to TLD by the direct condensation of TLA with Brønsted acid catalysts in the absence of sacrificial reagents is presented. Homogeneous sulfonic acids, such as p-TSA, proved to be very effective and an excellent TLD yield of 80% and a volumetric productivity of 11.2 $g_{TLD}$ $L^{-1}$ $h^{-1}$ were obtained (mesitylene, 24 h).[7] In addition, this method improved the atom economy ((molar mass of desired product/molar masses of reactants)*100) of the other reactions in literature with 63-88% and reduced the ecology factor (mass of total waste/mass of product) by 66-97%. However, heterogenizing the catalytic system for this reaction was challenging. Sulfonic acid containing ion-exchange resins afforded a maximum TLD yield of 39%. Even though proven to be very successful in the synthesis of LD from LA, an even lower yield was obtained with Brønsted acid beta zeolites (up to 28%). Reasons for these differences were investigated. First, TLA showed a lower tendency toward (poly)condensation than LA, reducing the need for shape-selective catalysis. Second, very strong interactions of TLA, compared to LA, with the zeolite were seen by FT-IR (Fourier-Transform Infrared) and hypothesized to counteract catalytic activity and induce diffusion limitations or sulfur poisoning. As a proof of concept, TLD was purified and polymerized with triethylamine as the catalyst to chains with a weight-average molar mass up to 56 kg $mol^{-1}$.

[*]*magnus.ronning@ntnu.no (M. Rønning)*

**Keywords:** Nitric Oxide, Nitric Acid, Industry, Ruthenium, Ceria, Alumina, Zirconia, Titania

**Introduction:** Nitric acid is an important chemical building block & is produced industrially by the Ostwald process, where ammonia is oxidized by atmospheric oxygen using Pt-Rh gauze catalysts to yield nitric oxide [1]. The typical NO concentration at the exit of the ammonia combustor is 10% [1], & NO is further oxidized in a homogeneous gas phase reaction to $NO_2$. $NO_2$ is absorbed in water to yield nitric acid. Use of a low temperature catalyst to oxidize NO to $NO_2$ is a sustainable alternative to reduce the industrial CAPEX. This is achieved by replacing the homogeneous oxidation process by a compact heterogeneously catalysed process. There is hardly any literature on catalytic NO oxidation at high concentrations, but a large body of literature on diesel engine exhaust treatment with NO concentrations at ppm level. In our in-house research, supported Ru shows promising performance compared to other catalysts at industrial conditions [2].

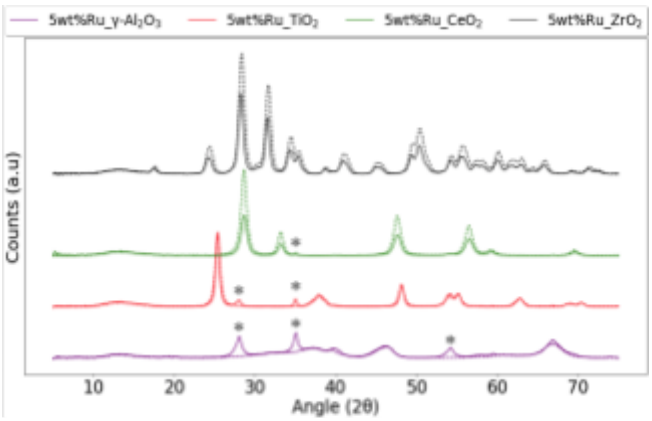

*Figure 1: XRD patterns recorded for different supported 5wt%. Ru catalyst samples in the 2θ range 5-75˚: **Catalysts** – & **Supports** - -; Peaks of $RuO_2$ is marked as **.***

**Experimental/methodology:** All catalysts were prepared using *incipient wetness* impregnation with 5wt%. Ru, & pre-calcined in synthetic air for 2hrs at 450°C. The following supports are studied in this work: $ZrO_2$, $CeO_2$, $TiO_2$, & $\gamma$-$Al_2O_3$. NO oxidation activity is evaluated by subjecting the catalysts to two different feeds (i) & (ii) (refer Figure 2), as a function of temperature (250 – 400°C) at atmospheric pressure. *In-situ* XAS-XRD will be performed February 2023, & the results will be used to discuss Ru behaviour during NO oxidation with respect to the two different feeds.

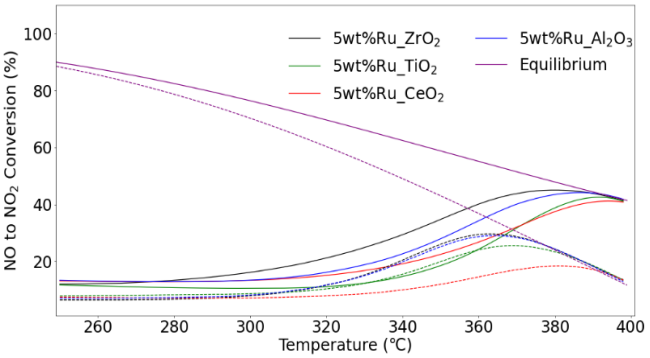

*Figure 2: Conversion of NO to $NO_2$ using 5wt%Ru on different supports in the presence of feed (i) & (ii) at 1bar: **Feed (i)** – 10%NO, 6%$O_2$, 15%$H_2O$ & balance Inert & **Feed (ii)** - - 5%NO, 5% $NO_2$, 3.5%$O_2$, 15%$H_2O$ & balance Inert*

**Results & discussion:** Figure 1 present X-ray diffractograms & Figure 2 present NO conversion results of Ru-based catalyst on different supports. Supported catalyst perform better than the other three supported catalyst in feed (i). The activity of Ru on all supports is significantly reduced when the feed was changed to feed (ii) (Figure 1), which indicates $NO_2$ inhibition. 5wt%Ru/$ZrO_2$ & 5wt%Ru/$Al_2O_3$ had similar activity in feed (ii).

**Acknowledgements:** This project is funded by iCSI center from the Research Council of Norway.

**Introduction.** The replacement of the toxic mercuric chloride acetylene hydrochlorination catalyst represents a major landmark in catalysis. Despite the successful commercialization of a gold catalyst, the challenge remains to identify catalysts that can operate at lower temperatures. Light-off temperature is a critical factor in applying gold catalysts to existing reactors, and catalysts must be able to operate within the available temperature range dictated by reactor design. Various methods have been used to increase the activity of gold catalysts such as the use of promoters, modification of the support, and incorporation of additional metals, however few studies focus specifically on light-off temperature. Surface oxygen functionality has been shown to influence the activity of gold[1] and other metals[2] for this reaction, with higher activity often being accompanied by poor stability. These studies often focus on relatively low O at.%, either studying commercial supports or mild oxidation methods. This work studies the effect of harsher oxidation methods on overall activity and light-off temperature of gold catalysts for vinyl chloride monomer (VCM) production [3].

**Experimental/methodology.** A series of oxidised carbon supports were prepared using a modified Hummers oxidation technique whereby the extent of support oxidation was controlled by using varied amounts of potassium permanganate (0-10g/5g carbon support). Gold was then deposited on the oxidised supports using the standard aqua regia method. Catalysts were characterised using XRD, XPS and XAS. All catalysts were tested for acetylene hydrochlorination under dilute conditions over a range of temperatures (140-200 °C) using a GC fitted with an FID detector for online analysis.

**Results and discussion.** XPS demonstrates that a range of O at.% was achieved by varying the amount of oxidant. After Au was supported on oxidized carbon, all catalysts demonstrated an increased activity at 200 °C when compared to the standard Au/C (Figure 1a). An optimum level of oxidation of ca. 18 O at.% is apparent, after which further oxidation leads to lower activity catalysts due to collapse of the pore structure and dramatic loss of surface area, confirmed using $N_2$ physisorption. The stability of these modified materials is low, with rapid deactivation being observed due to sintering of the gold and loss of the atomically dispersed active species. In addition, each of these materials displayed a remarkable low-temperature activity when compared to the Au/C standard with an apparent correlation between increasing O at.% and lower light-off temperatures (Figure 1b). C-O functionality, in the form of phenol, carboxylate and ether, was found to be a key descriptor of low temperature activity with relative concentration of C-O directly correlating with light-off temperatures, even when considering literature catalysts prepared by alternative oxidative treatments[1,4].

# Extrusion of Optimized Catalysts with Smart Extrusion Technology from ECT-KEMA – Perspectives and Potential –

Torsten Seidel[1*], Martin Simon[2]

[1]*ECT-KEMA GmbH, Görlitz, Germany*
[2]*ECT-KEMA GmbH, Görlitz, Germany*
[*]*info@ect-kema.de*

In recent years, ECT-KEMA GmbH has widened its range of auger and piston extruders for the extrusion of catalysts with different geometries in a goal-oriented process and developed a set of tools that can be used to optimize the extrusion of catalysts.
Global champions in the manufacture of catalytic converters use our technology.

**ECT-KEMA Smart Extrusion = 7 x optimization of extrusion with R&D**

1. Seamless online monitoring and logging of all relevant machine related parameters with state-of-the-art sensor and control systems.
2. Modular design of the extruders for soft and stiff extrusion to achieve pressures up to 350 bar for auger extruders and up to 500 bar for piston extruders.
3. Permanent optimization of wear technology based on the latest findings in coating systems for monolithic augers made of ceramic or carbide.
4. Supply of dies and pressure heads made of different materials – if wanted as well support to optimize the die geometry based on material specific simulations of the extruded masses of the customer.
5. Selective temperature control of all components that come into contact with the ceramic body like auger, barrel, pressure head and die – essential for temperature-sensitive bodies.
6. With sensor systems applied for ECT-KEMA in combination with newly developed cutting technology, we have succeeded in extruding catalysts with near-constant L/D ratio and if wanted to round off the extruded pellets into granulates.

Development of integrated solutions from preparation, optimization of the formulation in our laboratory, cutting and handling of the green extrudates.
We are looking forward to the talks and contacts at Europacat 2023 in Prague.

**Keywords:** Ostwald Process, Design-of-Experiment, Laughing gas

**Introduction**. The industrial production of nitric acid - and consecutively fertilizers - through the Ostwald Process represents one of the key technologies in our modern society, with an annual capacity of more than 100 million metric tons $HNO_3$ globally.[1] While the oxidation of ammonia over Pt-Gauzes exhibits practically full conversion and remarkable high selectivities of 95 - 97 % to nitric oxide, it still leaves room for improvement.[2,3] The remaining selectivities are roughly equally distributed between elemental nitrogen and dinitrogen oxide (laughing gas).[2] Both represent an economic loss, but the latter also acts as a potent greenhouse gas as well as an ozone-depleting substance.[3] Considering the global scale of the process, even miniscule emission reductions can have a profound impact. While several approaches for laughing gas reduction already exists on an industrial level, most of them focus on mitigating the emissions via postprocessing instead of lowering the formation in the first place.[4]

**Experimental/methodology**. The technological requirements necessary to study the Ostwald process on laboratory scale are quite considerable. Mimicking the industrial conditions alone, however, does not suffice for a sound design of experiment due to the narrow parameter range. Hence, the setup even has to exceed the harsh conditions by allowing for short residence times (~1 ms), higher reaction temperatures (up to 1100 °C), ammonia volume fractions just below the explosive limit (13 vol-%) and preheating temperatures (up to 450 °C), combined with pressure up to 5 bar. While this is challenging on its own, an increased level of control and reproducibility is required to minimize statistical noise in the generation of data. The presented setup allows for the independent setting of the preheating and the heating mantle temperature, the pressure, the volume flow, and the ammonia volume fraction. The design themselves are specifically chosen to extract information like linear or quadratic main effects or interactions coefficients of the process parameters.

**Results and discussion.** By using a combination of a two-level full factorial and a face-centered central composite design, the volume flow has been shown to have only minor relevance under the chosen settings. The temperature of the heating mantle also has limited influence on the laughing gas selectivities and mainly serves to support the quasi-adiabatic conditions of the setup. The remaining three parameters are the same that are varied in industrial setups and further validates the system. Additionally, the quadratic and interaction effects of the parameters could be described for the first time. This includes derived parameters like the partial pressure of ammonia, the nitrogen loading, the adiabatic temperature increase and more.

# OFMSW as a potential secondary raw material for chemical recycling

J. Bobek-Nagy[1], E. Tóth*[1], R. Fejes[1], K.Berta[1],A. Sarkady R[1]. Kurdi[1]
*1 Sustainability Solutions Research Lab, University of Pannonia, Veszprém, Hungary*

**Keywords:** OFMSW, plastic waste, chemical recycling, circular economy

**Introduction.** Municipal solid waste (MSW) management is crucial from the aspect of the environment, sustainability, and circular economy. In Europe, the MSW is generally handled in a Mechanical-Biological Treatment (MBT) plant. At the beginning of the process, the organic fraction (OFMSW) is mechanically sorted from MSW (usually <5-8 cm) [1]. The OFMSW can be counted as 40-85 % depending on the seasonality and location of the MSW such as developing or developed countries [2]. The OFMSW is commonly treated by biostabilization which means a 3-4 weeks long aerobic biological processing after that, the remaining material is directed to the landfill [3]. Accordingly, that way of the process does not fit the circular economy approach and moreover does not comply with the EU Landfill Directive of April 1999 (99/31/EC) furthermore the directive forces the decline of the total amount of deposited household waste under 10 % by 2035 (without derogation) [4,5]. According to the significant ratio (7-23 %) [6] of plastic in OFMSW, the plastic part can be a potential raw material for chemical recycling to reach the goal of the circular economy.

**Experimental/methodology.** OFMSWs were sampled in three different seasons (spring, summer, winter), from the biological fraction (particle size under 6 cm) of a Hungarian, MBT plant with 120 000 tonnes/year household solid waste capacity. The samples were stabilized in our laboratory. After the stabilization process, the particle size and the composition of them were established furthermore the types of the different plastic were determined by FT-IR.

**Results and discussion.** Investigating the composition of the total batch of OFMSW, the season has no significant effect on the plastic ratio. The quantity of plastic changes between 15 and 17 w/w% under 6 cm. However, in the aspect of plastic rate in different particle size fractions (1-2, 2-4, and 4-6 cm) in OFMSW, the season has more influence on plastic proportion. Over 4 cm, the plastic quantity is less in winter (24 w/w%) while the greatest in summer (42 w/w%). In the 2-4 cm particle size fraction, season indicates a continuous decrease, in spring the plastic rate is 30 w/w%, in summer is 24 w/w%, and in winter is 18 w/w%. Generally, it can be said that the average plastic content over a year is 12 w/w % in 1-2 cm, 24 w/w% in 2-4 cm, and 35 w/w% in 4-6 cm particle size of OFMSW fraction. However, in the aspect of plastic rate in different particle size fractions, In the case of particle size fraction According to the FT-IR measurement the PP and HDPE reach more than 70 w/w% among plastics which is a suitable secondary raw material for chemical recycling.

# Structure and Activity Relationship Studies of Double Metal Cyanide Catalyzed Ring-Opening Polymerization of Cyclic Monomers

C. H. Tran, H.-K. Choi, E.-G. Lee, B.-R. Moon, I. Kim*

*School of Chemical Engineering, Pusan National University, Busan, Republic of Korea*
**ilkim@pusan.ac.kr*

**Keywords:** double metal cyanide, ring-opening polymerization, polyether, polyester, polycarbonate

**Introduction.** Prussian blue analogue (PBA) complexes are presentative materials of metal-organic frameworks which are highly crystalline and stablematerials. The crystallinity and crystal structure of PBAs are subjected to change according to the preparations. PBAs with substantially amorphous structures, mostly known as double metal cyanide (DMC) catalysts, are well-established for numerous organic reactions, most notably ring-opening polymerization (ROP) of epoxides, copolymerization of $CO_2$ with epoxides, and ROP of lactones [1-3]. Thus, understanding of the structure-activity relationship is one of the important step to optimize the overall performance of this catalytic system.

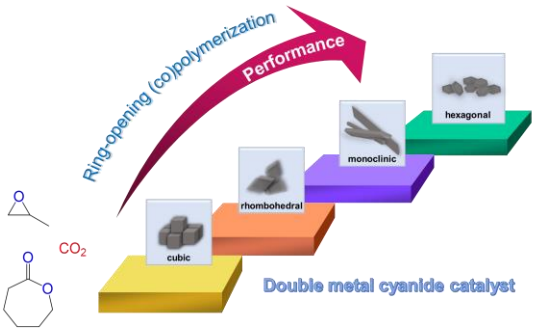

Figure 1. Illustration of the influence of morphology on activity of DMC catalysts.

**Experimental/methodology.** DMC catalysts of cubic, rhomboheral, monoclinic, hexagonal, and amorphous structure were prepared by modifying parameters such as temperature, precipitation method, and the use of organic additives or templates. The compositions and structural properties of the catalysts were determined by inductively coupled plasma optical emission spectrometer, elemental analysis, thermogravimetric analysis, X-ray powder diffraction (XRD), and scanning electron microscope (SEM). Indexing, Pawley fitting and Rietveld refinement of the powder diffraction data were performed using the Fullprof suit software. The textural properties of the catalyst were analyzed by $N_2$ sorption isotherms using Brunauer-Emmett-Teller method. The density functional theory (DFT) calculations were performed using BIOVIA Materials Studio 2020 (20.1)

**Results and discussion.** A series of Zn-Co DMC catalysts having a range of crystal structures have been investigated for the ring-opening polymerization of propylene oxide, ε-caprolactone, and copolymerization of propylene oxide and $CO_2$. The XRD patterns, refined by the Rietveld method, and SEM images indicate that DMC catalysts of cubic (c-DMC), rhombohedral (r-DMC), monoclinic (m-DMC), and hexagonal (h-DMC) morphologies with respectively *Fm*-3*m*, *R*-3*c*, $P2_1/m$, and *P*11*m* space groups were successfully fabricated under various conditions. m-DMC and h-DMC exhibit superior activities compared to those of c-DMC and r-DMC catalysts. DFT studies were further conducted to understand the structure-activity relationship.

**Keywords:** Silver, Oxidation, Methanol-to-Formaldehyde, Annular reactor

**Introduction.** The partial oxidation of methanol to formaldehyde (MTF) over a silver catalyst is an important process for the global formaldehyde production, being responsible for about 55% of the total production. A complex reaction system has been suggested but kinetic investigations to prove the mechanism have been challenging[1, 2]. Lab scale investigations have traditionally resulted in complete conversion of oxygen when running at near industrial conditions. Furthermore, interactions between oxygen and silver and the resulting surface morphology play a role in the activity of the catalyst[3]. An annular reactor concept has been developed and implemented to aid in conducting kinetic investigations. By using a cylindrical silver monolith (Ø 10mm) inside a narrow slit, the reaction can be run using short residence times while limiting the influence of mass transfer and suppressing gas phase reactions[4]. This allows us to conduct the MTF reaction at low conversion, to elucidate the role of different sub-reactions as well as the silver-oxygen dynamics[2].

**Experimental/methodology.** CO, $H_2$, and methanol oxidations are performed at industrially relevant temperatures (500-650°C) at atmospheric pressure. Both short- (<12h) and long-term(>80h) experiments are performed to evaluate the influence of the development of the silver surface over time on the activity. Post-experiment analysis of the catalyst to follow the restructuring is done by electron microscopy.

**Results and discussion.** Using the annular reactor setup a selectivity towards formaldehyde of 93-97% has been reached in the 540 to 600°C range, while maintaining incomplete conversion[2]. A significant effect of surface development over time is observed, as both methanol and oxygen conversion increases. $H_2$ and CO oxidation show similar trends with activity changing with increased time on stream. Furthermore, post-reaction analysis of the catalyst surface shows that reaction atmosphere has a significant influence on the resulting surface morphology. Hydrogen containing atmospheres show a significantly higher degree of restructuring and pinhole formation.

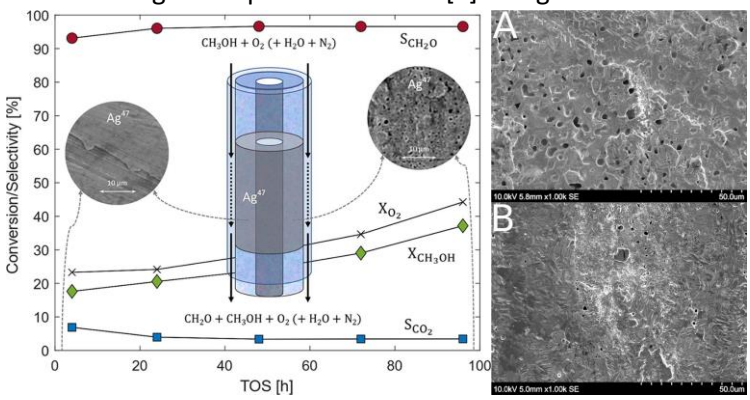

*Figure 1: Left: Evolution of conversion, selectivity and annular Ag catalyst surface over time for methanol oxidation. Right: Catalyst surface after (A) $H_2$ (88h) and (B) CO oxidation (91h)*

# Natural-polymers-based nanocomposites prepared through ultrasound-assisted hydrosolvothermal methods: Selective photoredox catalysis

Juan Carlos Colmenares*, Behdokht Hashemi, D. Lomot

*Institute of Physical Chemistry, Polish Academy of Sciences, Kasprzaka 44/52, 01-224 Warsaw, Poland*
**Corresponding Author's E-mail address: jcarloscolmenares@ichf.edu.pl*

**Introduction:** This work is a report of recent selected experiments of photocatalysts fabricated by an ultrasound-based technique for photocatalytic selective oxidation of aromatic alcohols (e.g. benzyl alcohol, BnOH), in the frame of the concept of lignin valorization, and the proof of concept of intensifying a flow selective photocatalytic oxidation process by acoustic cavitation.

**Experimental/methodology:**

A series of chitosan–lignin (CL) composites were prepared through a hydrothermal method by varying the weight ratio of chitosan and lignin. Subsequently, these CL composites were combined with titania (T) to form a nanocomposite (T/CL) using sol–gel and hydrothermal based methods. Additionally, ultrasonication (US)-assisted hydrosolvothermal method was used for the synthesis of metal-free-carbon-based composite photocatalysts. A plethora of parameters that affects the acoustic cavitation phenomena, and as a result the potential of sonication were investigated (e.g. ultrasound frequency and power). Various important photocatalytic parameters such as the wavelength and intensity of the irradiated light, photocatalyst loading, type of solvent, mixture of solvents, and solution pH were also optimized. The synthesized photocatalysts were characterized by using different techniques such as UV-Vis diffuse reflectance spectroscopy, X-ray diffraction, nitrogen sorption, thermal gravimetric analysis and transmission electron microscopy, among others.

**Results and discussion:**

T/CL nanocomposites exhibited improved photocatalytic performance in comparison with sol–gel and hydrothermally prepared pristine titania (SGH-$TiO_2$), towards the selective oxidation of benzyl alcohol (BnOH) to benzaldehyde (Bnald) under UV (375 nm) and visible light (515 nm).[1] More specifically, the 75T/CL(25:75) nanocomposite (a representative photocatalyst from the 75T/CL nanocomposite series) showed very high selectivity (94%) towards Bnald at 55% BnOH conversion under UV light. Whereas, SGH-$TiO_2$ titania exhibited much lower (68%) selectivity for Bnald at similar BnOH conversion. Moreover, the 75T/CL(25:75) nanocomposite also showed excellent Bnald selectivity (100%) at moderate BnOH conversion (19%) under visible light. Whereas, SGH-$TiO_2$ did not show any activity for BnOH oxidation under visible light. XPS studies suggest that the visible light activity of the 75T/CL(25:75) nanocomposite is possibly related to the doping of nitrogen into titania from chitosan. However, according to UV-visible-DRS results, no direct evidence pertaining to the decrease in band-gap energy of titania was found upon coupling with the CL composite and the visible light activity was attributed to N-doping of titania. Overall, it was found that T/CL nanocomposites enhanced the photocatalytic performance of titania via improved light harvesting and higher selectivity through mediation of active radical species. On the other side, the metal-free carbon-based photocatalysts presented promising activity (30%) and selectivity (>70%) in the partial oxidation of phenolics under flow sonophotocatalytic conditions.[2] The effort of our research is focused on the utilization of flow sonophotocatalysis for the selective transformation of lignin-based model molecules by metal-free carbocatalysts.

## Introduction

Besides the importance of $H_2$ as raw material for chemical industry, its role as C-free energy carrier has increased tremendously during recent years. Despite $CO_2$-neutral sources are desired, $H_2$ is produced currently at large-scale by reforming of fossil fuels, mainly by methane steam reforming (SR) [1]. A widely used catalyst for this process is $Ni/Al_2O_3$, with a metal loading ranging between 15-20 wt.% [2]. Alternatively, supports such as $MgO\text{-}Al_2O_3$ mixed oxides or bimetallic catalysts can be used. However, the main drawbacks of all Ni based catalysts are coke deposition and sintering due to the high temperature required for this reaction (up to 900°C). Both deactivation pathways can be hindered by adding small amounts of noble metals like Pt, Pd, Rh to the Ni-based catalyst [3]. In this context, our study aims at understanding the role of Ni-Pt/$MgAlO_x$ catalyst composition and synthesis method on the activity and particularly on catalyst deactivation behavior.

## Experimental/methodology

A series of Ni-Pt/$MgAlO_x$-based catalysts with various Ni:Pt:support ratios were prepared by conventional and advanced preparation methods, i.e. flame spray pyrolysis [4]. The resulting samples were characterized by electron microscopy, XRD, $H_2$-TPR, $N_2$-physisorption and Raman spectroscopy. Systematic methane SR tests were conducted in a plug-flow reactor for different steam-to-carbon (S:C) ratios. A FTIR spectrometer (Multigas FTIR Spectroscopy, MKS) and a mass spectrometer (Omnistar 320, Pfeiffer) were used for the analysis of the gas mixture at the reactor outlet. The evolution of Pt and Ni structure during methane SR was studied by *operando* X-ray absorption spectroscopy measurements at Pt $L_3$ and Ni K edges.

## Results and discussion

Transmission electron microscopy showed different morphologies of the support depending on the synthesis method. XRD analyses confirmed the synthesis of the desired phases and revealed compositional differences in the as-prepared catalysts according to the Ni and Pt concentrations. In general, a clear impact of the catalyst composition on catalytic performances was found especially during deactivation tests at low S:C ratios. Raman spectroscopy confirmed the presence of graphitic coke for the samples affected by coking. All in all, our findings contribute to the rational development of this class of catalysts based on fundamental understanding.

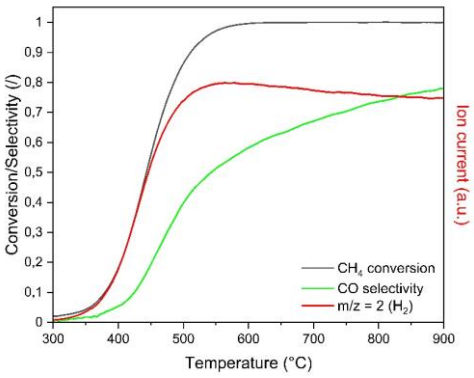

**Figure 1: Catalytic activity of a typical Ni-Pt/$MgAlO_x$ catalyst during a temperature ramp (S:C = 3, 6600 ppm $CH_4$).**

# Palladium-catalyzed double reductive amination of bisphenols to high value diamines

M. Degelin[1*], S. Van Minnebruggen[1], D.E. De Vos[1]

[1]*centre for membrane separations, adsorption, catalysis and spectroscopy for sustainable solutions (cMACS) KU Leuven, Belgium*

---

Polyurethane is one of the most prevalent condensation polymers being produced at 18.6Mt scale [1]. This important polymer finds applications in many industries such as automotive, insulation and textiles. An important precursor for this polymer is (hydrogenated-)methylenedianiline ($(H_{12}$-)MDA). However, the majority of this precursor molecule is produced via the condensation of aniline with formaldehyde. Traditionally, the production of aniline is based on the nitration reduction of benzene [2]. Producing large acidic waste streams and starting from fossile resources- e.g. benzene, this multi-step process shows distinct technological disadvantages. Additionally, the poor regioselectivity for the 4,4'-isomer during the acid catalyzed condensation reaction between aniline and formaldehyde further highlights the need for alternative pathways.

In previous works, Cuypers et al. succesfully reported the amination reaction of phenols towards both anilines and cycohexylamines using heterogeneous palladium- and nickel-catalysts respectively [3,4]. Both works proposed a one-step catalytic system obtaining excellent yields and selectivities for the desired primary amines. Nevertheless, the problems of the condensation reaction towards MDA were not solved in these reports. An alternative and more sustainable route to these high value dimamines could be found in the upgrading of bisphenols due to their similar chemical skeleton to (H12-)MDA. Bisphenols are produced on a vast scale for polycarbonate (PC) (4.7 Mt/yr)[4]. Phenol, the starting material of bisphenol, is a cheap greener alternative to aniline to produce MDA. Besides, the condensation reaction of phenols to bisphenols shows an increased 4,4'-isomer preference. Combining the more efficient synthesis of bisphenols with reductive amination improves the overall synthetic pathway of MDA's. Additionally, no clear end-of-life solution is known for PC currently, implying that polycarbonate is either incinterated or landfilled. Efficiently depolymerizing PC back to bisphenols would provide a new feedstock for ($H_{12}$-)MDA and while revalorizing a plastic waste stream.

In this work, we tackled the listed problems above. Focussing on the heteregeneously catalysed double reductive amination of bisphenols using ammonia and hydrogen-gas as green reagents. A dedicated amination set-up was built in which precise control over the $H_2$ and $NH_3$ concentrations in the liquid phase was possible. Both commercially available and self-prepared supported palladium catalysts were assessed. Thourough evaluation of the critical reaction parameters such as $H_2$- and $NH_3$-pressure, catalyst support, time and temperature led to excellent yields (>90%) and (>90%) for H12-MDA starting from bisphenol F (BPF). During this research the equilibrium position between the primary and secondary amine was investigated using dicyclohexylamine as a model compound. This concluded that secondary amine formation can not be excluded during reductive amination reactions. Characterisation of the catalysts revealed a structure-sensitivity relationship allowing us to further optimize the catalytic system. Small Pd carticle sizes was of great benefit for the reaction time and improved selectivity for the primary diamine greatly [5,6]. In the final part of this research, the susceptibility for nucleophilic attacks of the carbonate bond was eploited to isolate Bisphenol A (BPA) from polycarbonate (PC). Ammonolysis proved to be a succesful method, efficiently depolymerizing PC to BPA on gram scale (87% isolated yield) generating only urea as a stoichiometric side-product. The virgin as well as the isolated BPA was used in the reductive amination. Both obtained excellent yields, however, their reaction rate were significantly reduced.

**Keywords:** Ruthenium, single-site, regioselectivity, hydroformylation

**Introduction.**

Olefin hydroformylation is one of the major examples of a homogeneous catalytic process at industrial scale to produce bulk chemicals[1]. Currently the process is carried out using expensive Rh-based catalysts with phosphine ligands[2]. The high cost and low abundance of Rh has made recycling and catalyst recovery key from both the economic and environmental point of view. In response different heterogeneous catalytic systems, mostly using Co and Rh[3], have been developed with limited success due to expensive synthesis or subpar activity/regioselectivity results. As an alternative, we propose a new type of heterogeneous ruthenium catalyst consisting of isolated single atoms and disordered clusters stabilized in a mesoporous N-doped carbon matrix with very good activity and remarkable regioselectivity (up to 92%) towards the production of n-heptanal from 1-hexene.

**Experimental/methodology.**

The catalytic tests were performed using a stainless-steel autoclave fitted with a PEEK (poly- ether-ether-ketone) liner at 150 °C and 40 bar of syngas pressure ($CO:H_2$ = 1:1). The reactor was equipped with temperature and pressure control and the reaction mixture was stirred magnetically. The extraction of liquids at high pressure was carried out through a gas-tight syringe. A 250 µL gas-tight Hamilton syringe was used to extract 25 µL aliquots at different reaction times.

**Results and discussion.**

Several catalysts were synthesized varying the Ru loading, from 0.01% wt. to 0.4% wt., and tested in the hydroformylation of 1-hexene. A significant increase of the catalytic activity could be noticed by decreasing the metal loading (Figure 1). A priori, these results indicate a strong relationship between the catalytic activity and the size of these Ru entities. The structure-activity relationship of the Ru species was further studied by means of Aberration Corrected Electron Microscopy, revealing the presence of uniformly distributed Ru single atoms (SAs) in samples with low loading, low atomicity clusters for intermediate loadings and bigger agglomerates at high loadings (Figure 2). By combining the catalytic experiments with the observed HAADF-STEM particle distribution, it is possible to determine de intrinsic activity for each Ru entity, hence assigning the remarkable activity observed at low loadings to SAs, whereas the lowest activity to formation of larger size agglomerates such as medium size clusters and nanoparticles.

Next, to check the re-usability of the catalyst, two samples with 0.01% and 0.2% wt. Ru were subjected to 4 consecutive reaction cycles (Figure 3) in which only a small decrease in the activity parameters (TON, TOF) can be noted, though selectivity towards 1-heptanal is maintained during all recycles for both catalysts. Finally, the effect of the $\alpha$-olefin chain length was analysed, obtaining in all cases similar results as with 1-hexene.

# Methyl Acetate production over cation exchange resin catalysts

N.S Govender[1*], J. Miranda[1], R. Balasubramanian[1], S. B Mamilla[1]

[1]*Sahara International Petrochemical Company, Jubail, Saudi Arabia*
[*]*ngovender@sipchem.com*

**Keywords:** Methyl aceate, methanol, acetic acid, resin catalyst, esterification

**Introduction.** The esterification of acetic acid with methanol to produce methyl acetate can be catalysed with either homogeneous or heterogenous catalysts (1). Homogeneous catalysts are preferred commercially mainly due to their higher activity. However, these catalysts have a higher corrosive nature, result in more side reactions, and are difficult to separate from the reaction medium. For these reasons, heterogeneous catalysts such as cation exchange resins are considered as attractive alternatives, as they potentially offer less of these undesirable features. In this present work, we demonstrate a scaled-up process for methyl acetate production by reactive distillation catalysed by a cation exchange resin. We also present here the laboratory development work prior to scale-up.

**Experimental/methodology.** Six different cation resin catalysts were tested with sulphuric acid being the reference catalyst. Initial screening tests were performed on batch reactors at 60 °C for 90 min with stirrer speed set to 500 rpm. Gas chromatography was used to determine the acetic acid conversions. A reflux setup (2) was used to measure the esterfication kinetics by changing the catalyst loadings, feed ratios, and reaction temperature. These results were then used to design the scale-up experiments.

**Results and discussion.** The laboratory experimental tests on different cation resin catalysts showed varying activities compared to the reference sulfuric acid catalyst. The most active resin catalyst tested showed 80 % relative activity to sulfuric acid (see Figure 1). The other reaction parameters tested (catalyst loadings, feed ratios, and temperature) gave valuable insights into the performance of this resin relative to sulfuric acid. Overall, the kinetic response of the resin is slower than sulfuric acid thus making direct replacement in existing equipment more challenging. A scale-up pilot study using a reactive distillation column will provide more detailed kinetics and show the robustness of the resin catalyst under these conditions.

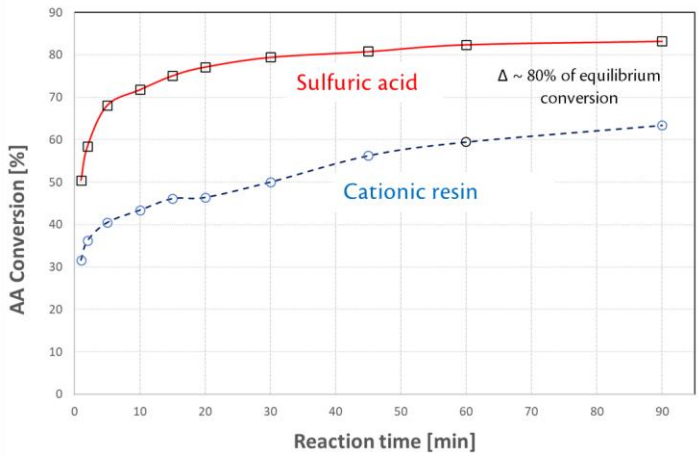

**Figure 1.** Acetic acid conversion versus time for the esterification with methanol catalyzed by (☐) 1g $H_2SO_4$ and (○) 1 g Thermax Tulsion T-6812MP resin. Reaction conditions: 60 °C with feed mole ratio = 1.

**Keywords:** hydrogen delivery, green hydrogen, alkene hydrosilylation, dehydrogenative coupling, cobalt complex, homogeneous catalysis.

**Introduction.**
The development of a circular economy is a key target to reduce our dependence on fossil fuels and create more sustainable processes. Concerning hydrogen as energy vector, the use of liquid organic hydrogen carriers is a promising strategy.[1] However, most of them present limitations for hydrogen release, such as harsh reaction conditions, poor recyclability, and low-value by-products.

**Results and discussion.**
A novel sustainable methodology to produce added-value silicon precursors and concomitant hydrogen via dehydrogenative coupling by using an air- and water-stable cobalt-based catalyst synthesized from cheap and commercially available starting materials has been developed.[2] This methodology is applied to the one-pot synthesis of a wide range of alkoxy-substituted silanes using different hydrosilanes and terminal alkenes as reactants in alcohols as green solvents under mild reaction conditions (room temperature and 0.1 mol% cobalt loading). We also demonstrate that the selectivity toward hydrosilylation/hydroalkoxysilylation can be fully controlled by varying the alcohol:water ratio. This implies the development of a circular approach for hydrosilylation/hydroalkoxysilylation reactions, which is unprecedented in this research field up to date. Kinetic and in situ spectroscopic studies (EPR, NMR, ESI-MS), together with DFT simulations, further provide a detailed mechanistic picture of the dehydrogenative coupling and subsequent hydrosilylation. Finally, we illustrate the application of our catalytic system in the synthesis of an industrially-relevant polymer precursor coupled with the production of green hydrogen on demand (Figure 1).

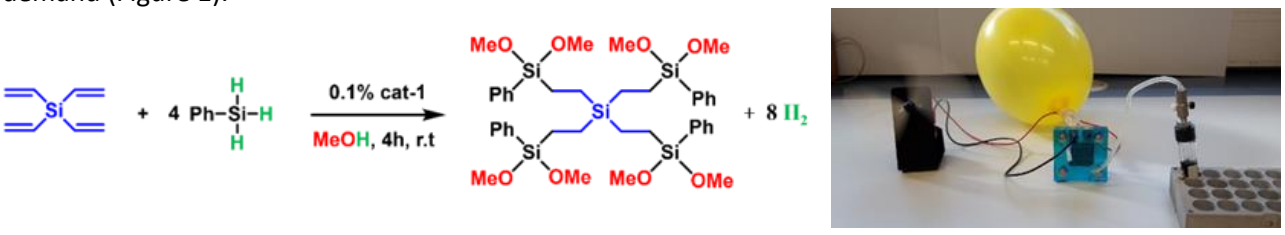

**Figure 1.** Hydroalkoxysilylation reaction of tetravinylsilane and phenylsilane to obtain a silicon precursor (left) and a picture of energy generation via recombination of hydrogen obtained in the hydroalkoxysilylation reaction and oxygen balloon in a fuel cell (right).

# Utilizing Water-Catalyst Interactions to Stabilize the Transition State During Alkane Dehydrogenation

J.P. Haven[1], L. Lefferts[1], J.A. Faria Albanese[1*]

[1]*Catalytic Processes and Materials, Faculty of Science and Technology, MESA+ Institute for Nanotechnology, University of Twente, the Netherlands*
[*]*j.a.fariaalbanese@utwente.nl*

**Keywords:** ethane dehydrogenation, platinum, steam

**Introduction.** Ethylene is a widely used chemical building block that is conventionally produced via cracking processes. A more direct route to produce ethylene is via ethane dehydrogenation (EDH, $C_2H_6 \leftrightarrow C_2H_4 + H_2$, $\Delta H^0$ = +137 kJ/mol). EDH requires high temperatures (500-700 °C), is limited by thermodynamic equilibrium (ethylene yield: ~30%), and is therefore currently not industrially attractive. Ethylene yields can be increased by using $H_2$ permeable dense ceramic membranes [1]. Co-feeding $H_2O$ (0-5 V%) is known to enhance $H_2$ permeation through these membranes [1] and is known to improve the lifetime of Pt-based catalysts [2]. Alkane dehydrogenation on Pt catalysts has been widely investigated in the past, but the role of $H_2O$ on the corresponding reaction kinetics is still poorly understood. In this contribution, we will show the effect of $H_2O$ (0-5 V%) on the reaction kinetics of non-oxidative dehydrogenation of ethane using a $Pt/ZnAl_2O_4$ catalyst.

**Experimental/methodology.** The $ZnAl_2O_4$ support is functionalized with 4.0 wt% Pt via wet impregnation. Catalytic tests were performed in a continuous flow, fixed-bed reactor setup, equipped with a syringe pump to co-supply $H_2O$. The typical testing conditions were: temperatures of 475-550 °C, atmospheric pressure, 10-150 mbar ethane, 10-150 mbar $H_2$, 0-15 mbar $H_2O$. The composition of the reactor outlet was analyzed while performing the reaction using an on-line gas chromatograph.

**Results and discussion.** The reaction orders in ethane (=1), ethylene, and $H_2$ (both -0.5) for EDH on $Pt/ZnAl_2O_4$ were determined to be similar under dry and wet conditions, indicating similar reaction mechanisms. The reaction rate constant is determined as a function of temperature for $Pt/ZnAl_2O_4$ in presence and absence of $H_2O$ (***Fig. 1a***). Interestingly, the enthalpy of the transition state is found to be lowered in wet conditions compared to dry conditions (slope proportionality, 85 vs. 120 kJ/mol), indicating stabilization of the transition state at the Pt surface by $H_2O$. This is schematically visualized in ***Fig. 1b***, illustrating that polar $H_2O$ facilitates the removal of H-atoms from ethane. This happens at the cost of an entropic penalty (***Fig. 1a***, y-intercept proportionality: -154 J/mol.K instead of -113 J/mol.K), as the number of degrees of freedom of the transition state is reduced by this stabilization effect.

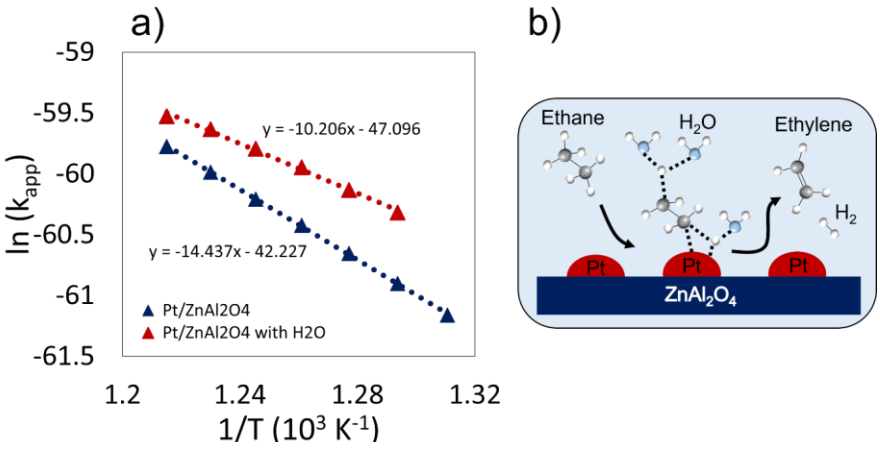

**Figure 1: a) Arrhenius curves for ethane dehydrogenation on $Pt/ZnAl_2O_4$ under dry (blue) and wet (red) conditions, T = 490-550 °C, b) schematic of the proposed role of $H_2O$ in the EDH reaction mechanism.**

[*]*rmr189@psu.edu*

**Keywords:** intermetallics, active site, hydrogenation, kinetics, reaction mechanism

**Introduction.** Intermetallic compounds, composed of two or more metals, possess long-range crystallographic order (i.e., well defined site occupancy) with distinct differences in catalytic behavior from their parent metals [1]. We demonstrate intermetallic Pd-Zn γ-brass ($Pd_{8+x}Zn_{44-x}$, $0 \leq x \leq 2$) represents an ideal platform to tune the size (nuclearity) and composition of active sites to control selectivity during hydrogenation [2]. Active sites in this system are composed of Pd-M-Pd (M = Zn, Pd, Cu, Au, Ag) units with an angle of 120°. The composition of these PdMPd moieties is controlled by the stoichiometry. $Pd_9Zn_{43}$ ($Pd_9$) displays a mixture of M = Pd and Zn, while $Pd_{10}Zn_{42}$ ($Pd_{10}$) only exposes M = Pd. Pd-Pd-Pd sites are unselective for alkyne semi-hydrogenation, while PdZnPd was highly selective towards the olefin. Coinage metals (Cu, Ag, Au) in the system displayed intermediate selectivity. To further explore the active site structure-function relationship, we utilize site isolated Pd-M-Pd (M = Pd, Cu, Ag, Au) trimers to fully elucidate the mechanism of ethylene hydrogenation through combined experimental measurements, density functional theory (DFT) and microkinetic modeling (MKM) [3].

**Experimental/methodology.** Catalysts are synthesized by a solid-state diffusion technique whereby solid powders of Zn, Pd and either Cu, Ag or Au are physically mixed and heated under vacuum. The resulting bi- or tri-metallic ingot is crushed and then annealed under vacuum to produce the final bulk catalyst. Phase identification and site occupancy is determined by Rietveld refinement of X-ray or neutron diffraction data. The catalytic activity of each material is measured using a plug-flow reactor coupled to a gas chromatograph/mass spectrometer. DFT calculations were performed in VASP to evaluate elementary reaction energetics. Microkinetic modeling was executed by a home-built code. CALPHAD modeling is used to predict the site occupancy and therefore active site composition in the trimetallic case.

**Results and discussion.** The well-defined active site afforded by the γ-brass phase allows for kinetic models that can accurately describe apparent activation energies and reaction orders for ethylene hydrogenation. Previous studies of the kinetics of ethylene hydrogenation on late transition metal surfaces have required the use of a "special" site on which H can adsorb without competition from ethylene within a Langmuir-Hinshelwood framework. The molecular level definition of such sites is elusive, arising from the complex combination of mixed coverages and differences in adsorbate size between ethylene and hydrogen. The isolation of $Pd_1$ and $Pd_3$ sites allows us to provide a precise definition of all possible ethylene-hydrogen co-adsorption structures and hydrogenation reaction paths, enabling a precise definition of site requirements. The high sensitivity of the $H_2$ reaction order on monomer-and trimer-containing $Pd_9Zn_{43}$ surfaces is due to the significant influence of Pd monomers on the degree of rate control due to competitive adsorption of ethylene and hydrogen on the monomers. This competition decreases at higher temperature as the ethylene coverage decreases on the monomer, leading to a decrease in the $H_2$ order. This sensitivity disappears on trimer-only containing $Pd_{10}Zn_{42}$ surfaces. The incorporation of a coinage metal (Cu, Ag, Au) into the central atom of the trimer site has distinct kinetic consequences on the kinetics of ethylene hydrogenation. Contrary to $Pd_9$, the $Pd_8Cu_1$ reaction orders show non-monotonic behavior with respect to temperature. The increased barrier of $H_2$ adsorption and dissociation on Cu versus Pd, hydrogen dissociation on Pd-Zn-Pd edge atoms increases the kinetic significance relative to Pd-Cu-Pd trimers, especially at low temperatures.

# Design of Multimetallic Alloys Highly Efficient for Oxidative Dehydrogenation of Propane Using $CO_2$

S. Furukawa[1*], F. Xing[1]

[1] *Institute for Catalysis, Hokkaido University, Sapporo, Japan*
[*] *furukawa@cat.hokudai.ac.jp*

**Keywords:** $CO_2$, propane dehydrogenation, carbon neutral, intermetallics, high-entropy

**Introduction.** The oxidative dehydrogenation of propane using $CO_2$ ($CO_2$-ODP) is a promising technique for high-yield propylene production and $CO_2$ utilization. The development of a highly efficient catalyst for $CO_2$-ODP is of great interest and benefit to the chemical industry as well as net zero emissions. Here, we report unique catalyst materials and design concepts based on pseudo-binary alloys [1] and high-entropy intermetallics [2] for this challenging chemistry. A pseudo-binary alloy is a ternary alloy in which a part of A(B) site in a binary intermetallic $A_mB_n$ is substituted with a third element A'(B') to form $(A_{1-x}A'_x)_mB_n$ ($A_m(B_{1-p}B'_p)_n$) (Figure 1a). Introducing an appropriate third element allows to flexibly tune and improve the catalytic performance, particularly for reactions involving more than one molecules that have quite different properties such as light alakne and $CO_2$. Futher multimetallization of the A and B sites forms a high-entropy intermetallic $(A_{1-x-y}A'_xA''_y)_m(B_{1-p-q}B'_pB''_q)_n$, which exhibits much greater thermal stability in the high-temperatrue reaction due to entropy effects (Figure 1b).

**Experimental/methodology.** All the catalysts were prepared by a simple co-impregnation method using $CeO_2$ (JRC-CEO-2, $S_{BET}$ = 123.1 $m^2g^{-1}$) as a support. $CO_2$-ODP was performed in a quartz fixed-bed reactor with a 6 mm internal diameter at 550 °C or 600 °C ($C_3H_8$: $CO_2$: He = 1:1:2, a total flow rate of 20 mL/min).

**Results and discussion.** In this study, we designed $(Pt_{1-x}Co_x)_2In_3/CeO_2$, in which Pt, Co, In, and $CeO_2$ were chosen for facile C-H scission, $CO_2$ activation, inhibiting side reaction (ensemble effect), and coke combustion (oxygen releasing ability of $CeO_2$). HAADF-STEM-EDX, XRD, and XAFS analyses confirmed the formation of nanoparticulate pseudo-binary alloy ($x$ = 0.33) on $CeO_2$. This catalyst showed high catalytic activity and stability in $CO_2$-ODP at 550 °C compared with the corresponding monometallic Pt and Pt-based binary alloy catalysts (Figure 1c) [1]. The specific activity of $(Pt_{0.67}Co_{0.33})_2In_3/CeO_2$ was five times higher than that of the best catalyst ever reported, even with a long catalyst life (Figure 1d). However, the stability of this catalyst was not satisfactorily high at 600 °C due to irreversible sintering of alloy nanoparticles. Therefore, we then designed (PtCoNi)(SnInGa)/$CeO_2$ high-entropy intermetallic catalyst. This catalyst exhibited much longer catalyst life in $CO_2$-ODP at 600 °C due to greater thermal stability [2]. In the presentation, we discuss about the structural analysis, reaction mechanism, and the roles of each metals in detail.

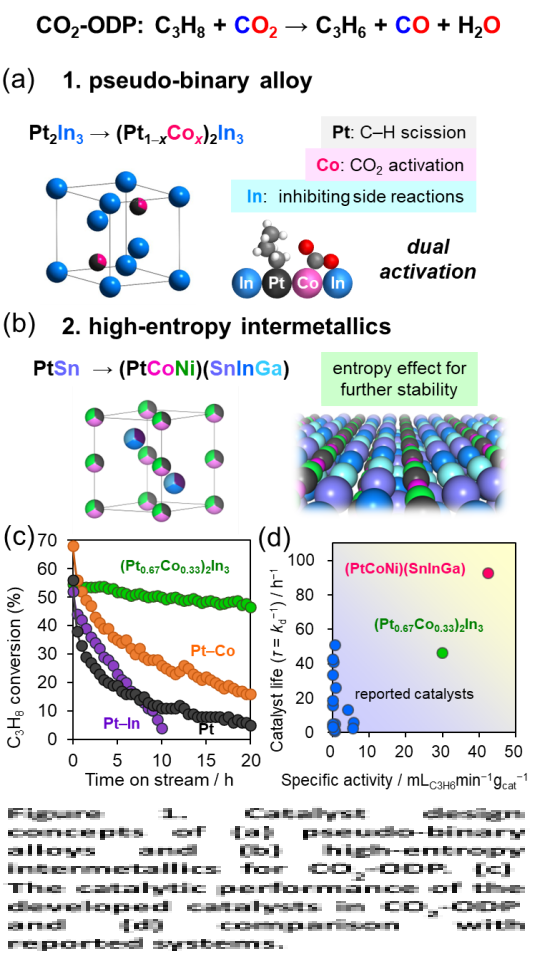

Figure 1. Catalyst design concepts of (a) pseudo-binary alloys and (b) high-entropy intermetallics for $CO_2$-ODP. (c) The catalytic performance of the developed catalysts in $CO_2$-ODP and (d) comparison with reported systems.

**Keywords:** bimetallic catalysts, structure-performance, $CO_2$ hydrogenation, in-situ, operando

**Introduction.** Many industrially relevant catalysts have active sites that contain more than one metal species [1]. However, even in well-established systems, such as the commercial Cu-Zn(O)-based methanol synthesis catalyst, structure-performance relationships remain debated [2]. In this study, we focused on the detailed characterization of Ni-Ga-based catalysts for the hydrogenation of $CO_2$ to methanol [3]. The use of in-situ and operando experimentation allowed us to describe its phase, short-range order, electronic structure and surface under relevant conditions (20 bar $CO_2$:$N_2$:$H_2$ = 1:1:3, 230°C) and correlate these with catalytic performance.

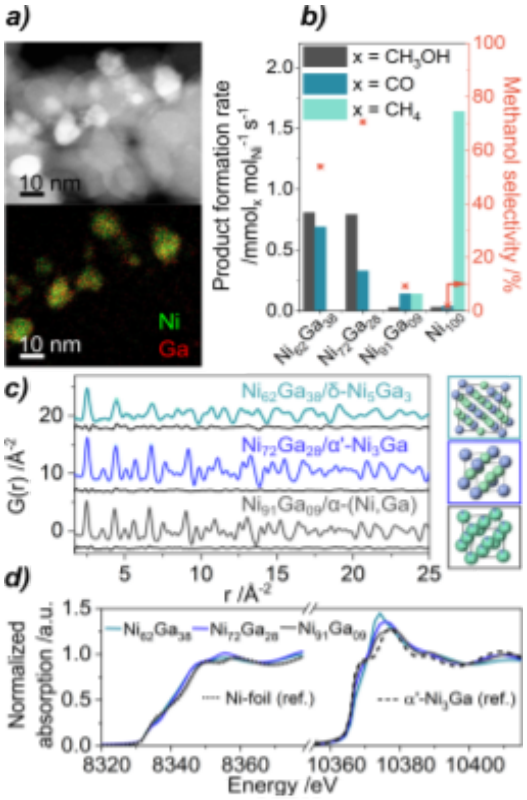

*Figure SEQ Figure * ARABIC 1* **a)** Electron microscopy images of $Ni_{60}Ga_{40}$, **b)** Product formation rate and selectivity, **c)** d-PDF with fitted model structures, **d)** Ni and Ga K edge XANES of Ni-Ga catalysts and reference materials.

**Experimental/methodology.** $SiO_2$ supported Ni-Ga catalysts (~ 5 wt% Ni+Ga) were prepared via the hydrothermal deposition precipitation of Ni and Ga nitrate onto colloidal $SiO_2$ and a subsequent reduction treatment (700°C, 10% $H_2/N_2$), yielding the as-reduced materials denoted as $Ni_xGa_{(100-x)}$ (x by ICP-OES). Catalytic $CO_2$ hydrogenation tests were performed in a fixed bed flow reactor (25 bar $CO_2$:$N_2$:$H_2$ = 1:1:3, 230°C, GHSV = 60 L $g_{cat}^{-1}$ $h^{-1}$) after a pretreatment in $H_2$ (700°C). Operando X-ray total scattering and operando X-ray absorption spectroscopy experiments were performed at the European Synchrotron Radiation Facility (ID15A and BM31). Difference pair distribution function analysis (d-PDF) of the X-ray total scattering data was determined as d-PDF = $PDF_{Ni\text{-}Ga/SiO2}$ - $PDF_{SiO2}$.

**Results and discussion.** Electron microscopy imaging indicated the formation of Ni-Ga nanoparticles of ca. 10 nm Ø (Fig. 1a). Catalytic $CO_2$ hydrogenation tests revealed a strong dependence of the methanol formation rate and methanol selectivity on the Ni:Ga ratio (Fig. 1b), whereas both $Ni_{62}Ga_{38}$ and $Ni_{72}Ga_{28}$ showed high activities (both ~ 0.8 $mol_{CH3OH}$ $mol_{Ni}^{-1}$ $s^{-1}$) and selectivities (~ 54% and 70%, respectively). D-PDF of $Ni_xGa_{(100-x)}$ (Fig. 1c) revealed the presence of the intermetallic δ-$Ni_5Ga_3$ ($Ni_{62}Ga_{38}$) and α'-$Ni_3Ga$ ($Ni_{72}Ga_{28}$) phases in these catalysts under reaction conditions, whereas the poor-performing $Ni_{91}Ga_{09}$ catalyst contained a Ni-rich α-(Ni,Ga) alloy. X-ray absorption near edge structures (XANES, Fig. 1d) indicate that Ni is in a fully reduced $Ni^{0/\delta-}$state and Ga is mostly in reduced state, with only a small fraction of Ga being present in the form of oxidized species; the fraction of oxidized Ga species increases in the following order: $Ni_{62}Ga_{38}$ > $Ni_{72}Ga_{28}$ > $Ni_{91}Ga_{09}$. In summary, our results indicate that the intermetallic δ-$Ni_5Ga_3$ and α'-$Ni_3Ga$ phases are highly active for the hydrogenation of $CO_2$ to methanol, whereas a Ni-rich α-(Ni,Ga) alloy is a poor catalyst for this reaction.

**Keywords:** intermetallic compounds, hydrogen generation, isotope labelling

**Introduction.** Due to its high energy density, methanol is a feasible substitute for conventional fuels and can be used for on-board hydrogen production for mobile applications.[1] To release hydrogen-on-demand with high purity, methanol steam reforming (MSR, $CH_3OH + H_2O \rightarrow CO_2 + 3\ H_2$) is a well-suited reaction. The most promising catalytic materials are based upon intermetallic compounds of palladium or platinum and have been discovered by Iwasa.[2] While a beneficial effect of the intermetallic compound and the support was detected in the case of ZnPd/ZnO,[3] the underlying reasons for the teamwork are unknown. As intermetallic Pt-In/$In_2O_3$ has revealed even better catalytic properties in the reaction, this study explores the reasons for the superior activity and selectivity.

**Experimental/methodology.** Pt/$In_2O_3$ materials were synthesized by an aerogel route and subsequently turned into Pt-In/$In_2O_3$ by controlled reductive treatment in hydrogen atmosphere. After characterisation by XRD, DTA/TG/MS and TEM, the materials were tested in methanol steam reforming at varying water-to-methanol-ratios. Mechanistic studies were conducted using $^{18}O$-labelled water and methanol in sequence.

**Results and discussion.** After synthesis, the material consisted of $In_3Pt_2/In_2O_3$ which changed under reaction conditions and depending upon the water methanol ratio to $In_2Pt/In_2O_3$ or $In_2Pt$-$In_7Pt_3/In_2O_3$.[4] This revealed a highly mobile and redox-active material which adjusts quickly to the reaction conditions. This was further corroborated by experiments using isotope-labelled reactants, which reveal an oxygen-reservoir function of the oxidic support, thus providing strong indications of a Mars-van-Krevelen mechanism. Since this also has been shown for In-Pd/$In_2O_3$,[5] it is likely that the same principle is applying generally for methanol steam reforming on supported intermetallic compounds.

**Keywords:** intermetallic, nanoparticles, heterogeneous catalysis

**Introduction**

Development and research of sustainable alternatives for energy utilization is mandatory to deal with the challenges of a steadily increasing demand for enery and associated effects on the climate. Key reactions of sustainable energy utilisation include water splitting and steam reforming reactions. Hence, the optimization and development of catalyst materials for respective key reactions play a vital role in current research.[1]

Intermetallic nanoparticles possess unique chemical and physical properties, which make them particularly interesting for catalytic applications. The utilization and synthesis optimization for nanoparticulate intermetallic compounds gained increased attention in recent years. The adjustability of intermetallic materials promises high potential in a variety of heterogeneous catalysed reactions.[2]

State of the art synthesis approaches often lack flexibility and precise composition control while significantly expand particle size distributions, hindering the broad application of intermetallic nanoparticles in catalysis.[3]

**Experimental/methodology**

A very promising alternative method is the direct vapour solid synthesis of intermetallic nanoparticles by interaction of a metal with high vapour pressure in the gaseous phase with solid metal nanoparticles. In principle, the reaction is driven through the equilibration of a solid component with the vapour of a volatile element. The thermodynamic activity, vapour pressure and thus the product composition are controlled by the reaction temperatures in a temperature gradient.

**Results and discussion**

In a present approach, we performed the vapour-solid method to prepare various, intermetallic phases as supported Ni-Zn and Ni-Te nanoparticles. Investigation of the samples was carried out by SEM-EDX, TEM, powder XRD, tXRF and gas adsorption. The synthesis method was suitable for producing homogeneous intermetallic compounds of precise and predictable composition. The vapoursolid synthesis is a promising method for the preparation of nanoparticulate intermetallic catalysts. Further metal reactants of interest are the volatile elements Selenium, Antimony and Phosphorus in combination with Nickel, Cobalt, Iron, Gold, Iridium, Platinum, Palladium, Ruthenium and Rhodium. Characterization includes testing of the synthesized nanoparticles in various heterogeneous catalytic reactions. Particularly, water splitting and steam reforming reactions are of interest for investigation.

**Keywords:** Single atom catalysts, Intermetallic compound, Nanowires, Hydrogen evolution, Electrocatalysis

**Introduction.** The production of alternative hydrogen energy is considered to be a promising way due to its inherent qualities, such as clean, having a high energy density, being affordable, and being a sustainable method. The hydrogen evolution process (HER) in an alkaline medium is one of the practical techniques for the generation of hydrogen due to the significant amount of water electrolysis produced. In particular, Ru-based electrocatalysts have drawn much attention as a benchmark for HER because of their low cost, ability to decrease the reaction barrier of the rate-determining step by weakening the hydrogen-binding energy, and promotion of OH adsorption during HER. Various types of support for anchoring Ru single atoms (SAs) have been widely reported in recent years. Nevertheless, intermetallic nanocrystals (NCs) have yet to be explored among the various supports. Moreover, intermetallic NCs have been shown to have fascinating features due to their ordered atomic arrangement, which is generally more stable in preventing etching during electrocatalytic processes. In this work, we prepared $RuSA_x$-$Pd_3Pb$ NWs via a facile method. The prepared $RuSA_{1.73}$–$Pd_3Pb$ NWs delivered a lower overpotential and Tafel slope than their counterparts. By shedding light on the function of Ru single atom tailoring in intermetallic $Pd_3Pb$ NWs, this study paves the way for developing novel electrocatalysts with increased activity and stability.

**Experimental/methodology.** First, the intermetallic $Pd_3Pb$ NWs were synthesized via a facile route. In the process of forming intermetallic $Pd_3Pb$ NWs, there was an obstacle in which the nanocubes also produced. Then, the separation method was applied through several steps to increase the yield of nanowires. After the separation method, the ruthenium precursor was added to the organic mixture containing $Pd_3Pb$ NWs. For comparison, $Pd_3Pb$ nanocubes and $RuSA_{2.90}$-$Pd_3Pb$ nanocubes were prepared.

**Results and discussion.** We have successfully prepared Ru single atom on intermetallic $Pd_3Pb$ NWs through a facile route. The HAADF-STEM images display an ordered atomic structure of $Pd_3Pb$ without any defect after the addition of Ru atoms, confirming the stability structure of the intermetallic phase. Furthermore, the elemental mapping of $RuSA_{1.73}$-$Pd_3Pb$ NWs demonstrates the Ru atoms are atomically dispersed, and no cluster or particles can be found. From ICP-OES measurement, the ratio of Pd/Pb/Ru of $RuSA_{1.73}$-$Pd_3Pb$ NWs was 71.28/26.88/1.73. In addition, the XRD pattern of $RuSA_{1.73}$-$Pd_3Pb$ NWs and $Pd_3Pb$ NWs exhibited diffraction peaks corresponding to the intermetallic $Pd_3Pb$ phase. The XPS survey spectrum confirmed the presence of the Ru element, and the result indicated that Ru received the electron from the $Pd_3Pb$ substrate. The electrocatalytic HER performances of catalysts were evaluated in a typical three-electrode system with $N_2$-saturated 1.0 M KOH as the electrolyte. The overpotential of $RuSA_{1.73}$-$Pd_3Pb$ NWs is 26 mV at 10 mA $cm^{-2}$, 10 mV, and 68 mV lower than that of Pt/C and Ru/C, respectively. The Tafel slope of $RuSA_{1.73}$-$Pd_3Pb$ is 40 mV $dec^{-1}$, indicating the rate-limiting step is the recombination of chemical-adsorbed hydrogen and the HER over the catalysts following the Volmer-Heyrovsky mechanism. In addition, after the long-term stability test, the $RuSA_{1.73}$-$Pd_3Pb$ NWs exhibited excellent durability without any significant losses in potential. These results underlined that an appropriate amount of Ru dispersed on the surface of catalysts could accelerate electron transfer and water dissociation process, which maintain the active sites to alleviate the poisoning of $OH_{ads}$ on the Ru site.

# Ga-Sb-Pd Intermetallic Compounds as Catalysts in Semi-Hydrogenation of Acetylene

Kaartick Sivakumar[1], Yuri Grin[2], Marc Armbrüster[1*]

[1]*Chemnitz University of Technology, Chemnitz, Germany*
[2]*Max-Planck-Institut für Chemische Physik fester Stoffe, Dresden, Germany*
[*]*Email: marc.armbruester@chemie.tu-chemnitz.de*

**Introduction.** Semi-hydrogenation of acetylene is an important industrial process to remove traces of acetylene from the ethylene feed used to produce polyethylene.[1] Ga-Pd intermetallic compounds have been studied as catalysts in the semi-hydrogenation of acetylene and were found to exhibit high selectivities and high stability.[2] Substitution of gallium with another main-group element having a higher number of valence electrons results in compounds with different valence electron concentrations, thus the electronic influences in the semi-hydrogenation of acetylene can be studied. An example of this is the catalytic investigation on $Ga_{1-x}Sn_xPd_2$ ($0 \leq x \leq 1$), where the maximum activity was observed at $x = 0.28$.[3] In this work, Ga (with three valence electrons) is replaced with Sb (five valence electrons) to reduce the substitution degree while still improving the activity. Intermetallic compounds $Ga_{1-x}Sb_xPd_2$ ($0 \leq x \leq 0.2$) were synthesised, characterized and catalytically tested in the semi-hydrogenation of acetylene.

**Experimental.** Intermetallic compounds $Ga_{1-x}Sb_xPd_2$ ($x$ = 0, 0.02, 0.03, 0.035, 0.04, 0.05, 0.1 ,0.15, 0.2) were synthesised in a high-frequency furnace and subsequently enclosed in evacuated quartz glass ampoules before being annealed at 900 °C for three weeks in a resistance oven. Samples were then characterized using metallography and powder X-ray diffraction. This was followed by catalytic tests on crushed samples in a quartz glass tube reactor (plug-flow type) using a gas phase composed of 0.5% $C_2H_2$, 5% $H_2$, 50% $C_2H_4$, 44.5% He at 200 °C and a total flow of 30 mL/min.

**Results and discussion.** X-ray diffraction as well as metallography resulted in single-phase samples for all compositions. Catalytic testing of these samples revealed that the maximum activity was 16.44 $mol_{C2H2}$ $mol_{Pd}^{-1}$ $h^{-1}$ at $x$ (Sb content) = 0.035. Selectivity towards ethylene was around 80% for all samples. Most samples remained stable throughout the catalytic testing, while slight deactivation can be observed in some samples. The valence electron concentrations (total number of valence electrons divided by total number of atoms) were calculated for the Sb and Sn samples using each atom's valence electron count (Ga =three, Sb = five, Pd = zero, and Sn = 4). Since the valence electron concentration has been doubled for the Sb system compared to the Sn system, the highest catalytic activity should have been observed at half the Sb content ($x$ = 0.14). However, this is not observed and the highest catalytic activity is seen at $x$ = 0.035 (Figure 1). A possible reason for this unexpected behavior could be due to the inert pair effect of Sb, where, similar to Bi, the +3-oxidation state is more stable than the +5-oxidation state.

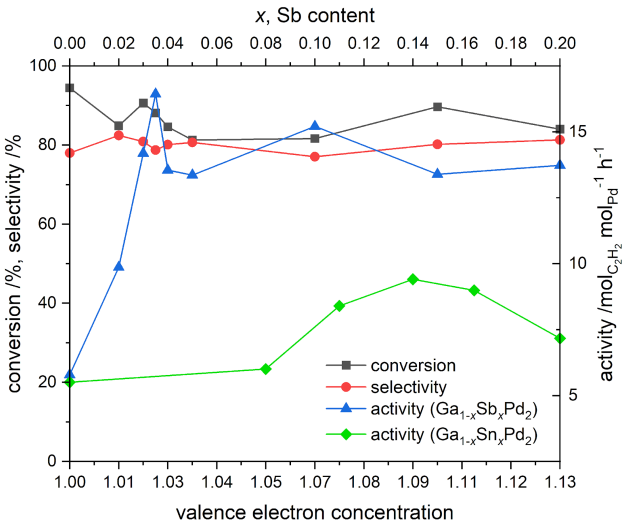

**Fig 1. Comparison of conversion, selectivity, activity of the $Ga_{1-x}Sb_xPd_2$ samples, and activity of the $Ga_{1-x}Sn_xPd_2$ samples as a function of $x$ (Sb content) and valence electron concentration**

# Photo-driven processes for fuel and organic synthesis

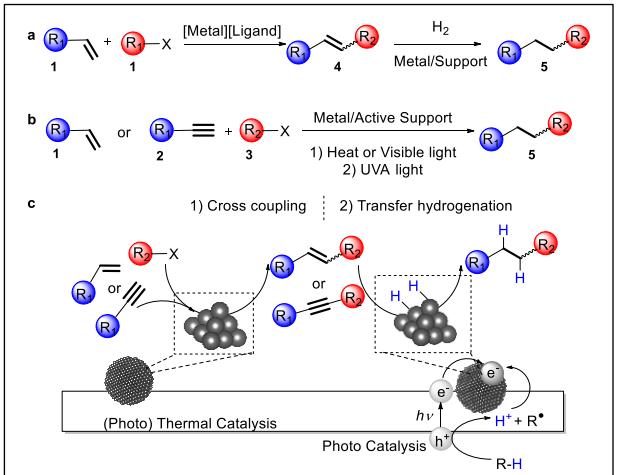
# Generation and Utilization of Oxygen Centred Radicals in C–C and C–O Bond Forming Processes

C-J. Wallentin

*Gothenburg, Sweden*
*carl.wallentin@chem.gu.se*

**Keywords:** photocatalysis, radical chemistry

Photocatalytic strategies have shown to not only complement but also expand our ability to achieve structural complexity under mild conditions as compared to methodologies inherently relying on polar mechanisms. Numerous new methods for bond forming transformations have been published in the last decade and the concept of photocatalysis in concert with synergistic catalytic systems have paved the way for innovative approaches for designing complexity generating processes. The generation and utilization of heteroatom centred radicals have lately acquired increased attention from the method development community owing to their useful intrinsic reactivity patterns that can be advantageously utilized in synthesis. However, achieving such high-energy entities in a selective manner under mild conditions is still challenging, and the repertoire of photocatalytic systems that can capitalize on such strategies are still scarce. In the Wallentin group we have developed several methodologies to generate oxygen centred radicals under visible-light mediated conditions and utilized these in various bond forming processes. The talk will cover the latest contribution form the Wallentin group on this topic.



# Heterogeneous photocatalysis for sustainable organic transformations: Challenges and opportunities

R. Whitehead, A. Lanterna*

*School of Chemistry, University of Nottingham, University Park, NG7 2RD, UK*
**anabel.lanterna@nottingham.ac.uk*

**Keywords:** Photocatalysis, palladium, semiconductors

**Introduction.** Photocatalysis is a promising technology in the synthesis of fine chemicals and pharmaceuticals allowing the conversion of solar energy into valuable chemicals. Although the widespread application of photocatalysis in industry is yet to be realised, the development of heterogeneous photocatalysts brings promissing advantages over their homogeneous counterparts such as easy separation and potential reusability, which together with the use of light, usually lead to more sustainable processes. Nevertheless, one of the main challenges is to ensure good performance after the first catalytic cycles. Active catalytic species can be inactivated during the catalytic process leading to reduced catalytic efficiency, and with that loss of the advantages of heterogeneous catalysis. We have recently developed an innovative approach to extend catalysts lifetime, 'catalytic farming', based on the crop rotation system used in agriculture.[1] In this innovative approach, different catalytic reactions are performed in sequence using the same catalyst (reaction rotation). As a result, poisoning of the catalyst is prevented because if one reaction depletes certain catalyst properties, they can be restored by another reaction during the next catalytic cycle, thereby extending the catalyst lifetime. However, the approach still relies on multiple separation steps and complete change of reaction conditions between cycles, which limits the sustainability of the process. Here we present our efforts to extend the catalyst lifetime by using the photocatalysts in sequential reactions with minimal changes in the reaction conditions. The catalyst of choice to illustrate this strategy is palladium-decorated titanium dioxide, Pd@$TiO_2$, is used in sequential catalytic reactions involving organic transformations such as C-C couplings [2] and hydrogenations[3] (Scheme 1).

**Scheme 1 | Method design. a.** Traditional two-step methodology for formation of new single C-C bonds from cross couplings involving alkenes. **b.** This work approach: sequential cross coupling and transfer hydrogenation reactions triggered by changing irradiation wavelength. **c.** Suggested mechanisms.

**Results and discussion.** Here we show a sequential photocatalytic method for Sonogashira coupling and transfer hydrogenation reactions is possible, using identical reactions conditions but replacing the irradiation energy. Both, transfer hydrogenations or C-C couplings can be triggered under room temperature and atmospheric pressures and remarkably, the photocatalyst selectivity can be easily tuned by subjecting the reaction to different photon flux. Apparent poisoning of the catalyst is circumbented by filtration of organoiodide species during the first reaction step. The results are rationalised using *in situ* surface analyses (XPS) that suggest changes on the Pd oxidation state are triggered by the presence of the solvent.

**Keywords:** photocatalysis, halogen bond, autocatalysis, biaryl sultams, continuous flow, DFT

**Introduction.** Cyclic biaryl species are relevant bioactive compounds in medicinal chemistry research and are ubiquitous in pharmaceuticals. Specifically, biaryl sultams (**BASN**) are biologically active compounds and are emerging anticancer species.[1] Classically, biaryls are accessed by expensive transition metal catalysis. Our group explores how non-covalent preassemblies benefit organophotocatalytic system.[2] Thereby, we now report the discovery of a photo-autocatalytic pathway, an efficient process where the product itself acts as a photocatalyst, for the synthesis of **BASN**.

**Experimental/methodology.** Photochemical batch reactions were carried in a degassed 5 mL crimp vials using 451 nm LEDs. Commercially available Vapourtec R-series was used for scaling up the reaction under continuous flow conditions. Design of Experiments (DoE) was used to optimize the reaction conditions and Gaussian was utilized for the density functional theory (DFT) computational analysis of the reaction mechanism.

**Results and discussion.** We discovered that **BASN** can be synthesized using visible light without the need of an external photocatalyst (Figure 1). In fact, our computational, kinetic, and other mechanistic studies reveal the slow visible light activation of trialkyl amine – substrate (**1a**) initiates the process, while the accumulation of deprotonated product **2b** (**BASN**) accelerates the reaction which is the key feature of autocatalysis. We have successfully applied the synthesis of various **BASN** (**2b** to **2e**) using flow with decagram per day of productivity, expanding this chemistry's utility for large scale synthesis. We envisage a translational impact from our research to other fields beyond only catalysis due to this autocatalytic behavior.

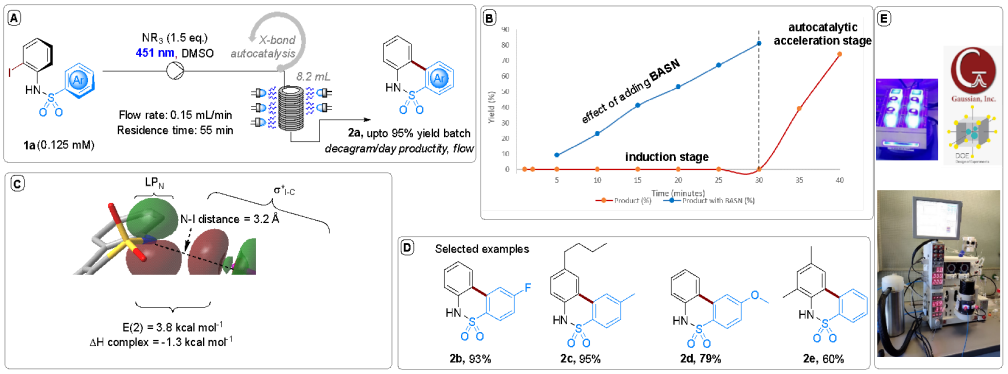

**Figure 1: [A] Synthesis of BASN using visible-light autocatalysis in flow set-up, [B] kinetic profile as key proof of autocatalysis, [C] DFT investigation of BASN$^-$-1a halogen bond, [D] selected substrate scope, and [E] reaction set-up in batch (top right) and flow (bottom) along with software (top and middle left) used in the study.**

# Photocatalytic oxygen transfer as an innovative route for $N_2O$ upgrading

O. Delaunay, A. Denicourt-Nowicki*, A. Roucoux*

*Univ Rennes, Ecole Nationale Supérieure de Chimie de Rennes, CNRS, ISCR – UMR 6226, F-35000 Rennes, France.*

**audrey.denicourt@ensc-rennes.fr ; alain.roucoux@ensc-rennes.fr*

**Keywords:** photocatalysis, nitrous oxide, oxygen transfer, sustainable chemistry, silver on titanium dioxide

**Introduction.** Nitrous oxide ($N_2O$) is the third greenhouse gas after carbon dioxide and methane, with a global warming potential of almost 300 times higher compared to $CO_2$ owing to its long lifetime (114 years) in the atmosphere.[1] The emissions principally arise from chemical industries, for instance those producing nitric or adipic acid, which will have to face more drastic European standards concerning this gas, currently burnt in flares,[2] a destructive and energy-consuming process. In a sustainable way, upgrading $N_2O$ as an oxygen source in oxidation reactions appears relevant, but its activation remains challenging due to its weak reactivity. To alleviate the drastic temperatures generally required, photocatalysis constitutes a milder alternative to activate $N_2O$ and selectively oxidize organic compounds. Herein, we demonstrate the efficient photoactivation of $N_2O$ with silver-doped titanium dioxide and unlock its potential as oxygen atom transfer, using phosphines as molecular probes.[3]

**Experimental/methodology.** Silver-doped titanium dioxide ($Ag/TiO_2$) catalyst was easily prepared by a straightforward photodeposition process. Oxidation of phosphines was performed under UV-light irradiation, at nitrous oxide atmosphere (1 bar), with low metal loadings. Composition of the gas phase in the reactor, monitored by GC-BID, was a proof of concept of the efficient decomposition of $N_2O$ into dinitrogen ($N_2$).

**Results and discussion.** Silver-doped $TiO_2$ catalyst specifically activates nitrous oxide at a very low metal loading (0.16 wt%) and the efficient oxygen transfer from $N_2O$ to phosphines under photocatalytic activation in a gas-liquid-solid system was achieved with complete conversion and selectivity, only releasing $N_2$ as sole benign co-product (Figure 1). Moreover, nitrous oxide is more selective than dioxygen, allowing only transfer to the phosphorus atom without mineralization. The reaction was extended to other phosphines in various organic solvents and also innovatively in water. Finally, the presence of silver was found crucial to catalytically activate $N_2O$ and a mechanism corroborated by blanks experiments was proposed.

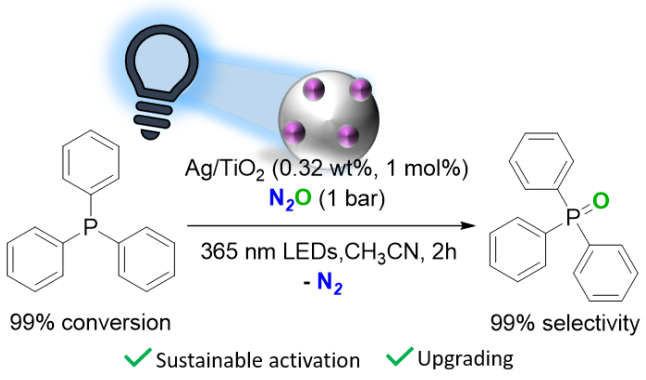

**Figure 1. $Ag/TiO_2$ catalyzed photocatalytic activation of $N_2O$ coupled with oxidation of triphenylphosphine.**

# Photocatalysis for artificial photosynthesis aiming at carbon neutral

A. Kudo

*Faculty of Science & Carbon Value Research Center, Tokyo University of Science, Tokyo, Japan*

**Keywords:** Photocatalyst, Water splitting, $CO_2$ reduction, Artificial Photosynthesis, Carbon neutral

**Introduction.**

Photocatalytic water splitting and $CO_2$ reduction are promising reactions to solve resources, energy, and environment issues, and achievement of carbon neutral. These reactions are regarded as artificial photosynthesis, because light energy is converted to storable chemical energy. In the present paper, various metal oxide and sulfide photocatalysts and semiconductor photoelectrodes for water splitting and $CO_2$ reduction using water as an electron donor are introduced and discussed.

**Results and discussion.**

(1) Photocatalytic water splitting for green $H_2$ production

$Rh_{0.5}Cr_{1.5}O_3/AgTaO_3$ (BG 3.4 eV) of a valence-band-controlled metal oxide photocatalyst gave 40% of an apparent quantum yield at 340 nm and 0.13% of a solar to hydrogen conversion efficiency [1]. However, this photocatalyst responds to only UV light because of the wide band gap. It is a challenging topic to develop photocatalysts responding to light with long wavelength. Rh and Sb-codoped $SrTiO_3$ photocatalyst loaded with $IrO_2$ was active for water splitting into $H_2$ and $O_2$ under visible light and simulated sunlight irradiations as a single particle type photocatalyst [2]. This photocatalyst responds to 520 nmof visible light. Moreover, we recently developed Ir-doped $SrTiO_3$ that showed the activity for water splitting up to 600 nm of visible light. On the other hand, $SrTiO_3$:Rh and several metal sulfides of a $H_2$-evolving photocatalyst and $BiVO_4$ of an $O_2$-evolving photocatalyst constructed various type of Z-schematic photocatalyst systems with $Fe^{3+}/Fe^{2+}$, $[Co(bpy)_3]^{3+/2+}$, $[Co(phen)_3]^{3+/2+}$, and a conductive reduced graphene oxide (RGO) as an electron mediator and even without an electron mediator [3]. Various types of Z-scheme systems for water splitting under visible light irradiation were also successfully developed by employing Rh- and Ir-doped metal oxide powdered materials with relatively narrow energy gaps (EG) to utilize wide range of visible light [4].

(2) Photocatalytic $CO_2$ reduction using water as an electron donor for CCU

Ag cocatalyst-loaded $ALa_4Ti_4O_{15}$ (A = Ca, Sr, and Ba) [5] and tantalates photocatalysts [6,7] such as $NaTaO_3$:Ba with 3.79–4.1 eV of band gaps showed activities for $CO_2$ reduction to form CO and HCOOH in an aqueous medium without any sacrificial reagents. CO is the main reduction product rather than $H_2$ even in an aqueous medium. Especially, the $Ag/NaTaO_3$:Ba photocatalyst gave ca. 90% of the selectivity for the $CO_2$ reduction [6]. When Rh-Ru cocatalyst is used instead of Ag, $CH_4$ was formed with ca. 10% of the selectivity [7]. Thus, an uphill reaction of $CO_2$ reduction accompanied with water oxidation was achieved using the Ag- and Rh-Ru-loaded metal oxide photocatalysts with wide bandgaps. We also constructed a Z-scheme system consisting of $(CuGa)_{0.5}ZnS_2$ of a $CO_2$-reducing photocatalyst with $BiVO_4$ of an $O_2$-evolving photocatalyst and RGO of an electron mediator for $CO_2$ reduction using water as an electron donor. The Z-scheme system gave $H_2$, $O_2$, and CO simultaneously under visible light irradiation [8].

**Keywords:** hydrogen peroxide, photocatalysis, heterogeneous catalysis, hydrogen energy, green chemistry

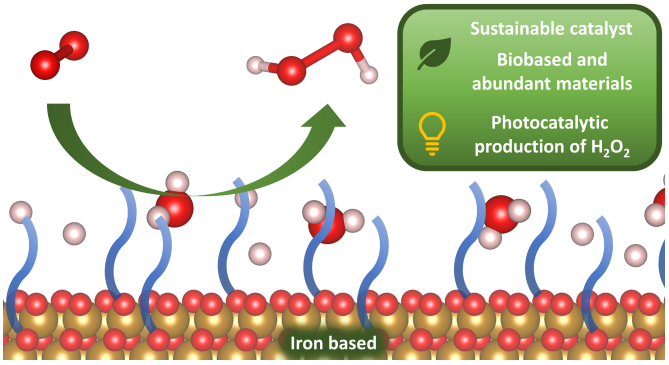

**Figure 1: Graphical abstract depicting photocatalytic oxygen reduction to hydrogen peroxide.**

Over the last decade, researchers across the globe strived for a more sustainable production of hydrogen peroxide ($H_2O_2$) as powerful disinfectant, detergent, or oxidant in chemical synthesis.[1] As the global market for $H_2O_2$ is estimated to grow at a compound annual growth rate (CAGR) of 3.2% to 5.7 million tons by 2027, the demand for a greener alternative to the 80-year-old anthraquinone (AQ) process increases dramatically.[2] Facing climate change, the AQ oxidation process is considered untenable as it produces harmful organic waste and requires significant energy input generated from fossil fuels. As hydrogen peroxide is an efficient and environmentally benign oxidant ($H_2O$ and $O_2$ as only sideproducts), sustainable modernization of its manufacturing process is key. $H_2O_2$ recently was suggested as an advantageous energy carrier over $H_2$ – being fully soluble in water, thus storable, safer operation, and transportation can be realized. A $H_2O_2$ fuel cell with + 1.09 V vs. the normal hydrogen electrode (NHE) is comparable to a conventional hydrogen fuel cell (+ 1.23 V vs. NHE), consequently utilizing green and sustainable energy sources such as solar energy to produce $H_2O_2$ directly from water would be a significant breakthrough.[3] The future energy transition towards renewables (solar and wind energy) could lead to the application of $H_2O_2$ as energy carrier to overcome seasonal and day and night cycles. Thus, the decentralized photocatalytic production of $H_2O_2$ from $O_2$ or $H_2O$ on smaller scales could deliver cost-effective dilute $H_2O_2$ on demand, which is more suitable for a wide range of applications. In this research we are focusing on the development of a new photocatalytic system for the production of $H_2O_2$ from water and sunlight. Hence skipping the (solar-)electricity needed for water oxidation in electrolyzers and directly utilizing the solar energy to produce $H_2O_2$ as future energy carrier for the energy transition would be considered as substantial advancement. A new heterogeneous photocatalyst for the formation of $H_2O_2$ has been developed, based on green principles: Only allowing earth-abundant materials and metals, biomass-based sources for organic compounds as catalyst material, synthesis of the catalyst only in ethanol and avoiding solvent-intense purification techniques (extraction, chromatography etc.). The heterogeneous catalyst material offers for recycling for up to 7 rounds and is producing $H_2O_2$ with blue light (445 nm) within 5h photocatalytically at room temperature. It was also successfully applied by testing the production of $H_2O_2$ with real sunlight and in seawater.

**Keywords:** Photocathode; donor-acceptor dye, molecular twisting, $H_2$ evolution

The performance of dye-sensitized photoelectrochemical (DSPEC) cells is currently limited by the low efficiency of the photocathode.[1-3] Donor-acceptor (D-A) dyes for photosensitization of the p-type semiconductor have been designed to prolong light-induced charge separation by spatially separating electrons and holes.[4] However, other effects of photoinduced changes on the performance have not been extensively investigated. We demonstrate that photoinduced twisting of a D-A P1 dye adsorbed onto NiO determines the ultrafast dynamics and photoelectrochemical performance. Twisting can be manipulated by co-adsorption of myristic acid, which has a carboxyl anchoring group and a long apolar alkyl chain. Time-resolved photoluminescence and Density Functional Theory studies show that the probability of twisting is lowered by the presence of myristic acid and that this increases the energy levels of the photoexcited state of the D-A dye. The presence of myristic acid also favors light-induced charge separation, as apparent from femtosecond transient absorption, and increases the photocurrent. Very interestingly, only in the presence of myristic acid light-induced $H_2$ evolution is observed in aqueous media, despite the absence of a $H_2$ evolution catalyst.(Figure 1b) We assign the $H_2$ generation to a synergetic effect of inhibited twisting of the D-A dye radical anion increasing its electrochemical potential, combined with adsorption of $H^+$ on the hydroxylated NiO surface. Our work demonstrates that control of twisting offers a simple design approach for efficient solar fuel devices.

**Figure 1. **Introduction**

Photo-thermal catalysis offers the advantage of exploiting both thermal and non-thermal contributions of sunlight[1], overcoming the inherent limitations of traditional photochemical processes. This approach offers the possibility to produce the so-called solar fuels from carbon dioxide ($CO_2$) and thus represents a promising approach not only to alleviate $CO_2$ emissions but also to efficiently store renewable energy in the form of chemical bonds. In this work, we demonstrate the synthesis of Ni NPs dispersed on a carbon matrix via controlled pyrolysis at different temperatures of a metal-organic framework (MOF) precursor. The optimized catalyst was tested in the light-mediated $CO_2$ methanation reaction, displaying high conversion rates, selectivity, and long-term stability.

**Experimental/methodology**

Ni-MOF-74 was synthesized according to the reported method[3]. Once synthesized, Ni-MOF-74 was pyrolyzed in a tubular oven under a continuous flow of $N_2$ for 6 hours at temperatures of 500, 600, and 700 ºC. Samples were characterized by powder X-ray diffraction (PXRD), transmission electron microscopy (TEM), Raman spectroscopy, and X-ray photoelectron spectroscopy (XPS). The catalytic activity was tested in a batch quartz reactor using a 300 W Xe lamp as light source.

**Results and discussion**

Among all the samples, Ni@C-600 displayed the highest temperature under light radiation, thus leading to very high $CH_4$ production rates of 488 mmol $g^{-1}$ $h^{-1}$ (Figure 1a). Further mechanistic studies revealed that the system is mainly operated by a light-to-heat conversion. We also performed an additional catalytic test using a flow-type reactor and, under optimal conditions, the Ni@C-600 catalyst exhibited a notable $CO_2$ conversion ranging from 42 to 57 % after more than 12 consecutive hours of reaction without evident deactivation (Figure 1b)[4].

**Keywords:** photocatalysis, water splitting, liquid solar fuels, Density functional theory

**Introduction.** Renewable generation of fuels via solar energy offers promising pathways towards sustainable energy future. Its deployment hinges on the discovery of electrochemically durable materials with good solar-to-chemical conversion efficiency. Prerequisite visible spectrum photoresponse from electrochemically stable materials is however quite rare. On the other hand, the oxygen evolution reaction (OER) requires electrodes that are not only catalytically active, but also stable under harsh electrochemical environments

**Methodology.** Electronic Structure Calculations of bulk geometries and surface slabs were perfromed at the spin-polarized, GGA Hubbard U-level within the computational hydrogen electrode model. Composition library synthesis and XRD/TEM/XAS characterization and OER Catalytic and Photo-electrochemistry measurements

**Results and discussion.** In this talk, we report on and theoretical understanding of photo-electrochemical behavior an amorphous and crystaline versions of Ni-Sb-Ox and Co-Sb-Ox oxide photoanodes discovered via high-throughput experimental screening. The newly discovered amorphous phases [1, 2] meet the requirements of operational stability, visible photoresponse, and appreciable photovoltage. Guided by experimental X-ray absorption characterization of these systems we use density functional theory calculations to perform a prototype phase search to identify a broad family of stable and metastable mixed rutile and hexagonal-like phases for other compositions [3]. Detailed Pourbaix analysis of the identified phases show excellent electrochemical stability, consistent with experimentally measured low metal ion concentrations in the electrolyte of photoelectrochemical cells. We analyze when he identified phases form favorable oxygen vacancies formation energies under the reducing synthesis conditions which match measured Ni K-edge x-ray absorption spectra. The calculated OER overpotentials for the most active sites decreases with increasing Ni/Co content, which captures the experimentally observed trend. Stable amorphous metal-antimonates photoanodes established are important systems for computational understanding of both the structural and catalytic behavior of these complex oxides and elucidating the co-optimization of activity and durability in metal antimonates.

# Modulating the Nanostructure of Carbon Nitride for Improved Continuous-Flow Trifluoromethylation of (Hetero)Arenes

Alessandra Sivo[1], Vincenzo Ruta[1], Dr. Mark A. Bajada[1], Prof. Dr. Gianvito Vilé[1]*

[1]*Politecnico di Milano, Piazza Leonardo da Vinci 32, 20133 Milano (Italy)*
[*]*Corresponding author email: gianvito.vile@polimi.it*

**Introduction.** In recent years, visible light catalysis has emerged as a game-changing technology for creating a new generation of chemical processes. However, scaling up these reactions has proven difficult due to light transmission limitations in batch reactors and the high cost of commonly-employed Ir or Ru-based homogeneous photocatalysts [1]. For example, trifluoromethylation reactions, widely used in fine chemical production, rely heavily on batch methods and expensive transition metals. Herein, we report using metal-free carbon nitride, a material with excellent photostability and adjustable surface area [2], for the trifluoromethylation of heteroarenes, examining the impact of catalyst structuring to enhance reaction efficiency and production capacity. This approach offers new possibilities for scalable, cost-effective trifluoromethylation of heteroarenes.

**Experimental/methodology.** The catalysts in powdered and structured form were characterized via various techniques, such as XRD, $N_2$ physisorption, XPS; XAS, TEM, FIB-SEM, and tomography. A structured reactor was contructed using a FEP tube (2 mm internal diameter, 500 mm length) fileld with a mixture of base (1.32 mmol), glass beads (2.4 g), and catalyst (50 mg). The (hetero)aryl reagent and TfCl were introduced via syringe pumps into the assembled photoreactor. The reaction mixture was exposed to light using a PhotoCube reactor. Yields and conversions were determined by $^1$H, $^{13}$C NMR, and HPLC.

**Results and discussion.** Initial batch photocatalytic studies showed that mesoporous graphitic carbon nitride ($mpgC_3N_4$) had superior catalytic properties compared to bulk graphitic ($gC_3N_4$) and nanosheet ($nC_3N_4$) carbon nitrides, resulting in a substantial increase in yield of trifluoromethylpyrrole (from 6 to 80%), at 60 min. Flow technology was adopted in order to provide a uniform radiation distribution inside the reactor, and satisfy the constraints imposed by the Beer-Lambert Law for photoinduced chemical transformations. We demonstrated that the packed-bed and structured reactor designs with porous framework of $mpgC_3N_4$ offered a unique environment to scale-up the process and minimize mass transfer limitations of the multicomponent reaction, showing an increase in the production rate of the desired model trifluoromethylpyrrole of almost 50%, in relation to the batch method. Also, the use of glass beads and polymeric structural motifs as a packing material reduced particle competition for the absorption of visible-light photons. The stability of the catalyst (as verified by time-on-stream analysis) and the facile recyclability of the photocatalytic system (as a consequence of the immobilization of $mpgC_3N_4$) corroborated the importance of continuous flow reactor design for the photocatalyzed trifluoromethylation process. The protocol was successfully applied to trifluoromethylate pyrroles, indoles, and imidazoles, demonstrating the technique's versatility for various compounds.

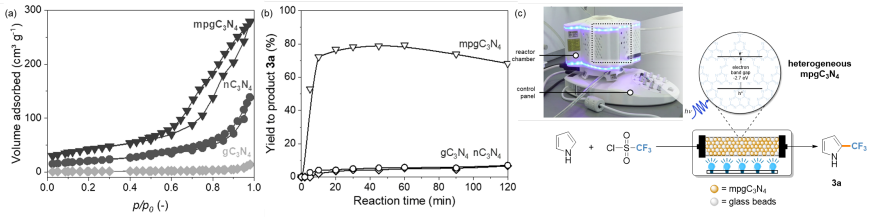

**Figure 1.** $N_2$ physisorptions of $nC_3N_4$, $nC_3N_4$, and $mpgC_3N_4$ catalysts (a), comparison of the microkinetic performance of the catalysts at T = 40°C (b), sketch of the structured photoreactor (d).

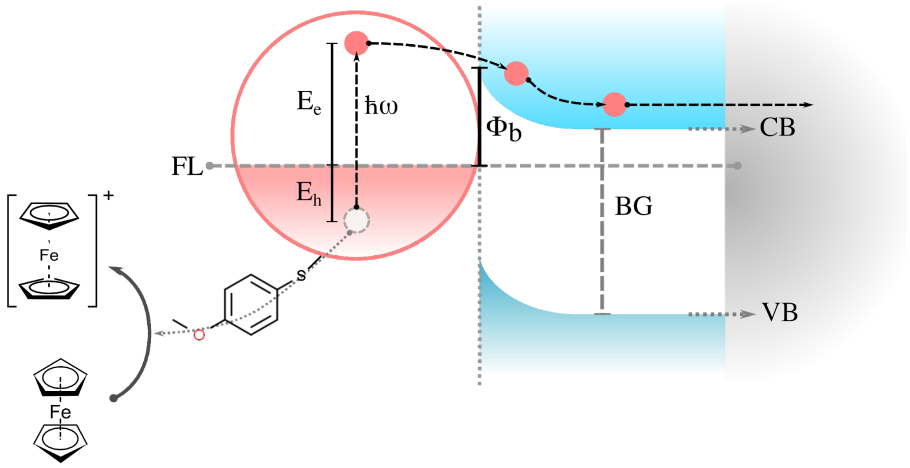
# Surface molecularization of plasmonic systems for photo-redox catalysis

R. Bericat-Vadell[1*], P.Senkar[1], X. Zou[1], J. Sá[1, 2]



[1]*Physical Chemistry Division, Department of Chemistry – Ångström, Uppsala University, Uppsala, Sweden.*
[2]*Institute of Physical Cemistry, Polish Academy of Sciences, Warsaw, Poland.*
[*]*robert.bericat.vadell@kemi.uu.se*

**Keywords:** Plasmonics, Photo-redox catalysis, Ultrafast Time-Resolved Spectroscopy, Chronoamperometry.

**Introduction.** Organic photo-redox catalysis is one of the fastest growing fields in the research on Organic Chemistry, with high relevance for both the academic and industrial sector. Currently, the most frequently used light absorbers, also termed photocatalysts, are transition metal complexes or organic pigments that have been known for many decades. We argue that some approaches fundamentally different from these traditional means to initiate the photochemical reactions have the potential to open up new avenues in the field. In this sense, our research is focused on the development of novel gold plasmonic nano-hybrid architecture as light absorbers, aimed at photo-redox organic synthesis. More specifically, the project presented herein studies "molecularization" strategies for plasmonic systems; we design catalytic systems where plasmonic structures can behave as molecular catalysts. The aim with this research is to merge the qualities of plasmonic systems (efficient and tuneable absorption of light) with those of molecular photo-systems (single charge transfer capabilities and high chemical selectivity).

**Experimental/methodology.** To fabricate the studied systems, the surface of our plasmonic structure is functionalized with molecules (thiols) capable of acting as catalytic centres. During photoexcitation, hot carriers are generated at the plasmonic nanoparticle. Hot electrons inject in the n-type semiconductor (TiO2) and subsequently travel to the electrode, while hot holes are transferred first to the thiols and from there are used to oxidise ferrocene. The photo-system photocatalytic performance is tested via ultrafast transient spectroscopy and electrochemical studies, which provide information on the system capability of converting light into charge carriers and then oxidising the substrate.

**Results and discussion.** For the time being, we have already gathered spectral evidence of the charge transfer between the plasmonic gold (light absorber), the attached thiol (4-methoxythiophenol) and TiO2. We have also measured photocurrents associated to the oxidation of ferrrocene by our photocatalytic system.

**Keywords:** gold nanoparticle, surface plasmon resonance, photodissociation

**Introduction.** Gold(Au) nanoparticles possess unique properties and absorb visible light at around 550 nm due to a phenomenon called surface plasmon resonance (SPR). Two main mechanisms have been proposed for reactions over plasmonic photocatalysts. One of them is a plasmon-induced electron transfer mechanism; hot electrons are injected to the conduction band of metal oxides and then redox reactions proceed. Various plasmon-induced reactions such as water splitting and hydrogen production have been reported [1][2]. The other is a direct molecule activation mechanism; transfer of electrons from Au particles to molecules in a specific electronic state induces dissociation and desorption of the molecules. In previous study, it was reported that hydrogen ($H_2$) molecules are dissociatively adsorbed on Au nanoparticles under irradiation of visible light[3]. However, this dissociated hydrogen has not been used for hydrogenation reaction. Therefore, we attempted to use hydrogen photodissociatively adsorbed on Au particles for hydrogenation of organic compounds. In this study, we investigated hydrogenation of styrene (ST) to ethylbenzene (EB) over $Au/ZrO_2$ and propose the expected mechanism of this reaction.

**Experimental/methodology.** $Au/ZrO_2$ was prepared by a deposition-precipitation method. The $ZrO_2$ powder was suspended in 100 $cm^3$ of an aqueous solution containing an $HAuCl_4$ and NaOH. The suspension was stirred at 343 K for 2 h and the resultant powder was thermally treated in a tubular furnace under a flow of $H_2$ at 527 K for 2 h. $Au/ZrO_2$ (50 mg) was suspended in 5 $cm^3$ of an acetnitrile solution in a test tube and, after replacing the gas phase with $H_2$, ST (*ca*. 30 μmol) was added. The test tube was photoirradiated at 20°C with a green LED. The liquid phase after the reaction was analyzed with a gas chromatograph.

**Results and discussion.** Hydrogenation of ST over $Au/ZrO_2$ did not occur under the dark, indicating that hydrogen molecules are not dissociatively adsorbed on Au particles in the dark. On the othe hand, under irradiation of visible light, ST was hydrogenated to EB, which means that $H_2$ molecules are dissociated on Au particles under light irradiation and can be used for the hydrogenation. To determine whether the observed reaction occurs via a plasmon-induced process, we collected the action spectrum. Figure shows the absorption spectrum of $Au/ZrO_2$ and the action spectrum of hydrogenation of ST over $Au/ZrO_2$. Apparent quantum efficiency (AQE) at each centered wavelength of light was calculated from the ratio of the double amount of EB and the amount of photons irradiated using the following equation.

$$\mathrm{AQE}=\frac{2\times \text{the amount of EB}}{\text{the amount of incident photon}}\times 100$$

As shown in Figure, the tendency of AQE was similar to the absorption spectrum of $Au/ZrO_2$. Therefore, it can be concluded that hydrogenation of ST to EB over $Au/ZrO_2$ was induced by photoabsorption due to SPR of Au nanoparticles.

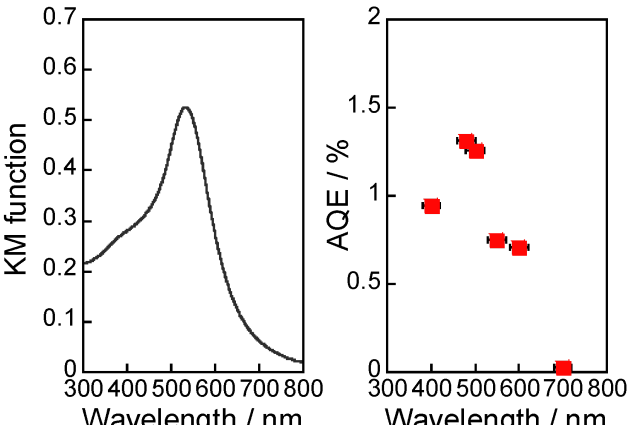

**Figure Absorption spectrum of $Au/ZrO_2$ (left) and action spectrum of $Au/ZrO_2$ in hydrogenation of ST to EB (right).**

**Keywords:** Trifluoromethylthiolation, Photocatalysis, Radical, Difunctionalization, Alkenes.

**Introduction.**Trifluoromethylthio ($SCF_3$) group is considered to have excellent lipophilicity due to its high Hansch's hydrophobicity parameter ($\pi$ = 1.44).Thus it is highly desirable to develop practical synthetic methods for the introduction of $SCF_3$ group. Langlois reagent ($CF_3SO_2Na$) [1], which has cheap price and stable properties, is a well-known radical trifluoro-methylation reagent.[2] Recently,we developed a novel and practical trifluoromethylthiolation of activated alkenes with $CF_3SO_2Na$ through deoxygenative reduction and photoredox radical processes, which present an unprece-dented application of $CF_3SO_2Na$ as a radical $SCF_3$ source.

**Experimental/methodology.** A 25 mL Schlenk flask equipped with a magnetic stir bar was charged with $Ir(ppy)_3$ (1.7 mg, 0.001 mmol, 0.5 mol%) .The flask was evacuated and refilled with $N_2$ for three times. The vessel was then charged with dry MeCN (4.0 mL), activated alkene (0.5 mmol, 1.0 equiv), $PPh_3$ (655mg, 2.5 mmol, 5 equiv) and $CF_3SO_2Na$ (234mg, 1.5 mmol, 3.0 equiv) .The flask was placed at a distance of 2 cm from the blue LED. The mixture was stirred under nitrogen atmosphere and irradiated by blue LED for 6 h. Upon completion, the volatiles were removed under vacuum and the residue was purified by column chromatography to give the corresponding products.

**Results and discussion.** We investigated the scope of the transformation with respect to the aldehydes. A variety of N-methyl-N-phenylmethacryl amides with substituents at para, meta, as well as ortho positions ($R^1$) in the aniline ring were aryltrifluoromethylthiolated smoothly to give the corresponding oxindoles in moderate to good yields (75-83% yield). The substitute effect at the α-position ($R^2$) of the acrylamides was next explored, and it was found that several α-sustitutents, including benzyl, methoxyl, and ester, were compatible with this transformation to furnish the desired products in good yields (75-83% yield). Substrates with different protecting groups ($R^3$) also performed well (70-73% yield).

# $CO_2$ Hydrogenation with Plasmonic Nanomaterials: Black Gold and Nickel Nitride Nanosheets

Rishi Verma, Saideep Singh, and Vivek Polshettiwar*

*Department of Chemical Sciences, Tata Institute of Fundamental Research (TIFR), Mumbai, India*

**Abstract**

Localized surface plasmon resonance (LSPR) enables solar light catalysis of difficult reactions by generating hot charge carriers on the nanoparticle surface, leading to novel and targeted reaction pathways.[1-5] For efficient light absorption and catalytic activity, the photocatalyst should absorb the whole solar broadband spectrum. Dendritic plasmonic colloidosomes (DPC-C4)[6], commonly known as "black gold," a recently discovered novel nanomaterial from our group, might be a good option. Black gold, comprising Au nanoparticles on nanosilica (DFNS)[7], displays high absorbance of visible and near-infrared light due to its heterogeneous particle size distribution and interparticle lengths. However, its hot electron transfer efficiency is limited.[6] To extract these hot electrons, we then synthesized black gold loaded with nickel sites (DPC-C4-Ni).[8] Under light excitation, DPC-C4-Ni excel over DPC-C4 and DFNS-Ni in terms of photocatalytic $CO_2$ hydrogenation activities. DPC-C4-Ni shows a very high photocatalytic CO production rate (2464 ± 40 mmol $g_{Ni}^{-1}$ $h^{-1}$) with 95 % CO selectivity. Notably, the reaction was carried out in a flow reactor at low temperature and atmospheric pressure without external heating. The photocatalyst was stable for at least 100 h.[8]

Although black gold-nickel displayed promising catalytic activity for $CO_2$ hydrogenation, the requirement for high light intensity is a critical aspect to address. As an alternative, we suggest exploring the potential of hydroxy-terminated nickel nitride ($Ni_3N$) nanosheets as a feasible substitute for traditional plasmonic metals.[9] The synthesized $Ni_3N$ nanosheets exhibited broadband light absorption spanning from visible to near-infrared regions of the solar spectrum. The $Ni_3N$ nanosheets showed an excellent CO production rate (ca. 1212 mmol $g^{-1}$ $h^{-1}$) and 99 % selectivity towards CO under flow conditions using visible light (although it also required high light power).[9]

The photocatalytic $CO_2$ hydrogenation reaction mechanism and the role of non-thermal versus the thermal effect of plasmonic catalysis in the case of DPC-C4-Ni and $Ni_3N$ nanosheets were further explored by using (i) finite-difference time-domain simulations (FDTD), (ii) light-intensity-dependent production rate, (iii) light-intensity-dependent photocatalytic quantum efficiencies, (iv) wavelength-dependent production rate, (v) kinetic isotope effect (KIE), (vi) temperature program stability study of $Ni_3N$ nanosheets, (vii) *in-situ* diffuse reflectance infrared Fourier transform spectroscopy (DRIFTS), and (viii) ultrafast transient absorption spectroscopy studies.[8,9]

**Keywords:** Tailored crystals; Anatase; $TiO_2$; Nitroaromatics; Photocatalysis

**Introduction.** Titanium dioxide is one of the most widely used materials in photocatalysis. This material has also been established to be very active in organic synthesis reactions, including the reduction of nitroaromatic compounds. The crystallographic facets of titanium dioxide (especially anatase crystal facets) differ in their photocatalytic properties [1]. Upon UV light irradiation, the photogenerated charges, electrons and holes, segregate into the facets of tailored crystals. As a result, the particular facets become enriched with holes or electrons. In general, depending on the proceeding photocatalytic reaction (reduction or oxidation), crystals with predominantly exposed different facets should be considered as favoured photocatalysts. Furthermore, different atomic arrangements, as well as Ti-O-Ti bond angles at various exposed facets, can differently interact with reagents. The impact of exposed facets in the context of photocatalytic organic synthesis, in particular the reduction of nitroaromatic compounds, has so far been studied to a limited extent.

**Experimental/methodology.** The phase compositions and crystal shapes of materials were studied by powder X-ray diffraction and scanning electron microscopy. The photocatalytic reduction reactions were conducted with 3-nitrophenol and 1-iodo-4-nitrobenzene. The changes in the concentration of substrate and products were detected with HPLC analysis. The electron transfer activity of $TiO_2$ electrodes was measured using a rotating disk electrode.

**Results and discussion.** The studies showed that the photocatalytic reduction of nitroaromatic compounds (3-nitrophenol and 1-iodo-4-nitrobenezene) strongly depends on the exposed facets and increases in the order: sheets, tetragonal truncated bipyramids, belts, showing the predominant role of the {100} facet.

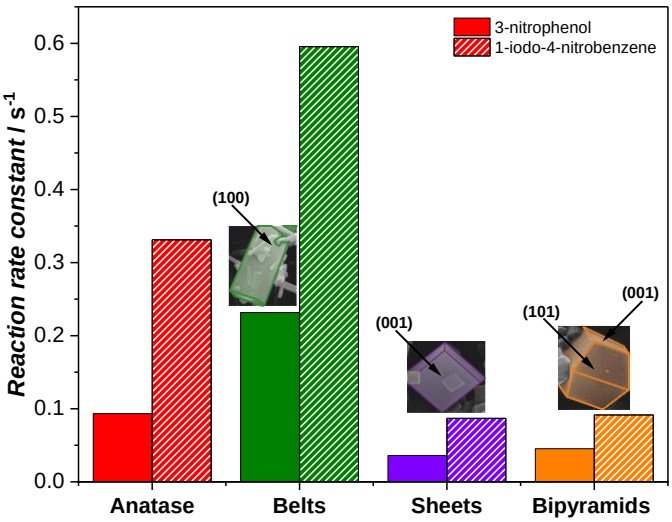

**Fig. 1.** Reaction rate constants at tailored anatase-$TiO_2$ in reduction of 3-nitrophenol and 1-iodo-4-nitrobenzene.

# $H_2$ Production by plastics photoreforming using SiC-g-$C_3N_4$ composites

Maria Teresa Armeli Iapichino [1*], Stefano Andrea Balsamo[1], Roberto Fiorenza [1], Salvatore Scirè[1]

**Keywords:** Carbon nitride, silicon carbide, Hydrogen, Photoreforming.

**Introduction.** Hydrogen is regarded as one of the most promising energy carrier thanks to its high energy density and its lower heating value. One of the green ways to obtain hydrogen is photocatalysis through solar photoreforming of water. This process combines the water reduction with the organic oxidation on a semiconductor material. In a typical process, the electrons in the photocatalyst are excited by sunlight to the conduction band (CB) and these reduce the protons of water to $H_2$. The choice of the organic substrate is fundamental to drive selectively the byproducts formation with the contextual $H_2$ evolution, and to enhance the charge carriers separation on the surface of the photocatalysts, being the organic substrate a holes scavenger. In this context, bisphenol A (BPA) and polyethylene terephthalate (PET), employed as sacrificial agents, can play an important role also considering the plastics water pollution. However, one of the necessary steps for the photoreforming reaction is the efficient solubilization of these organic substrates by various pre-treatments, that requires hard conditions which can deactivate the photocatalysts [1]. The focus of this work is the study of uncommon photocatalysts as silicon carbide (SiC) coupled with graphitic carbon nitride (g-$C_3N_4$). The SiC is a widely used semiconductor in the electronic industries which can be employed as photocatalyst in the plastics photoreforming due to its high mechanical and chemical resistance. The employment of the g-$C_3N_4$ can improve the activity with the formation of heterojunctions with the main photocatalyst.

**Experimental/methodology.** To obtain the SiC-g-$C_3N_4$ composites, the silicon carbide (Sigma Aldrich) was mixed with different amounts of urea and treated at 450°C for 5h with a 5°C/min ramp to favor the thermodegradation of urea and the formation of g-$C_3N_4$ with different wt%. The sacrificial agents were BPA (Sigma-Aldrich) and PET from commercial bottles. Photocatalytic tests were carried out in a Pyrex reactor irradiated with a solar lamp for 5h. 0,05 g of photocatalyst, 10 ml of a solution of dissolved organic substrates (after the pretreatments) and 40 ml of water were placed inside the reactor at T=30°C. The $H_2$ was quantified with GC-TCD [2]. The samples were characterized by UV-DRS, XRD, XPS, $N_2$ adsorption-desorption measurements and TEM.

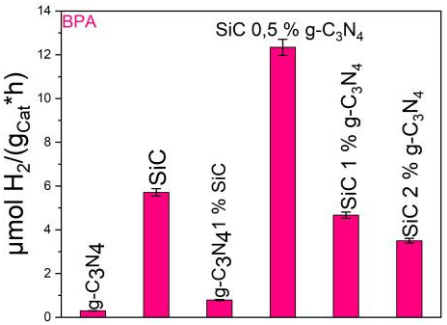

Figure 1 Photocatalytic $H_2$ production by photoreforming of BPA (pH=13)

**Results and discussion.** From Fig. 1 it is possible to note as the SiC 0,5% g-$C_3N_4$ sample was the most active towards the BPA photoreforming providing at an alkaline pH (13) 12 μmol $H_2/g_{cat}$·h. The same photocatalyst was the most active for the PET photoreforming, obtaining a minor amount of $H_2$ (2,7 μmol $H_2/g_{cat}$·h). No $H_2$ was produced at acid pH for both BPA and PET photoreforming, pointing to the strong influence on the photocatalytic activity of the pretreatment conditions of the organic substrates. Interestingly, a higher amount of g-$C_3N_4$ was detrimental for the activity, due to the covering of the SiC surface sites by the excess of carbon nitride. A low amount of g-$C_3N_4$ was essential for the formation of a SiC g-$C_3N_4$ heterojunction, that favored a strong interaction between the two components, as verified by the characterization measurements. The examined solar photoreforming reactions appear promising for an even more sustainable $H_2$ economy. The good interaction between unconventional photocatalysts as SiC and g-$C_3N_4$ allowed to explore new and green ways for the production of $H_2$ from plastic wastes.

**Keywords:** $\alpha$-$Fe_2O_3$ photoanode, CuO, solar water splitting

Hematite ($\alpha$-$Fe_2O_3$) can be an ideal photoanode material in photoelectrochemical (PEC) water splitting due to a suitable bandgap, proper band edge positions and low cost. However, the performance of hematite is limited by poor electronic conductivity, high density of surface states, short hole lifetime, and slow kinetics for oxygen evolution at the electrode/electrolyte interface. The design of $\alpha$-$Fe_2O_3$ heterostructure is a promising route for improved PEC performance.

Instead of expensive noble metal-based compounds, we introduced a Cu-based water oxidation catalyst on a nanostructured $\alpha$-$Fe_2O_3$ semiconductor. In our earlier study [1], the Cu-triglycine pre-catalyst complex resulted in $Cu_2O/CuO/Cu(OH)_2$ nanoparticle coating on indium tin oxide working electrode under the conditions of water oxidation electrocatalysis. This coating acted as an excellent electrocatalyst for water oxidation. Therefore, in this work, the $\alpha$-$Fe_2O_3$ photoanode grown on Ti substrate was modified with 'CuO' cocatalyst by the electrodeposition of the Cu-triglycine complex. The resulting hybrid nanostructure, 'CuO'/$\alpha$-$Fe_2O_3$, exhibited improved photocurrent density, charge separation and charge transfer efficiency, and lowered charge transfer resistance compared to the $\alpha$-$Fe_2O_3$ in PEC water oxidation under full spectrum irradiation.

To achieve high PEC performance, the proper attachment of the cocatalyst on the surface is essential, which depends on the preparation process and the contact between the 'CuO' and the hematite surface. The results on the PEC water oxidation of 'CuO'/$\alpha$-$Fe_2O_3$ were compared to photoanodes derived from Cu salts deposited on $\alpha$-$Fe_2O_3$ in order to show the beneficial effect of the metal complex used for the synthesis of the active cocatalyst on a semiconductor photoanode [2].

**Keywords:** ethanol photoreforming, P25, hydrogen production, in situ photodeposition, aggregates

**Introduction.** One of the most efficient photocatalysts for the photo-reforming hydrogen production is still based on the use of P25 in combination with Pt, which acts as co-catalyst[1]. However, such high cost of noble metals may hinder the practical application of this emerging technology. Herein, a significant enhancement of ethanol photoreforming hydrogen production over P25 was achieved through a simple process to create $TiO_2$ aggretates, assisted with in situ photodeposition of a lower content of Pt (0.05 wt%). A mechanism of enhancement and deactivation was then proposed based on the obtained results.

**Experimental.** The commercial Acros Organics aeroxide P25 was used as the raw photocatalyst. The aggregations were formed by the filtration of different titania suspensions. The reproducibility of this method was evaluated by replicating the synthesis more than 10 time.

**Results and discussion.** The results of XRD, XPS, $N_2$ adsorption-desorption and UV-Vis diffuse reflectance analyses indicate that the IA-P25 aggregates were successfully created without modifying the chemical and structural characteristics of the original P25. Based on SEM images, the average aggregate size of IA-P25 was measured to be 35.4 ± 2.1 µm, which is approximately 10 times larger than that of P25. According to the hydrogen production results (Figure 1), the IA-P25 presented significantly higher activities than the raw P25. Additionally, distinct deactivation behaviors could be observed between them, which could be attributed not only to the interaction of Pt atoms and oxygen vacancies, but also to the constant accumulation of intermediates[2]. After ultrasound treatment, IA-P25 showed a very similar activity as raw P25, indicating that the formation of $TiO_2$ aggregates was the main reason for the improvement and deactivation. Based on all results, the utilization efficiency of $TiO_2$ particles in IA-P25 with the presence of low content Pt was considered to be higher than in raw P25 benefiting from the formation of aggregates, which facilitated the transfer of photogenerated charge carriers from $TiO_2$ particles to the surface of Pt for hydrogen evolution, instead of recombination.

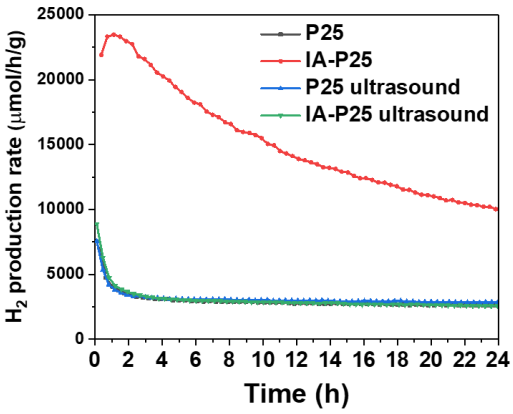

**Figure 1**. Photocatalytic hydrogen production rate of samples with 0.05 wt% Pt.

**Keywords:** plasmon catalysis, photocatalysis, syngas, CCU, *in operando* monitoring

**Introduction.** To proceed towards an energy and climate neutral chemical industry, it is vital to use sustainable energy and carbon sources for the production of carbon containing chemicals and fuels. Sunlight-powered chemical processes using biogenic $CO_2$ as feedstock fulfill these requirements. Here, we present the sunlight-powered conversion of $CO_2$ and green $H_2$ to CO, catalyzed by $TiO_2$-supported plasmonic Au nanocatalysts. Both for fundamental understanding and for rational reactor and process design, it is of vital importance to distinguish between thermal and non-thermal contributions. Therefore, we accurately monitor the temperature at multiple positions inside the catalyst bed *in operando* using a tailor-made fiber Bragg grating-based fiber optic sensor (FBG-FOS).

**Experimental/methodology.** We developed a tailored FBG-FOS to measure the temperature of the illuminated plasmonic catalyst bed at multiple positions: at the surface (0 mm), and at 0.15 mm, 0.30 mm and 0.50 mm depth. We applied this sensor for *in operando* temperature monitoring in the sunlight-powered reverse water gas shift reaction. We varied the irradiance, flow rate and feedstock composition and studied their effect on production rate, yield, selectivity, surface temperature and temperature gradient inside the catalyst bed. We applied a Au/$TiO_2$ nanocatalyst, which we prepared by deposition-precipitation of Au nanoparticles on $TiO_2$. We extensively characterized chemical composition, nanostructure and optical properties of this plasmonic catalyst.

**Results and discussion.** We successfully prepared a plasmonic Au/$TiO_2$ catalyst by deposition-precipitation of Au on anatase, and achieved a Au loading of 3.12% w/w (ICP-AES).[1] The average size of the Au nanoparticles was 1.6 nm (lognormal distribution), and their (111) lattice planes were perfectly alligned with the (101) $TiO_2$ planes. The catalyst displayed a strong plasmonic absorption in the visible, with a maximum in the wavelength range between 500 nm and 600 nm. We demonstrated that under illumination with sunlight (irradiance up to 14.4 $kW \cdot m^{-2}$), CO was produced at high selectivity of 98% without external heating of the reactor. In comparative dark experiments at similar catalyst bed temperature (~200°C), only $CH_4$ was produced. Under optimized conditions, we achieved a CO production rate of 429 $mmol \cdot g_{Au}^{-1} \cdot h^{-1}$ and reached an apparent quantum efficiency of 4.7%.[1] When studying the CO production rate as function of solar irradiance, we obtained an exponential relationship indicating the presence of a photothermal contributor. [1] To distinguish between photothermal heating and non-thermal contributors, we performed experiments using a tailored FBG-FOS temperature sensor for *in operando* temperature monitoring. We previously demonstrated this concept for off-line measurements only. [2]

**Introduction.** Hybrid halide perovskites appeared as a class of emerging semiconductors materials with broad application in the field of solar cells and, more recently, for $CO_2$ reduction, hydrogen production and organic synthesis using photocatalysis technology [1]. Unfortunately, the most efficient hybrid perovskites contain lead, a severe toxic disadvantage for its applicability. Thus, it is crucial to find non-toxic alternatives to replace lead from the perovskite structure while preserving its optical properties. Bismuth halide perovskites have attracted interest due to their photocurrent efficiency, low toxicity, and air stability.
Increased attention has been focused on the direct synthesis of imines through the oxidative coupling of benzylamines using sustainable technologies such as photocatalysis, owing to reduced energy consumption and a simplified process. This work reports an efficient procedure using bismuth hybrid perovskites as photocatalysts for oxidative coupling of amines to imines.
**Experimental/methodology.** $Cs_3Bi_2Cl_9$ (CBC) and $Cs_3Bi_2Br_9$ (CBB) perovskites were synthesized by mixing a certain amount of CsBr-to-$BiBr_3$ and CsCl-to-$BiCl_3$ precursors, respectively, using DMF as solvent at 60 °C under continuous stirring for 12 h. The photocatalytic efficiency of perovskite-based materials was evaluated using benzylamine (BZA) as subtract for N-benzylidenebenzylamine (BZI) synthesis. The reactions were performed under visible light irradiation.
**Results and discussion.** Different techniques were used to characterize the synthesized catalysts. The synthesized CBC and CBB photocatalysts match very well with the characteristic reflections in the X-ray diffraction pattern, indicating the high crystallinity of the samples. DRUV-Vis spectroscopy analyses revealed that all the materials exhibited a high absorbance band edge in the visible region. The calculated bandgap energies for CBC and CBB were 2.64 and 3.10 eV, respectively. The photocatalytic performance of the perovskites was evaluated in the oxidative coupling of BZA using CBB and CBC as photocatalyst.

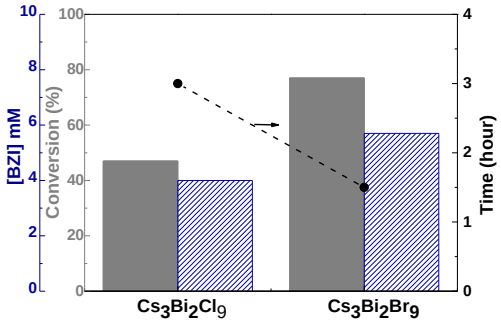

**Figure 1- BZA conversion, BZI concentration (bars) and reaction time for maximum BZI production.**

A maximum BZI concentration of 5.7 mM was attained after 1.5 hours for 77% conversion of BZA (Figure 1).

# Plasma assisted photocatalytic non-oxidative coupling of methane over FeNi-layer double hydroxides

G. De Felice[1*], S. Li[1], F. Gallucci[1] and E. Rebrov[1,2]

[1]*Eindhoven University of Technology, Eindhoven, The Netherlands*

**Keywords:** layer double hydroxides, photocatalysis, methane activation, non-thermal plasma

**Introduction.** In the last decades, light-driven catalysis for methane activation has been object of intensive studies[1]. Amongst the different photocatalysts, layered double hydroxides (LDHs) are attracting attention as efficient visible light driven photocatalysts due to their unique layered structure, tunable band gap, high versatility in chemical composition, uniform distribution of metal ions and relatively low cost[2]. In this study, FeNi-LDHs were prepared and employed in plasma assisted photocatalytic non-oxidative coupling of methane in a planar dielectric barrier discharge (PDBD) reactor.

**Experimental/methodology.** FeNi-LDHs were synthesized by hydrothermal method at a pH of 7-12. Briefly, an aqueus solution containing desirable amounts of Ni and Fe precursors, hexamethylenetetramine and sodium hydroxide was stirred for 1 h at room temperature. Then, the suspension was transferred into a Teflon lined autoclave and placed in an oven at 393 K for 24 h. The catalyst was characterized with XRD, UV-Vis, SEM/EDX, $N_2$ chemisorption, and kinetic measurements under plasma, visible light, and plasma/visible light combination. The kinetic experiments were carried out in the reactor composed of a stainless steel electrode, and a transparent ITO electrode separated by a quartz dielectric layer. The catalyst was illuminated with a visible light using a set of LED with different wavelengths.

**Results and discussion.** The results establish a uniform distribution of Ni and Fe elements in the catalyst, and the mole ratio of Ni and Fe is close to the nominal ratio. The UV visible spectra of FeNi-LDHs synthesized at different pH are shown in Fig. 1.

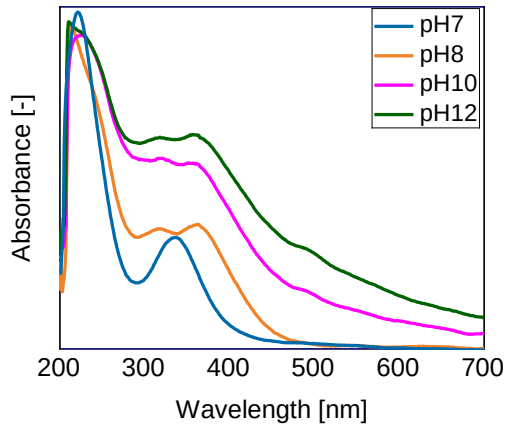

Figure 1. UV-vis spectra for samples at different pH.

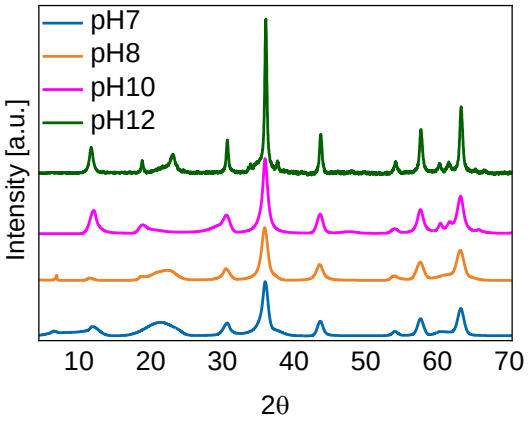

Figure 2. XRD pattern of NiFe-LDH prepared at different pH.

All the samples show a very strong UV absorption peak in the UV region (band centered at 215 nm). Samples obtained at pH>10 exhibit strong absorption characteristics in the full range from ultraviolet to visible and near-infrared light. As the pH increases, the absorption in the visible light region broadens due to a highly crystalline structure formed. The sample synthesized at pH=12 demonstrated the highest crystallinity. The XRD pattern of the synthesized FeNi-LDHs shows a lamellar structure with R3m rhombohedral symmetry (JCPDS card 22-0700)[3]. Different distributions of hydrocarbons were obtained over the catalysts.

# Photo-thermal catalysis as a tool to investigate the reverse water gas shift reaction over $Cu/Al_2O_3$

Kristijan Lorber[1,2], Jordi Sancho-Parramon[3], Janez Zavašnik[4], Iztok Arčon[2], Anže Prašnikar[1], Blaž Likozar[1] and Petar Djinović[1,2*]

[4]Institute Jožef Stefan, SI-1000 Ljubljana, Slovenia
**petar.djinovic@ki.si*

**Keywords:** photo-thermal catalysis, reaction mechanism, *in-situ* spectroscopy

**Introduction.** The Reverse Water Gas Shift reaction (RWGS) is an attractive approach for $CO_2$ conversion to CO using renewable hydrogen[1], and could play an important role in the transition to sustainable, large-scale $CO_2$ utilization for fuel manufacture via syngas chemistry.[2] Photo-thermal catalysis is an emerging approach towards utilization of symbiotic effects of light (photon energy) and thermal energy to accelerate the catalytic turnover and influence selectivity.[3,4] Photo-thermal catalysis could have important consequences for enabling a more widespread use of solar irradiation to help drive catalytic reactions at mild conditions, and overcome conversion and/or selectivity limitations of equilibrium reactions.[5]

**Experimental/methodology.** A commercial $\gamma$-$Al_2O_3$ was used as a support to deposit between 5 and 14 wt.% copper. Structural analysis was performed using XRD, $N_2$ sorption, $N_2O$ chemisorption, $H_2$-TPR, *in-situ* XAS and HRTEM techniques. *In-situ* UV-Vis and DRIFTS were used to analyze light-matter interactions and surface species during RWGSR in dark and under illumination. Catalytic tests with variable temperature, irradiance and wavelength dependent experiments were performed in fixed bed reactor.[5]

**Results and discussion.** The RWGS performance of Cu/$\gamma$-$Al_2O_3$ catalysts in thermally driven and photo-thermal RWGS reaction is notably different. When the reaction is driven by a combination of visible light (790mW/cm$^2$, which equals about 7 sun intensity) and thermal energy, the $CO_2$ rates were consistently lower compared to thermally driven reaction in dark. The linear correlation between irradiance and decreasing reaction rate suggested the rate attenuation is driven by a single photon process, and is not a temperature induced artefact. In photo-thermal mode, the Ea values were larger (~85 kJ/mol compared to ~67 kJ/mol in dark), suggesting light disrupts the energetically more favorable reaction pathway which is active in dark. Also, illumination of the catalyst can be used to steer selectivity away from methane (into CO), especially over catalysts with a higher copper content (9-14 wt.%) which contain larger Cu particles. The *in-situ* DRIFTS analysis of the Illuminated catalyst shows a substantial and only partly irreversible surface dehydroxylation, revealing the importance of OH groups in the RWGS pathway. There appears to be no correlation between formate and CO yield, identifying its minor active role in the RWGS pathway. This work provides a novel approach to manipulate the abundance, and analyze the role of different surface species with the capability to steer activity and selectivity in the RWGS reaction.

**Introduction.** The abounding environmental issues of our time have pushed sustainability at the forefront of scientific research. Due to the surging energy demand, many researchers are turning to clean and renewable resources such as solar power. In chemistry, light-driven processes have been blooming through photocatalysis, a valuable tool for implementing greener strategies. Ruthenium and iridium-based polypyridyl complexes are prominent organometallic photocatalysts but their rareness, elevated cost, and toxicity can be inconvenient. Alternatives, such as fully organic photocatalysts, have been researched and could constitute adequate replacements.[1] However, due to the homogeneous nature of these chromophores, recyclability remains an issue,. The aim of this project therefore consisted in the development of a recyclable and accessible photocatalytic system, applicable to fine organic synthesis, namely photooxidation steps.

**Results and discussion.** Based on benzophenazines investigated for photodynamic therapy,[2] a new set of organic chromophores were developed (Fig. 1). Their synthesis was achieved through a straightforward two-step pathway and photocatalytic activity was benchmarked by the photooxidation of citronellol.[3] The tested chromophore displayed excellent photocatalytic yields of up to 99 % in 2 hours, hence confirming its photocatalyst status. A theoretical study was also performed to reach a finer understanding of the molecule's properties as well as to establish a structure-activity relationship. It was found that photocatalysts with electron donating groups on their southern site (Fig.1, blue) tend to absorb at longer wavelengths, which is desirable for reaching lower energy activation.

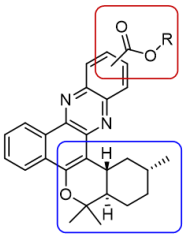

***Figure 1. Organic chromophore.***

Heterogenization was carried out using silica nanoparticles (SNPs) functionalized with primary amines. After screening different sizes, characterized by DLS and TEM, silica nanoparticles of 40 nm (Fig. 2) were found to be of ideal size as light scattering was minimized. The immobilization of the organic photocatalyst was successfully achieved through peptide coupling between the surface amines of the nanoparticles and the activated ester of the chromophore (located on the northern site: Fig.1, red). Quantification of the anchored chromophore was achieved by TGA and XPS was used to verify its unaltered presence on the surface. Solids with loads ranging from to 2 to 8 wt.% of photocatalyst were obtained through our method. The resulting silica-supported photocatalyst was tested over several runs using the same benchmark reaction as the homogeneous tests. Remarkable photocatalytic activity was observed as the heterogenized photocatalyst reached up to 97 % yields in overnight photooxidation runs and conserved similar activity for 4 cycles with only a slight decrease. The grafted chromophore also displayed improved resistance to photodegradation. These new photocatalysts are currently being extended to flow reactors. In homogeneous conditions, up to 95 % of conversion was observed with 1 min of residence time for the photooxidation of N-Carbobenzyloxy-L-methionine. This is a promising result as we look towards potentially implementing heterogeneous photocatalytic reactions in flow reactors. These findings attest the utility of heterogenizing homogeneous photocatalysts for obtaining greener catalytic systems.

**Keywords:** Photocatalysis; carbon nitride, visible light; GCN-T/3D-structure

**Introduction.** Hydrogen peroxide ($H_2O_2$) is an important commodity compound listed as one of the 100 most widely used worldwide [1]. Demand for sustainable energy and chemical synthesis has encouraged the scientific community to expand the concept of artificial photosynthesis that mimics nature to convert water and light energy into value-added products. Heterogeneous photocatalysis has been appointed as a promising alternative route for $H_2O_2$ generation due to its advantage of operating under mild temperatures and exempting the use of hazardous reagents [2]. The key to applying this technology lies in developing innovative catalysts and using sustainable resources to compete with the traditional industrial process of $H_2O_2$ production. Among the optical semiconductors applied in the field of photocatalysis, graphitic carbon nitride (g-$C_3N_4$) has revealed significant potential for $H_2O_2$ production using aqueous solutions in the presence of alcohols, such as 2-propanol, ethanol, and methanol [2]. Alternatively, saccharides as biomass derivatives may constitute a sustainable solution by acting as electron donors during the photocatalytic process.

**Experimental/methodology.** A bulk g-$C_3N_4$ synthesized by thermal condensation of dicyandiamide and post-treated at 500 $^{o}$C (here labeled as GCN-T) [3] was used as a photocatalyst towards the production of $H_2O_2$ under visible light exposure. Saccharides, such as arabinose, cellobiose, fructose, and glucose, were used as sacrificial electron donors. Operational parameters, such as the effect of the initial concentration of the electron donor and the presence of ionic species, were investigated, aiming for the enhancement of $H_2O_2$ generation. Seeking a sustainable technological approach for $H_2O_2$ production, GCN-T was immobilized on a 3D printed structure prepared by additive manufacturing. In addition, synthetic water, mimicking the salinity of seawater, as well as natural seawater samples, was used.

**Results and discussion.** The results showed that the scavenging efficiency of the photogenerated holes rapidly increases with the number of –OH groups and differs as a function of the molecular structure of the sacrificial agents. Among the polyhydroxy compounds used, a high concentration of $H_2O_2$ was detected using cellobiose as the electron donor. When GCN-T was immobilized on the 3D structure, the photocatalytic system exhibited high efficiency and robust stability for $H_2O_2$ production. In addition, the GCN-T/3D-structure demonstrated promising results, revealing a superior apparent quantum efficiency at 412 nm compared with the results attained using GCN-T suspensions.

**Keywords:** Photo-thermal catalysis, Carbon dioxide, Sabatier reaction, Supported ruthenium nanoparticles

**Introduction:** The Sabatier reaction have undergone a revival in the last years due to its potential for the obtainment of $CH_4$ (synthetic fuel and hydrogen carrier), while depleting $CO_2$ responsible of greenhouse effect[1]. In this sense, photo-thermal catalysts have the potential of driving this reaction in gentle conditions, by exploding the whole sunlight spectrum in the form of heat and charge-carrier generation. Some well-known Sabatier catalysts, like supported Ru, have already reported higher activity under photo-thermal conditions[2], although a deeper understanding of the light-catalyst interaction is still needed.

**Experimental/methodology:** In this work, metallic ruthenium nanoparticles at a total loading of 2% have been deposited on different metal oxides ($TiO_2$-P25, $TiO_2$-Anatase, $ZrO_2$, $CeO_2$ and $SiO_2$) and fully characterized by ICP-AES, $H_2$-TPR, CO-Chemisorption, $N_2$-Physisorption, TEM, DR UV-Vis spectroscopy and XRD. Their catalytic activity has been tested in a commercial Harrick reactor with an additional thermocouple in the catalytic bed, under Sabatier reaction conditions. During the test the catalysts were exposed to 300W Xe lamp (AM 1.5G) illumination at a total irradiance of 0.3 W $cm^{-1}$, and the experiment was repeated without light for comparison.

**Results and discussion:** The synthesis yielded materials with metallic ruthenium nanoparticles smaller than 5 nm homogeneously dispersed, as verified by TEM (Figure 2) and $H_2$-TPR. All catalyst showed metal loadings close to the nominal value, confirmed by ICP-OES, and absorption in the whole UV-Vis spectrum. According to figure 1 $Ru_{0.02}$@$TiO_2$-P25 and $Ru_{0.02}$@$ZrO_2$ were the most active catalysts followed by $Ru_{0.02}$@$CeO_2$, while $Ru_{0.02}$@$SiO_2$ and $Ru_{0.02}$@Anatase yielded less conversion. All the materials were highly selective towards $CH_4$. The addition of light clearly improved the catalytic activity in all cases, being this enhancement most marked for $Ru_{0.02}$@$ZrO_2$ and $Ru_{0.02}$@$TiO_2$-P25. New catalytic tests are scheduled to confirm this tendency and shed light on the causes of the support effect observed.

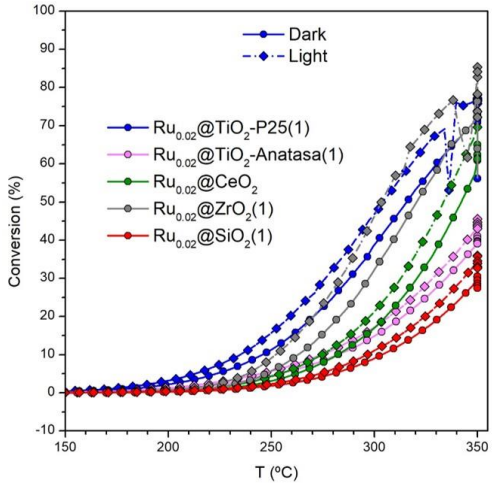

**Figure 1.** Catalyst activity during $CO_2$ methanation.

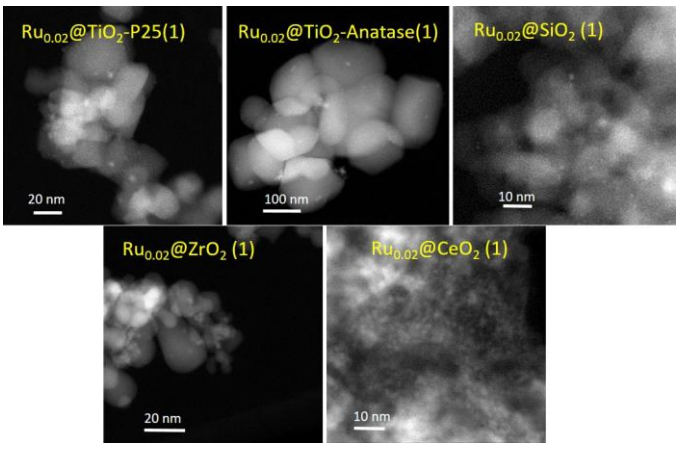

**Figure 2.** TEM micrographs of all the catalyst before reaction.

[*]*anna.jakiminska@doctoral.uj.edu.pl, macyk@chemia.uj.edu.pl*

**Introduction.** Metallic nanostructures are widely used as the modifiers in photocatalysis. Most of the research reports the salutary influence of surface plasmon resonance (SPR) on the modified photocatalysts activity, especially in the visible light range [1-3]. Nevertheless, despite the fact that the presence of metallic nanostructures can be advantageous, the hot-electrons injection or plasmon induced resonance energy transfer processes are not very efficient. Moreover, activity of such materials under visible light irradiation is disputable. How then the presence of metallic nanostructures enhances the activity of modified materials?
**Experimental/methodology.** During this research, the influence of metallic nanostructures presence on the activity of titanium dioxide in hydrogen production from methanol oxidation and pure water splitting was examined. Metallic nanostructures were photodeposited at the $TiO_2$ surface and the hydrogen evolution was monitored using gas chromatography. Additionally, measurements of spectral, photoelectrochemical and spectroelectrochemical properties of modified materials were performed.
**Results and discussion.** Received results indicate that the influence of metal type and the structures size are the most important in terms of enhanced activity, whereas the presence of SPR phenomenon is not. Therefore, implementing of SPR in the mechanisms of activity of metallic nanostructures decorated materials should be reconsidered.

**Keywords:** photocatalyst, hydrogen peroxide, tungsten oxide

**Introduction.** Hydrogen peroxide ($H_2O_2$) attracts attention in various fields in synthesis of pharmaceuticals and organic functional materials, and recently as an energy carrier [1] that can replace hydrogen. It is also becoming increasingly valuable as a green chemical, since the only decomposition products of $H_2O_2$ are water and oxygen ($O_2$). However, the anthraquinone method [2], the current industrial manufacturing method, requires a multi-step synthesis process, toxic organic solvents, and explosive gases. Therefore, there is a need for a synthetic method that is simpler and has less environmental impact, and the photocatalytic method is being studied as one of the promising methods [3]. $H_2O_2$ can be produced over various photocatalysts by reduction of $O_2$ by photogenerated electrons. Since $H_2O_2$ decomposes by UV light, visible light-driven photocatalysts such as tungsten(VI) oxide ($WO_3$) are favorable. In addition, the position of the conduction band more positive than the potential of one electron reduction of $O_2$ makes the $H_2O_2$ production advantageous. Here we achieved $H_2O_2$ production by two electron reduction of $O_2$ ($O_2 + 2H^+ + 2e^- \rightarrow H_2O_2$) in an aqueous 2-propanol (IPA) suspension of metal-free $WO_3$ photocatalyst. We also found thermal acceleration of the photocatalytic reaction, i.e., the rate of $H_2O_2$ production greatly increased at slightly elevated temperatures. This study aims to analyze the mechanism in this reaction and to achieve more efficient $H_2O_2$ production.

**Experimental/methodology.** $WO_3$ powder (50 mg) was suspended in a 90 vol% 2-propanol-$H_2O$ (5 mL) in a test tube and the gas phase was placed with $O_2$. The test tube in a glass-type water bath kept at various temperatures was irradiated with visible light ($\lambda > 400$ nm) using a Xe lamp equipped with an L-42 cut filter. After the reaction, $O_2$ in the gas phase and acetone in the liquid phase were analyzed by gas chromatography, while the $H_2O_2$ in the liquid phase was colored by Trinder's reagent and analyzed spectrophotometrically.

**Results and discussion.** Figure shows effects of the reaction temperature on the yield of $H_2O_2$ after visible light irradiation for an hour. The yield of $H_2O_2$ was very small at 27 °C. We found that the yields drastically increased with an elevation of the reaction temperature and, finally, the yield reached 80 μmol at 60°C, which corresponded to 16 mmol $L^{-1}$. These results indicate that an activation energy barrier exists in the $O_2$ reduction process and/or the oxidation process. In the photocatalytic production of $H_2O_2$, oxidation of IPA by positive holes simultaneously occurred, resulting in formation of acetone ($IPA + 2h^+ \rightarrow$ acetone $+ 2H^+$). To analyze this reaction in detail, electron utilization efficiency (EUE) was calculated and plotted in Figure. If two electron reduction of $O_2$ and oxidation of IPA occur stoichiometrically, the value of EUE should be unity. However, the values of EUE were 20-25% at any temperatures, suggesting that self-decomposition of $H_2O_2$ and/or oxidation of IPA by $H_2O_2$ occurred.

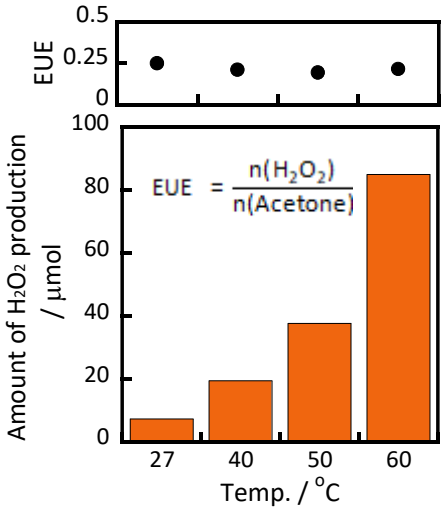

**Figure Effects of reaction temperature on production of $H_2O_2$ and electron utilization efficiency over $WO_3$ photocatalyst in 90 vol% 2-propanol under irradiation of light from Xe lamp with L-42 cut-filter for 1 h.**

**Keywords:** photocatalysis, methane activation, cascade process, formic acid, high selectivity

**Introduction.** Direct oxidation of methane into value-added fuels and chemicals remains a major challenge in modern science [1, 2]. Formic acid is one of the most promising platform-molecules for hydrogen storage, low-temperature membrane fuel cells and synthesis of platform molecules. Photocatalysis proposes an attractive route for methane partial oxidation to value added chemicals under mild conditions. The radical mechanism of methane photocatalytic oxidation often restricts the selectivity to the target products. In this paper, we propose a strategy to break the conventional limitations of methane photocatalytic oxidation by adding a thermo-catalyst and conducting the whole process in a one-pot reactor at ambient temperature.

**Experimental/methodology.** The cesium salt of phosphotungstic acid (CsPW) was prepared by mixing heteropolyacid hydrate aqueous solution with the stoichiometric amount of $CsNO_3$ aqueous solution. For preparation of CsPW-$TiO_2$ photocatalyst, CsPW was mechanically mixed with a necessary amount of $TiO_2$. The catalysts were characterized by XRD, UV, STEM, photoluminescence and EPR. A commercial 230 mL batch photoreactor equipped with a quart window on the top was used for photocatalytic methane oxidation reaction tests. In the photo- thermo-catalytic experiments, the photoreactor was equipped with a sand filter to isolate CsPW-$TiO_2$ photocatalyst and Ru/$Al_2O_3$

**Results and discussion.** Methane photocatalytic oxidation results in a mixture of $C_1$ oxygenates (Fig. 1a). The selectivity of methane oxidation to formic acid is dramatically improved in the proposed photo-thermo-catalytic cascade process. The process involves a photocatalyst prepared from caesium salt of phosphotungstic acid mixed with titania and an alumina supported ruthenium catalyst. In the photo-thermo-catalytic process (Fig. 1b), a yield of formic acid over 5000 µmol $g^{-1}$ and a selectivity of 85% were achieved. $CO_2$ is the only gaseous compound of methane oxidation. Optimization of catalyst structure and reaction conditions allows a one pot synthesis of HCOOH solution from methane with a concentration of 1.1 mmol $L^{-1}$. Our findings offer valuable guidance for the direct and highly selective methane oxidation to HCOOH in water using $O_2$ as an oxidant.

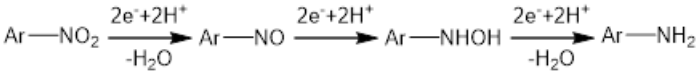
**Keywords:** Glycerol, hydrogenation, photocatalyst



**Introduction.** Hydrolysis of fats and oils with alkalis such as sodium hydroxide and potassium hydroxide (saponification) produces glycerol and salts of higher fatty acids [1]. The salts of higher fatty acids have been used as soaps and surfactants for a long time because the anions of higher fatty acids show osmosis, emulsification, and dispersing action. Recently, conversion of fats and oils to methyl esters (biodiesel fuels) with methanol via an ester exchange reaction has been extensively investigated from the viewpoint of reduction in consumption of fossil fuels and utilization of biomass as carbon-neutral resources [2]. In both saponification and ester exchange reaction of fats and oils, glycerol is produced as a by-product. Glycerol is harmless to the human body and is used as a sweetener and a moisturizer in cosmetics. However, a large amount of energy is required to recover glycerol from aqueous wastes emitted from the soap production process due to its high solubility in water and high boiling point (290°C). In this study, we used glycerol as an electron and hydrogen source for photocatalytic hydrogenation of 4-nitrobenzenesulfonic acid (4-NBS) to 4-aminobenzenesulfonic acid (4-ABS) in an aqueous suspension of $TiO_2$.

**Experimental/methodology.** $TiO_2$ powder was suspended in 5 $cm^3$ of water containing 4-NBS (typically 50 µmol) and glycerol (typically 450 µmol) in a Pyrex test tube (18ϕ × 180 mm). After replacing the gas phase with argon, the test tube was sealed with a rubber septum and then photoirradiated at 20°C with the high-pressure mercury lamp (λ> 300 nm) under continuous stirring.

**Results and discussion.** Figure shows the time course of the photocatalytic hydrogenation of 4-NBS in an aqueous suspension of $TiO_2$ (25 mg) in the presence of glycerol (450 µmol). Just after photoirradiation, the amount of 4-NBS decreased and was no longer detected, while the amount of 4-ABS increased and the yield reached 95% at 2.5 h. The apparent quantum yield was roughly estimated to be ca 10%. As Figure 4 also shows, $CO_2$ was produced as the oxidation product and the final amount was 10 µmol. These results mean that oxidation stops when 4-NBS to be reduced is consumed. Ideal mineralization of glycerol to $CO_2$ is shown in Equation:

$$C_3H_5(OH)_3 + 3H_2O \rightarrow 14e^- + 14H^+ + 3CO_2.$$

According to the stoichiometry, 47 µmol of electrons (= (10/3) × 14) was provided for the reduction (hydrogenation) of 4-NBS. However, production of 45 µmol of 4-ABS requires 270 µmol of electrons (= 45 × 6) because conversion of 4-NBS to 4-ABS is a 6-electron process as shown below.

The large gap between yields of $CO_2$ and 4-ABS indicates that a large amount of a partial oxidation product(s) of glycerol was present in the liquid phase.

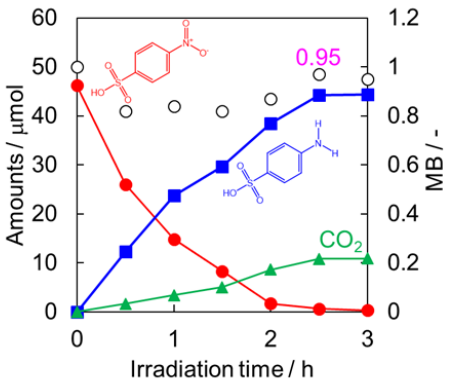


**Figure Time courses of amounts of 4-NBS (●), 4-ABS (■), $CO_2$ (▲) and MB (○) in an aqueous suspension of $TiO_2$ (25 mg) in the presence of glycerol (450 µmol) under irradiation of UV light.**

# Mechanistic study of glucose photoreforming over $TiO_2$-based catalysts for $H_2$ production

Lan Lan[1,*], Christopher Hardacre[2,*]

[1, 2] *The University of Manchester, Manchester, United Kingdom*
[*] *lan.lan@manchester.ac.uk (L. L.), c.hardacre@manchester.ac.uk (C.H.)*

**Introduction.**

Glucose is a key substrate proposed as the main intermediate in cellulose photoreforming for $H_2$ production. However, the mechanism of glucose formation in cellulose photoreforming and the mechanism of glucose photoreforming over $TiO_2$-based catalysts are currently not well understood [1]. The reaction pathways of glucose photoreforming have predominantly been determined from analysis of gas phase and liquid products. As the nature of adsorbed species on the catalyst surface could influence the oxidising species and reaction pathway, determination of adsorbed species on the catalyst surface from an aqueous solution, is an important consideration in understanding the photoreforming mechanism. Attenuated total reflectance infrared (ATR-IR) spectroscopy has been utilised to study the liquid-solid interface to probe adsorption on a catalyst surface (dark adsorption [2]) and also under *in-situ* conditions with irradiation of UV light [3]. Therefore, detailed product analysis combined with in-situ ATR-IR spectroscopy under UV irradiation has potentials to provide inforamtion for further understanding of glucose photoreforming mechnism over $TiO_2$-based catalysts.

**Experimental/methodology.**

Detailed product analysis of the system was performed by liquid and gas chromatography. An *in-situ* ATR-IR spectroscopy of m-$TiO_2$ (*i.e.,* mixed phase of 85% anatase and 15% rutile) and Pt/m-$TiO_2$ under UV irradiation was carried out to probe the species adsorbed on the surface of the catalyst during the photoreforming of glucose. In addition, isotope mass spectrometry was also employed to study the origin of $H_2$ in glucose and formic acid photoreforming over Pt/m-$TiO_2$ catalysts.

**Results and discussion.**

This work presents a mechanistic investigation of glucose photoreforming over $TiO_2$ and Pt/m-$TiO_2$ catalysts. Analysis of the intermediates formed in the photoreforming of glucose confirmed the α-scission mechanism of glucose oxidation forming arabinose ($C_{n-1}$ sugar) and formic acid in the first oxidation step. The selectivity to sugar products and formic acid differed over Pt/$TiO_2$ and $TiO_2$ with lower selectivity to formic acid observed over Pt/$TiO_2$ attributed to enhanced adsorption/conversion of formic acid over Pt/$TiO_2$. *In-situ* ATR-IR spectroscopy of glucose photoreforming showed molecular formic acid and formate to be present on the surface of both catalysts at low glucose conversions, which suggests formic acid oxidation could dominate surface reactions in glucose photoreforming. Further *in-situ* ATR-IR of formic acid photoreforming showed Pt-$TiO_2$ interfacial sites to be key for formic acid oxidation as $TiO_2$ was unable to convert adsorbed formic acid/formate. Isotopic studies of the photoreforming of varied concentrations of formic acid in $D_2O$ showed that the source of the protons reduced to $H_2$ at Pt particles, was determined by the relative surface coverage of adsorbed water and formic acid.

**Keywords:** photocatalysis, titanium dioxide, zinc oxide, carbon spheres, carbon dioxide reduction

**Introduction.** $CO_2$ photoreduction into valuable products is one of the most promising methods of fighting dangerous climate changes. $TiO_2$ is the most commonly used photocatalyst. It shows high activity, especially when two phases are combined [1,2]. Also, ZnO is considered a material with similar properties. Relatively low production costs and non-toxicity characterize both of them. On the other hand, carbon spheres show excellent $CO_2$ adsorption properties and high surface area ($S_{BET}$). Thanks to this, they can improve the photocatalytic properties of $TiO_2$ and ZnO since the ability of $CO_2$ adsorption is crucial in photocatalytic carbon dioxide reduction. The study aimed to achieve a synergistic effect of materials containing photocatalysts and carbon spheres by combining the two components with specific properties.

**Experimental/methodology.** Materials tested in photocatalytic processes contained P25 type $TiO_2$ (AEROXIDE® $TiO_2$ P25, Evonik Industries AG, Germany), ZnO with particle size <100 nm (Sigma-Aldrich, USA), and carbon spheres (CS). The CS/$TiO_2$ and CS/ZnO mixtures were prepared using a microwave-assisted solvothermal reactor (Ertec, Poland), as described in a publication [3]. The photocatalytic tests were performed in a liquid-phase reactor with a 150 W medium-pressure mercury lamp TQ150 Z3 (Heraeus, Germany). The suspension of 200 mg of the tested sample in 0.2M aqueous NaOH solution was saturated with pure $CO_2$ and irradiated with UV light for 6 h. The products of $CO_2$ photoreduction were analyzed using a Master GC chromatograph (DANI Instruments, Italy) with micro-packed Shincarbon ST 100/120 column, TCD, and FID detectors. The carrier gas was argon. The $H_2$, CO and $CH_4$ amounts were calculated based on the calibration curve.

**Results and discussion.** The experiments were carried out to evaluate the photocatalytic activity of two groups of materials containing $TiO_2$ and ZnO by adding carbon spheres in the amount of 0.05-1.00 g of CS per 1 g of $TiO_2$/ZnO in $CO_2$ photoreduction. In the gas phase, the identified products of this process were hydrogen, carbon monoxide and methane. Based on the results, it can be concluded that materials containing $TiO_2$ exhibited slightly better activity than those with ZnO. Moreover, adding carbon spheres to titanium dioxide improved its photocatalytic activity towards carbon monoxide production. However, regardless of the photocatalyst, the main product was carbon monoxide. It can also be concluded that a minor addition of carbon spheres (0.10 g) was more efficient in the case of $TiO_2$. In turn, better results were obtained using zinc oxide for the mixture containing a high amount of carbon spheres (1.00 g).

**Keywords:** hydrogen, microreactor, photocatalysis

**Introduction.** The photoproduction of $H_2$ represents one of the most desired routes to obtain renewable hydrogen. However, the $H_2$ photoproduction rates reported so far are too low for practical application. Whereas there is an impressive number of works related to the design of photocatalytic materials to increase the efficiency of the photoprocess, less attention has been paid to the proper design of photocatalytic devices [1-3]. Obviously, no matter how good a photocatalyst is, the overall hydrogen yield will be strongly limited if a proper mass and photon transfer to the photocatalyst is not attained. Therefore, both the photocatalyst and the photoreactor are equally important to guarantee a suitable operation.

**Experimental/methodology.** Photoassisted electrochemical etching was used to prepare silicon micromonoliths with straight, parallel channels of 2 μm arranged in a square lattice with a periodicity of 4 μm side over ⟨100⟩ n-type float-zone silicon. The microchannels were oxidized at 1373 K to partially transform Si into $SiO_2$. Titanium(IV) isopropoxide was forced to pass through the microchannels by applying a pressure difference of ca. 75 kPa. With this method, the hydroxyl groups of $SiO_2$ reacted with the titanium precursor to form surface titanium alkoxide groups, which were subsequently calcined at 723 K to form a compact $TiO_2$ layer over $SiO_2$. The $TiO_2/SiO_2/Si$ structure was decorated with Pt (0.77 wt.%) using an aqueous solution of $(NH_3)_4Pt(NO_3)_2$. The photocatalytic tests were performed in a tubular glass photoreactor. A gaseous reactant mixture of $EtOH:H_2O$=1:10 (molar) was forced to pass through the channels of the photocatalytic microreactor (GHSV=100,000 $h^{-1}$), which were illuminated at 365±5 nm (80 mW $cm^{-2}$). The outlet of the photoreactor was connected on-line to a gas chromatograph.

**Results and discussion.** The $H_2$ production rates as a function of the photoreactor volume (μmol $H_2$ $h^{-1}$ $cm^{-3}_R$) and the photocatalyst loading normalized to the surface area ($mg_{cat}$ $cm^{-2}$) of various microreactors are plotted against the specific contact area ($m^2_{ch}$ $m^{-3}$) [4]. The fabulous rate of $H_2$ production on a reactor volume basis recorded with the macroporous silicon photocatalytic device (212 μmol $H_2$ $h^{-1}$ $cm^{-3}_R$) is directly related to its high specific contact area ($10^5$ $m^2_{ch}$ $m^{-3}$). There is an inverse trend between the specific contact area and the photocatalyst loading normalized to the surface area. As the number of channels increases and their diameter decreases, there is more contact area available and the thickness of the photocatalyst layer progressively decreases. This does not result in a decrease of the photocatalytic performance because photon absorption takes place only in the first micrometers of the photocatalyst coating.

**Keywords:** Metal-organic frameworks, Coordinatively unsaturated metal sites, $CO_2$ reduction, Catalysis, Molecular simulation, Understanding of mechanism, Rationalization, Prediction.

**Introduction.** (Photo)electrochemical driven $CO_2$ reduction becomes a promising way for both greenhouse gas mitigation and carbon-resource utilization which can provide renewable fuels with no net in-creases of $CO_2$. However, (photo)electrochemical $CO_2$ reduction requires multiple step transfers of protons and electrons generally associated with high energy barriers that require high overpotentials. Therefore, seeking catalysts with low overpotential is crucial to achieve efficient (photo)electrochemical $CO_2$ reduction. To this end, tremendous efforts have been devoted to exploring efficient catalysts for (photo)electrochemical $CO_2$ reduction, with particular attention given to Metal-organic frameworks (MOFs). MOFs containing metal oxo-trimer nodes with the chemical composition $M_3^{3+}(\mu_3\text{-}O)(X^-)(RCOO)_6$ (mono-metallic) or $(M_2^{3+}M'^{2+/3+}(\mu_3\text{-}O)(X^-)(RCOO)_6$ (bi-metallic) (M and M'=metal, X=counter-anion present to maintain charge neutrality in the case of all metal are 3+ and R=organic group of the linker) as secondary building units (SBUs) could be candidates for an effective catalytic $CO_2$ reduction, including MIL-88B(Fe),[1] MIL-101(Fe)[1], MIL-101(Cr)[2] and PCN-250-$Fe_2$M'(M=Fe, Mn, Zn, Ni, Co)[3] as they show catalytic activity for various (photo)electrocatalytic reactions. The identification of the optimum metal oxo-trimer nodes to be incorporated in the MOF framework is of utmost importance to design a catalyst with outstanding performance for (photo)electrochemical $CO_2$ reduction.

**Experimental/methodology.** All cluster optimizations were carried out using the unrestricted B3LYP exchange-correlation functional with the Gaussian 09 program suite. The oxo-trimer based cluster with terminal phenyl ring saturated by hydrogen atoms is in line with what has been reported previously in a number of theoretical catalysis investigations of MOF containing this oxo-trimer. The TZVP basis set was employed for all non-metal atoms; all metal atoms were treated by the LANL2DZ basis set. The DFT-D3 method was used to include the dispersion correction. These DFT calculations were combined with the computational hydrogen electrode (CHE) approach to investigate the $CO_2$ reduction mechanism.

**Results and discussion.** Employing density functional theory calculations, we explore the reaction mechanisms and activities for a series of metal oxo-trimer nodes within MOFs for catalytic $CO_2$ reduction to methanol. We first demonstrate that all investigated systems fulfill the thermodynamic requirement for $CO_2$ reduction regardless of pH value. Then we investigated the minimum energy pathways for $CO_2$ reduction over Fe-only system with experimentally proved activity as a benchmark. In comparison with Fe (II), Co(II) and Ni(II) substitution show equivalent or even better activity while Ni(II) is the most active one, whereas Cu(I), Cu(II), Zn(II), Cd(II), Ti(III), Y(III) and Ce(III) show poorer performance. Finally, we found that the stability of *COOH is a reliable descriptor to rank the catalytic activity and the origin is analyzed. Our computational efforts not only deliver a fundamental understanding of $CO_2$ reduction process over CUSs in MOFs, but also provide theoretical guidance for rational design of highly active catalysts for (photo)electrochemical $CO_2$ reduction based on MOFs containing metal oxo-trimer nodes.

# Low-temperature $NH_3$ decomposition using photo-thermal catalysis

Diego Mateo[1*], Angel Sousa[1], Luis Garzon-Tovar[1], Natalia Morlanes[1], Juan Carlos Navarro[1], Xinhuilan Wang[1], Kevin Brennan[2], Max Garcia-Melchor[2], Javier Ruiz-Martinez[1], Jorge Gascon[1*]

[2]*Trinity College Dublin, Dublin, Ireland*

[*]*diego.mateo@kaust.edu.sa*

**Introduction**. By virtue of its high volumetric energy density, well-defined distribution infrastructure and the possibility to obtain $CO_x$-free hydrogen ($H_2$) from its decomposition, ammonia ($NH_3$) is considered a key energy carrier in future neutral-carbon energy systems.[1] Unfortunately, the use of this carrier has been limited by the absence of an efficient $NH_3$ decomposition process. Photo-thermal catalysis, a hybrid approach that combines both thermal and non-thermal contributions of light, has showed a great potential to drive chemical reactions using sunlight as unique energy source.[2] In this work, we demonstrate for the first time the use of a MOF-derived photo-thermal catalyst to perform the $NH_3$ decomposition reaction at low temperatures and high conversion rates.

**Experimental/methodology.** Catalyst was obtained from the controlled pyrolysis under inert atmosphere of a metal-organic framework precursor. We studied the photo-thermal $NH_3$ decomposition under continuous flow configuration using a commercial Harrick cell equipped with a quartz window. The catalyst was loaded into the reactor system and it was irradiated from the top using a 300 W Xe lamp. The temperature was monitored with a thermocouple located a few mm below the catalyst surface and the evolved gases were quantified using a GC directly connected to the outlet of the reactor.

**Results and discussion.** As it can be seen in **Figure 1**, independently on the weight hour space velocity (WHSV), both the ammonia conversion and the temperature of the photocatalyst increased upon exposure to light until reaching a steady state. At 20000 mL $g^{-1}$ $h^{-1}$, the catalyst reached a temperature of 300 °C and a 55 % $NH_3$ conversion, which translated into a $H_2$ production rate as high as 653 mmol $H_2$ $g^{-1}$ $h^{-1}$. Indeed, at the lowest WHSV of 1000 mL $g^{-1}$ $h^{-1}$, our system was able to decompose $NH_3$ at nearly full conversion (~80 %). Additional blank experiments under dark conditions displayed negligible $NH_3$ decomposition rates, thus indicating that the synergy between light and heat is crucial to enhance the catalytic activity towards $NH_3$ conversion. To the best of our knowledge, this is the first example of the use of a MOF-derived catalyst for the efficient photo-thermal $NH_3$ cracking reaction under continuous flow configuration at high conversion rates.

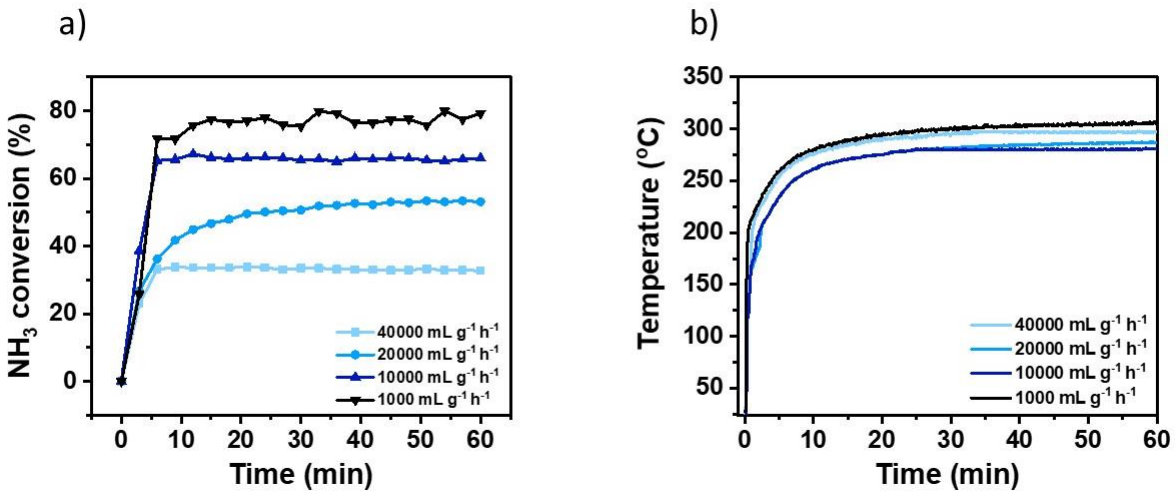

**Figure 1. a) Photo-thermal $NH_3$ decomposition under different WHSV. b) Temperature profile of the catalyst under reaction conditions.**

**Keywords:** Lignocellulosic biomass, photoreforming, copper and nickel co-catalysts, hydrogen.

**Introduction**

Hydrogen is a potential alternative to fossil fuels because it is a clean, efficient, and renewable energy source. Producing $H_2$ via photochemical routes, more specifically by water splitting (WS), is a promising avenue. To overcome the disadvantage of the low efficiency of WS, catalytic photoreforming using a sacrificial agent in the reaction medium is an interesting approach [1]. In this regard, the present study focuses on verifying the potential of different types of biomass-derived-substrates as sacrificial agents in photocatalytic reactions for enhancing $H_2$ production (photoreforming reactions) using Metal/$TiO_2$. The substrates include local almond shell waste (**AS**), α-cellulose (**C**, Sigma-Aldrich), and a liquid residue from the process of activated carbon preparation by hydrothermal treatment of **AS** in 25 wt.% $H_3PO_4$ (**HMAS-L**).

**Experimental/methodology.**

Almond shell (**AS**) and α-cellulose (**C**) were mechanically pretreated (milled) in a planetary ball mill for reducing the particle size to increase their reactivity, leading to **MAS** and **MC** (from milled **AS** and **C**, respectively). **MAS** and **MC** were characterized by elemental analysis, proximate analysis, and XRD. The total organic carbon (TOC) content of **HMAS-L** was analysed as well. The photocatalysts used were the commercial P25 $TiO_2$ (Degussa) and MP25 (M: Cu or Ni, 1 wt. %) samples [2], that were prepared by impregnation with aqueous solutions of $Cu(NO_3)_2{\cdot}3H_2O$ and $Ni(NO_3)_2{\cdot}6H_2O$ (both Panreac). The **1NiP25** and **1CuP25** photocatalysts were used without a previous reduction treatment and were characterized using XRD, ICP-OES, TEM, and XPS. Photocatalytic tests were conducted in a cylindrical glass reactor (Heraeus UV-RS-2) with a UV lamp (TQ 150-undoped, 47 W, λmax=365 nm), using a certain amount of substrate (**MAS, MC**, or **HMAS-L**), distilled water up to 500 mL, stirring in flowing He (30 mL/min) and 5 h illumination time. The generated gases were continuously analysed by mass spectrometry. Photodegradation of the 3 substrates (no catalyst), and water splitting tests were also carried out.

**Results and discussion**

Characterization of the solid substrates shows that **MAS** is richer in carbon and fixed carbon than **MC**, and that both substrates have low crystallinity. The total organic carbon (TOC) analysis of **HMAS-L** reveals that it contains a large amount of dissolved organic matter (20850 mg/L). ICP-OES analysis has confirmed that the metal content in **1CuP25** and **1NiP25** is very close to the nominal one. In both cases, TEM shows a good metal dispersion, and mean particle sizes lower than 3 nm. XRD patterns only exhibit the characteristic peaks of $TiO_2$ (P25), and XPS data show that the main species are Cu (I/0) in **1CuP25** and Ni (II) in **1NiP25**. The photochemical results highlight that the $H_2$ production largely depends on the substrate and photocatalyst used. **1CuP25** shows better photocatalytic activity than **1NiP25**, and the liquid **HMAS-L** leads to the highest $H_2$ production (1875 $\mu mol.h^{-1}.g^{-1}_{cat}$), which highlights the revalorization of these residues via photoreforming. Focusing on the $H_2/CO_2$ ratio, the combination of **1CuP25** and **MC** renders the best results. Furthermore, the present study has proved that a photodegradation test (in absence of a photocatalyst) is an indirect evaluation of the reactivity and degradability of a given substrate in photoreforming.

# Photothermal conversion of $CO_2$ to methane utilizing $Ru/TiO_2$

Kasper Wenderich, Annemarie Huijser, Guido Mul *

*PhotoCatalytic Synthesis Group, MESA+ Institute for Nanotechnology, University of Twente, P.O. Box 217, 7500 AE Enschede, the Netherlands.*

**Keywords:**

The photothermal reduction of $CO_2$ to value-added products is a fundamentally and practically interesting reaction to create a sustainable chemical process industry. In this work, we show that $TiO_2$ decorated with small Ru nanoparticles is a very promising photothermal catalyst for the conversion of $CO_2$ and $H_2$ to methane (i.e., the Sabatier reaction) under illumination at mildly elevated temperatures. We will first demonstrate that the light-sensitivity towards selective $CH_4$ production is very apparent at temperatures of 180 – 200 °C, a behavior observed not only under UV/Vis illumination, but also under visible light illumination. To elucidate the underlying mechanisms, we will show (i) DRIFT spectroscopy studies to understand the surface chemistry occurring and (ii) photoluminescence studies to elucidate the role of charge carriers under UV illumination (267 nm, photoexciting predominantly the $TiO_2$ support) or visible light illumination (532 nm, photoexciting predominantly the Ru nanoparticles). Through careful analysis of these results, we propose a model for the physical and chemical nature of photothermal $CO_2$ reduction occurring on the $Ru/TiO_2$ particles.

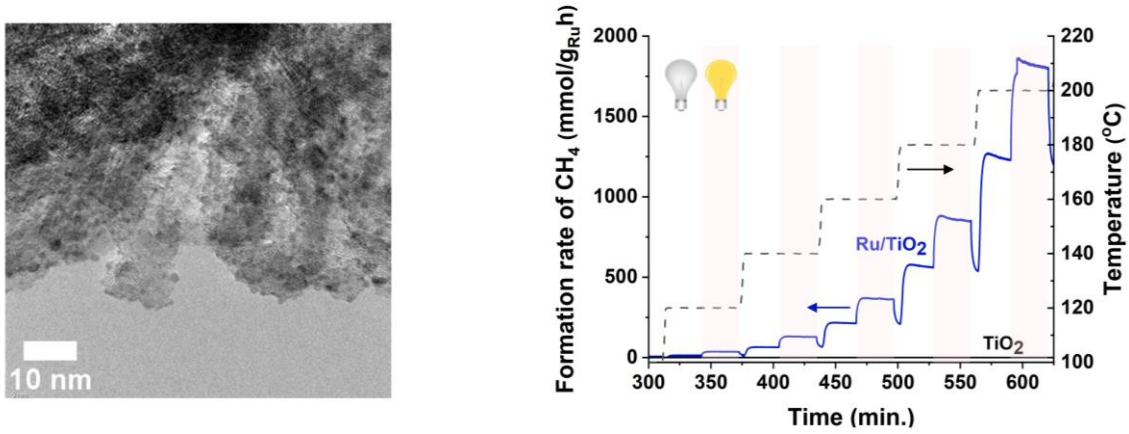

**Figure 1. (a) TEM micrograph of the Ru particles attached to the $TiO_2$ support. (b) Formation rate of methane at various temperature intervals in the absence or presence of radiation. Without Ru, $TiO_2$ does not show photothermal activity. Please note the strong rate increase upon illumination at 180 and 200**

# Dual photoredox catalysis toward alkoxy radicals

A. Ondrejková[1*], R. Lindroth[1], G. Hilmersson[1] and C. J. Wallentin[1]

[1]*Department of Chemistry and Molecular Biology, University of Gothenburg, Gothenburg, Sweden*

**Keywords:** alkoxy radical, photocatalysis, dual catalysis, chemoselective transformation

**Introduction.** Alkoxy radicals are species with significant potential in organic synthesis.[1] However, factors such as harsh conditions required for their generation and their highly reactive nature represent a major challenge for their application in a synthetic context.[1] The field of photoredox catalysis allows to access and utilize these reactive species in a controlled manner and simultaneously circumventing harsh reaction conditions.[2 - 4] Regardless, the development of reliable methods for harnessing and utilizing the reactivity of alkoxy radicals remains of great interest to the synthetic community.

**Methodology.** In this work, we present the photocatalytic method which allows for alkoxy radical-mediated oxidative C($sp^3$)-H bond functionalization in a structurally divergent fashion. The presented method employs photoredox/iron dual catalysis to facilitate the chemoselectivity of the transformation. This strategy gives access to two structurally distinct sets of products, tetrahydrofurans and γ-bromoketones, under one set of reaction conditions.

**Results and discussion.** Chemoselectivity control is achieved by modulating the presence of a metallic needle. In this context, the needle serves as an unprecedented earth-abundant metal catalyst source, which operates in synergy with photoredox conditions. With this photo-driven method in hand, we are able not only to generate alkoxy radicals under mild reaction conditions but also to utilize them in a chemoselectively controlled fashion for an elegant conversion of simple alcohols to two synthetically relevant synthons.

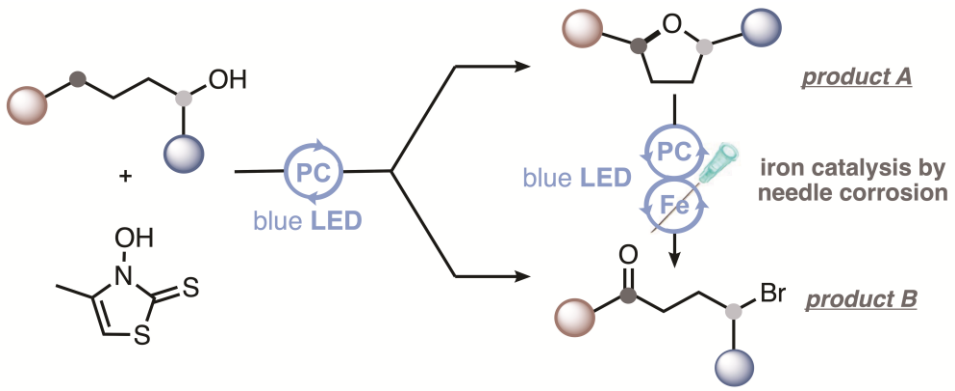

**Figure 1. Visible-light mediated oxidative transformation of alcohols to tetrahydrofurans (product A) and γ-bromoketones (product B) employing a dual catalysis approach**

**Keywords:** methane, photocatalysis, acetic acid, water

**Introduction.** Methane is one of the most abundant energy reserve feedstocks on earth, and its direct catalytic functionalization to value-added chemicals holds great interest to the modern scientific community. The current industrial route for methane transformation to obtain acetic acid (AcOH) as an important industrial chemical is an energy-intensive and indirect multistep route through methane reforming to syngas (CO and $H_2$), methanol synthesis, and subsequent methanol carbonylation to AcOH. The direct routes use strong oxidants such as corrosive acid or molecular oxygen leading to environmental issues, safety risks, and low selectivity[1]. Consequently, realizing a milder oxidative transformation of methane to produce acetic acid would be of great significance.

**Experimental/methodology.** The catalyst synthesis was realized by stepwise precipitating Pt-anchored ammonium phosphotungstic polyoxometalate (i.e.,$(NH_4)_xPW_{12}O_{40}$, abbreviated as NPW) particles and mixing them with $TiO_2$ via grinding and heat treatment. The photocatalytic $CH_4$ conversion was performed in a 100 mL batch photoreactor under 1 bar of CO and 10 bar of $CH_4$, with a 400 W Hg−Xe lamp used as a light source. Throughout the reaction, the catalyst−water suspension (10 mL) was magnetically stirred at 20 °C.

**Results and discussion.** Herein, we show that under the irradiation of UV light, $CH_4$ and CO can be catalytically converted to acetic acid, with $H_2O$ as the sole oxidant at room temperature according to the equation: $CH_4 + CO + H_2O \rightarrow CH_3COOH + H_2$[2]. The characterization shows that the catalyst is composed of isolated Pt atoms anchored by polyoxometalate clusters to $TiO_2$ (**Figure**). $Pt_1/NPW/TiO_2$ enables a stable synthesis of 5.7 mmol·$L^{-1}$ acetic acid solution in 60 h with the selectivity over 90% and 66% to acetic acid on liquid-phase and carbon basis, respectively, with the production of 99 mol of acetic acid per mol of Pt. Combined isotopic and in situ spectroscopy (XAS, FTIR, EPR) investigation suggests that the C-H activation of $CH_4$ and subsequent carbonylation occurs at the $Pt_1$ sites, facilitated by the photo-generated holes from $TiO_2$ producing ·OH radicals from water; in the meantime, with the assistance of photo-generated electrons, the underlying polyoxometalate cluster served as a reactive oxygen reservoir, realized the oxidation of methyl carbonyl intermediate with subsequent regeneration by water (**Figure**).

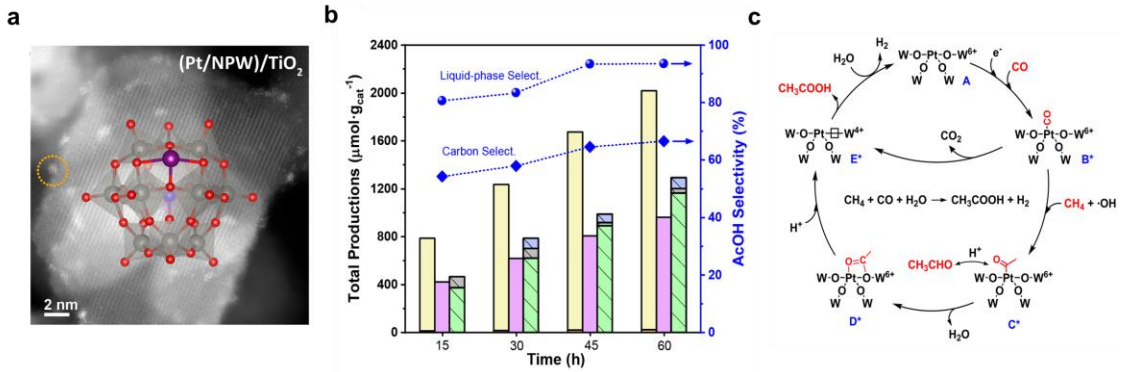

**Figure.** (a) Atomic-resolved HAADF-STEM image of $Pt/NPW/TiO_2$, (b) accumulated products and selectivity to AcOH, (c) scheme of the reaction.

# Photocatalytic Water Splitting Over Reduced $TiO_2$

Pınar Özdemir[1], Ramazan Yıldırım[1*]

[1]*Boğaziçi University, Istanbul, Turkey*
[*]*Corresponding Author's E-mail: yildirra@boun.edu.tr*

**Keywords:** Photocatalytic Glycerol Reforming, Hydrogen Production, Black $TiO_2$, Reduced $TiO_2$, Au/B-$TiO_2$

**Introduction.** Solar energy, as the largest source in earth, can be used directly or utilized to produce solar fuels such as the hydrogen produced from water via photocatalytic or photoelectrochemical processes. $TiO_2$ is the most widely used semiconductor in photocatalytic reactions as an abundant, inexpensive and relatively harmless material for human health and environment; however, it needs to be modified (like surface reduction) because its activity is low under visible light [1]. The aim of this study is to investigate the photocatalytic $H_2$ evaluation of reduced (black) $TiO_2$ (B-$TiO_2$), which is known to be more active under visible light, with 1 wt.% platinum (Pt), 0.2 wt.% gold (Au) and 1 wt.% copper (Cu) co-catalysts.

**Experimental/methodology.** B-$TiO_2$ was prepared by chemical reduction method with $NaBH_4$ [2]. Whereas Au and Cu were loaded on B-$TiO_2$ by deposition precipitation with urea [3], Pt was loaded using the incipient to wetness impregnation method. The $H_2$ production performance of all prepared catalysts were carried out in a semi-batch photoreactor system, equipped with a solar simulator having 300 W xenon lamp, at ambient condition using 1.0 gcat/L in 20 wt.% aqueous methanol (MeOH) or glycerol (GLY) mixtures under argon atmosphere. The determination of $H_2$ production rate was carried out via a gas chromatograph system.

**Results and discussion.** The photocatalytic $H_2$ evolution performance of Pt, Au, and Cu supported on reduced nano $TiO_2$ was tested in MeOH and GLY aqueous mixtures under visible light (Fig. 1a). The hydrogen production was much higher with GLY solution while Au was the best performing co-catalyst with GLY even though its loading was 1/5 of Pt. The characterization tests revealed that the reduction of nano $TiO_2$ with $NaBH_4$ was successful as evident from the change of color from white to black and TEM analysis that shows ~1.5 nanometer of disordered layer on the surface (Fig. 1b-d). Decreased band gap and higher light adsorption (Fig. 1e-f) in visible region indicates the visible light sensitivity of B-$TiO_2$ by reduction. Au was well dispersed on the surface as spherical particles as expected from the deposition precipitation method (Fig. 1g-h), and desirable to see the plasmonic effects under visible light.

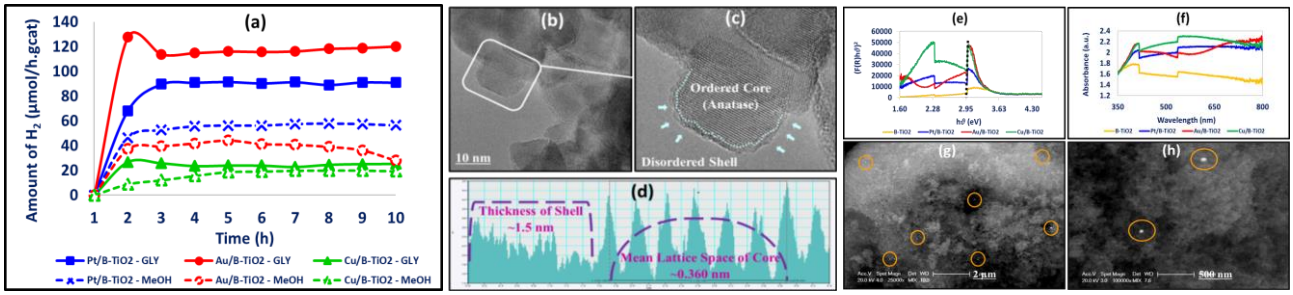

**Fig. 1. (a)** The $H_2$ evolution performance of B-$TiO_2$ based catalysts in MeOH and GLY aqueous mixture under visible light, **(b,c and d)** TEM images and lattice space of B-$TiO_2$, **(e-f)** UV-Vis absorption spectra and bandgap energy of B-$TiO_2$ based samples, **(g-h)** SEM images of 0.2 wt.% Au over support, respectively.

**Keywords**
Optofluidic planar microreactor, Iridium oxide, Titanium dioxide thin film, Photocatalytic water splitting, Oxygen evolution; Sol-gel spin coating

## Introduction

Since the discovery of photoelectrochemical cell (PEC) using $TiO_2$ material for water splitting to produce $H_2$ and $O_2$ by Fujishima and Honda, the semiconductor photocatalysis has been receiving considerable attention[1]. Powder suspensions are usually implemented to study the photocatalytic water splitting activity. Although the reactor system (e.g., slurry reactor) is simple, it has drawbacks such as lower light penetration because of solution turbidity, lower utilization of active catalytic sites, lower surface area to volume ratio and separation of catalyst material after reaction. These problems can be alleviated by employing immobilized photocatalyst based optofluidic microreactors[2]. Such microreactors can provide high surface area to volume ratio and thus excellent mass and photon transfer efficiency. Among various optofluidic microreactors, the planar microreactor has advantages of higher photon receiving area, throughput and easy scale-up[3]. Therefore, the objective of the present work was to fabricate the optofluidic planar microreactors with the immobilized $TiO_2$-based photocatalyst and to use it for the production of green hydrogen and oxygen from the photocatalytic water splitting under visible light by the deposition of Pt and $IrO_2$, respectively.

## Experimental/methodology

Optofluidic planar microreactor for production of oxygen[4,5,6]:

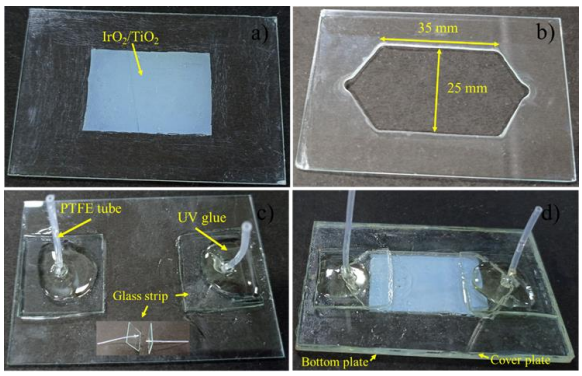

**Figure 1. a) Bottom plate with catalyst coating; b) Reaction chamber; c) Cover plate with inlet and outlet tubes; d) Fabricated planar microreactor. (Reproduced from Ref. 6 with permission)**

## Results and discussion

The effect of reactant flowrate on the rates of hydrogen (HER) and oxygen (OER) production is shown in Fig. 2. In both the cases, the production rate was increased initially (at lower flowrates) and then decreased passing through a maximum at 0.3 mL $min^{-1}$. The increase in the production rate with increase of flow rate up to 0.3 mL $min^{-1}$ could be due to the presence of the external mass transfer resistance at lower flow rates. Beyond 0.3 mL $min^{-1}$, the decrease in the production rate could be due to the decrease in the

reactant residence times. Therefore, 0.3 mL $min^{-1}$ was found to be an optimal reactant flowrate where the maximum production rates of both HER and OER were obtained.

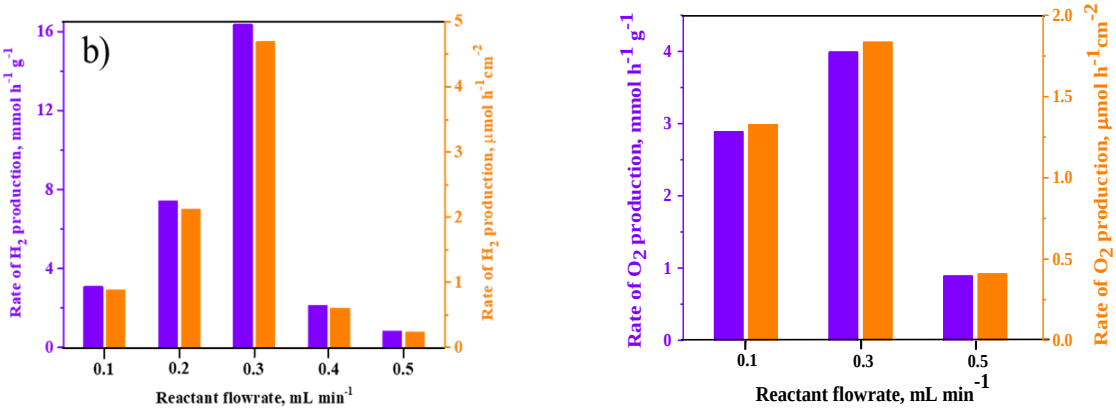

**Figure 2. (a) Rate of hydrogen production (Reaction conditions: Reactant-20 vol.% methanol in DI water, Pt/$TiO_2$ film); (b) Rate of oxygen production (Reaction conditions: Reactant-10 mM $NaIO_3$ in DI water, $IrO_2$/$TiO_2$ film); as a function of reactant flowrate. (Reproduced from Ref.s 5 and 6 with permission)**

## Conclusions

The optofluidic planar microreactors were fabricated and tested successfully for the photocatalytic water splitting for the production of both hydrogen and oxygen, under visible light. The rates of hydrogen and oxygen production were passed through a maximum with reactant flowrate. The hydrogen and oxygen production rates of 16.35 mmol $h^{-1}$ $g^{-1}$ (4.7 µmol $h^{-1}$ $cm^{-2}$) and 4.0 mmol $h^{-1}$ $g^{-1}$ (1.84 µmol $h^{-1}$ $cm^{-2}$) were obtained over the Pt/$TiO_2$ and $IrO_2$/$TiO_2$ films, respectively, at an optimum reactant flowrate of 0.3 mL$min^{-1}$.

# Photosensitised PCET mediated β-Scission of alcohols for addition reactions

Y. Patehebieke, H. P. Bryce-Rogers, C. J. Wallentin*

*Department of Chemistry and Molecular Biology, University of Gothenburg, 412 96 Gothenburg, Sweden*
*carl.wallentin@chem.gu.se*

**Introduction.** With recent advances in photocatalysis and radical chemistry, radical-mediated C-C bond cleavage has emerged as a powerful disconnection strategy for the rapid assembly of structurally diverse carbon skeletons. Among them the alkoxy radical mediated deconstruction and functionalization have attracted considerable research attention. As a highly reactive transitory species alkoxy radicals have a well-known variety of reactivity, such as hydrogen atom transfer, addition to π systems,and β-scission. The homolytic cleavage of an adjacent β-C-C bond provids C-centred radicals, such species can further be used in a variety of both intra- and intermolecular transformations. [1]

Due to the high bond dissociation energy (BDE ~105 kcal $mol^{-1}$) and redox potential of alcohol O–H bond the direct formation of an alkoxy radical from a free alcohol is formidably challenging. Hence, most common methods rely on O-functionalized precursors to generate alkoxy radicals. Employing prefunctionalised alcohol-auxiliary precursors that undergo thermal/photo/radical induced homolysis, has the drawbacks of tedious synthetic prefunctionalisation, poor stability, toxicity, and narrow functional group tolerance. [2]

Recent development in transitionmetal and photoredox catalysis have enabled direct access to alkoxy radicals from unprotected alcohols. However, many of these methods require the use of precious metalcatalysts or stoichiometric oxidants. [2] As such, the developing more sustainable approaches for the generation of alkoxy radicals directly from alcohols is an important and timely pursuit.

Here we present a novel photocatalytic method for one carbon-tethering of nucleophiles and electrophiles via β-scission of alkoxy radicals which directly generated from secondary and tertiary alcohols.

**Results and discussion.** In this work, a successful study utilising an indirect proton-coupled electron transfer (PCET) mediated procedure, showcasing the formation of a diverse library of C-$sp^3$ radical nucleophiles. Subsequently, these radical intermediates are synthetically utilised to build molecular complexity onto a range of coupling partners. The protocol allows for the efficient intermolecular tethering of a nucleophile and an electrophile via a methylene group.

**Keywords:** Photocatalysis, Formic acid, Hydrogen production, $CO_2$ hydrogenation, $N_2$ hydrogenation.

**Introduction.**

Tranditionally, $H_2$ releasese from formic acid needs the input of external energy to reach a high temperature for a decent activity, especially when heterogenous catalyst is applied. The aim of this research is to explore the production of $H_2$ from formic acid with the assistance of light, eliminating or minimizing the need for external energy input. Additionally, we aim to utilize the released $H_2$ for cascade hydrogenation reactions. However, many hydrogenation reactions, such as $CO_2$, CO, and $N_2$ hydrogenation, typically require high temperatures. Recent advancements have shown that solar energy can promote reactions through photothermal processes. Plasmonic metal nanoparticles (NPs) can absorb incident solar light and induce high localized temperatures. This localized surface plasmonic effect allows most metal NPs to respond to visible to near-infrared light, which matches the solar spectrum, maximizing the utilization of solar energy. Therefore, another objective of this research is to achieve hydrogenation reactions under milder conditions with minimal fossil fuel energy input.

**Experimental/methodology.**

The formic acid reaction was tested in a semi-batch system connected to a burette, allowing the measurement of produced $H_2$, as well to maintain ambient pressure. The incident light can be introdued through the top of the photo reactor.

The hydrogenation reactions were performed in a customized fixed bed reaction, in which the incident light can introducd from the top (more detailed information of the reaction can be see in ref. 1).

**Results and discussion**

(1) We have proved that the formic acid dehydrogenation can be realized upon light irradiation with the absence of external heating, reaching an activity comparable with state of the art activity reported in thermal fashion.
(2) Efficient photocatalysts were obtained for the $CO_2$ and nitrogen hydrogenation. Specifically, earth abundant hydroxylapatite based catalyst was synthesized, and it exhibited high selectivity towards CO production. For nitrogen hydrogenation, Cs promoted Ru catalyst supported on $SrTiO_3$ or $ZrO_2$ were synthesis, and both catalysts exhibited high acitvity towards ammonia production.
(3) We have established an efficient photo-assisted hydrogenation reaction setup, and demonstrated that the activity for both $CO_2$ and $N_2$ hydrogenation can be efficiently enhanced upon light irradiation.
(4) The role of incident light was elaborated by plenty of experimental results. Specifically, the thermal and nonthermal contribution to the activity were carefully studied.

# Photocatalytic selective oxidative cleavage of β-O-4 linkages of a lignin based model compounds by Novel $TiO_2$ nanomaterials

Abdul Qayyum*, Dimitrios A. Giannakoudakis, Darius Lomot, Juan Carlos Colmenares*
*Institute of Physical Chemistry, Polish Academy of Sciences, Kasprzaka 44/52, 01-224 Warsaw, Poland*
*aqayyum@ichf.edu.pl, jcarloscolmenares@ichf.edu.pl*

**Introduction:** Heterogeneous photocatalysis using metal oxide semiconductors is one of the most promising method to achieve the high value aromatic compounds via the cleavage of the inter-unit linkages/bridges of lignin [1]. Titania based nanocatalysts are considered a promising candidate for heterogeneous catalysis due to specific unique physicochemical properties [2]. The reported $TiO_2$ samples possessed less selectivity toward the products. The key goal of this research work was to synthesize the novel US-assisted $TiO_2$ nanomaterials for the significantly higher photocatalytic selective cleavage of β-O-4 bond of a lignin based model compounds to the corresponding products.

**Experimental:** In this research work, low-frequency ultrasound (US) 22 kHz with varying the amplitudes (such as 10, 30, 50, 70 and 90 µm) was used during the precipitated synthesis of $TiO_2$ catalysts. The synthesized $TiO_2$ catalysts were characterized with different characterization techniques such as XRD, UVDRS, TEM, XPS and TGA. All the synthesized $TiO_2$ samples were studied for the catalytic selective cleavage of lignin based model compounds such as benzyl alcohol and 2- phenoxy-1-phenylethanol (PP-ol) to the corresponding products **(Figure 1a)** under the UV (365 nm) light irradiation.

**Results and discussion:** The US-assisted $TiO_2$ sample by using 30 µm showed the highest specific surface area (319 $m^2/g$) and total pore volume (0.339 $cm^3/g$) as compared to all other synthesized samples. Electron microscopy analysis showed the utilization of US during step led to the formation of nanorods. The photocatalytic performance of all the US assisted $TiO_2$ samples was pre-screened by evaluating the partial selective oxidation of benzyl alcohol to benzyl aldehyde. The US22-30µm catalyst showed the highest conversion of benzyl alcohol (75%), and yield of benzyl aldehyde (68 %) as compared to all other US assisted synthesized $TiO_2$ catalysts.

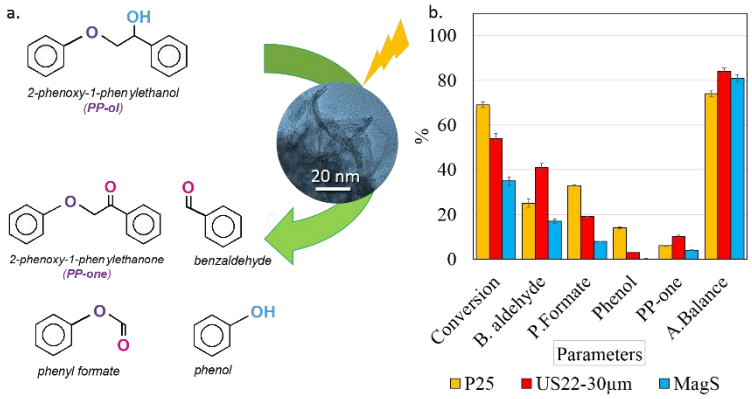

**Figure 1**. The schematic of the targeted reaction (a), photocatalytic activity of $TiO_2$ samples (b)

P25 showed the highest conversion (67 %) of PP-ol with the 25 % yield of the benzyl aldehyde, which is the desired product, whereas as US22-30µm showed lower conversion (56%) of PP-ol but a higher yield (45%) of benzyl aldehyde **(Figure 1b)**. Whereas, the MagS showed the least PP-ol conversion of 34 %. This research work showed that optimizing not only the frequency but also the amplitude of the sonication play a key role on the synthesis of metal oxide-based catalysts and the physicochemical features as well as the photocatalytic performance of synthesized catalysts can be tuned accordingly.

**Keywords:** Plasmonic catalysis, nanorattles, visible light, $CO_2$ reduction

**Introduction.**

Plasmonic nanorattles (PNRs) have gained attention due to their unique and enhanced optical properties compared to spherical nanoparticles. Their structure consists of a core inside a shell which are separated by a void between them. This results in the hybridization of localized surface plasmon resonance modes between the core and shell leading to the formation of electromagnetic hot-spots, that can contribute to improved performances in plasmonic catalysis relative to spherical nanoparticles.[1] Additionally, the porous shell can be comprised of a combination between a plasmonic and catalytic component, providing a unique antenna-reactor design.[1,2] In this poster, we will present recent advances on the development of PNRs consisting of an Au core, surrounded by an alloy shell of Ag and Pt or Pt, respectively, as a plasmonic catalyst towards the $H_2$ evolution reaction (HER) and $CO_2$ reduction reactions.

**Experimental/methodology.**

The PNRs were fabricated by a solution-phase approach consisting of a three-step process. The first step involved the preparation of Au NPs by the Turkevich method. In the second step, an Ag shell is formed by a seeded-growth process, whereby ascorbic acid is used as reducing agent in both steps. The third step involved the galvanic replacement of Ag with Pt or Pd by using PVP as a capping agent.[1] The particles were characterized by elemental analysis, electron microscopy, and using UV-Visible absorption spectroscopy. For HER studies linear sweep voltammetry (LSV) measurements are performed in 0.5 M $H_2SO_4$ with a scanning potential range from 0.1 to -0.3 V (vs. RHE). To prepare the electrodes, an ink consisting of a mixture of the sample and vulcan carbon in a Nafion solution is drop-casted onto a glassy carbon electrode. The $CO_2$ reduction reactions are investigated in a fixed bed reactor under different parameters, such as temperature, pressure, and light excitation of the PNRs. The reduction products are measured by a GC-MS.

**Results and discussion.**

We focused so far in PNRs containing Au as a core and two types of plasmonic-catalytic shells: AgPd or AgPt, leading to Au@AgPd and Au@AgPt PNRs, respectively. Our data shows that our procedures were effective for the synthesis of the PNRs with the desired morphological and compositional features, presenting LSPR bands in the visible range. In terms of the activity towards the HER, our initial catalytic data with the Au@AgPd PNRs suggest a reduction in the overpotential under visible light illumination. Regarding the $CO_2$ reduction reaction, the performances and the establishment of structure-performance relationships are under investigation. To this end, the PNRs synthesis has been scaled-up and the PNRs have been deposited into commercial $SiO_2$ as supports by dry impregnation. A detailed investigation of catalytic performances as a function of the PNRs compositions, morphological features, light excitation wavelength and intensity, as well as the benchmarking of performances relative to dark conditions and conventional NPs catalysts or plasmonic materials are under investigation.

**Conclusion.**

In this work, PNRs have been prepared by a combination of seeded growth and galvanic replacement approaches. These PNRs are being employed as plasmonic catalysts towards both the HER from water and the $CO_2$ reduction. Initial catalytic data indicate that visible light excitation leads to an activity enhancement. We aim to combine advanced optical and morphological characterization with results from the catalytic tests to unravel structure-performance relationships and enhancement mechanisms under light excitation.

# Photoelectroreduction of nitrates to ammonia in hybrid plasmonic nanocatalysts

Vitor R. Silveira [1], Robert Bericat-Vadell [1], Jacinto Sá [1 *]

[1] *Physical Chemistry Division, Department of Chemistry - Angstrom Laboratory, Uppsala University, Box 523, 751 20 Uppsala, Sweden*

[*] *jacinto.sa@kemi.uu.se*

**Introduction.** Advancements in farming practices have resulted in the widespread use of nitrogen-based fertilizers, such as ammonia, produced by the nitrogen reduction in the Haber-Bosch process. [1] Extensive efforts have been made to create alternative, eco-friendly methods for ammonia production on a large scale that can be implemented locally. In that sense, the reduction of nitrates ($NO_3^-$) present as a potential method to substitute the nitrogen reduction reaction. [2] We suggest a NiO/Au/$TiO_2$ photosystem that selectively creates ammonia from nitrates using visible light at normal pH and temperature through plasmon hot electrons.

**Experimental/methodology.** The catalyst's thin films were synthesized over a conductive glass (FTO) by a combination of screen printed NiO (Solaronix®), spray coated Au NPs (8 nm, synthesized by Turkevich method), and spin coated $TiO_2$ (Solaronix®). These catalysts were then characterized with steady-state and transient spectroscopy. Electrocatalytical studies were conducted in a gas-tight single compartment cell, using Ag/AgCl reference electrode and Pt wire counter electrode in $KNO_3$ 0.2 M aqueous solution. The cell worked under continuously flow of Ar (30 mL $min^{-1}$) and its outlet was connected to a quadrupole mass spectrometer, which measured online the gas produced during the reaction. In the end of the reaction, $NH_4^+/NH_3$ and $NO_2^-$ production were quantified through photometric methods.

**Results and discussion.** Figure 1 depicts the generation of ammonia and nitrite using the full photocatalyst (NiO-Au-$TiO_2$) and its counterparts. It is noteworthy to observe that all systems exhibit the formation of $NO_2^-$, indicating that this species acts as an intermediary in the reaction, aligning with previously documented mechanisms of nitrate hydrogenation. [2] Furthermore, the results suggest that $TiO_2$ presents high selectivity towards ammonia production, even in the absence of light, due to its ability to effectively bind both $NO_3^-$ and the intermediate $NO_2^-$. On the other hand, the other catalysts generate $NO_2^-$ which is then released into the solution, thereby cleaning the active sites, resulting in greater conversion of $NO_3^-$ to $NO_2^-$. This leads to the interesting conclusion that the active site for $NO_3^-$ reduction is the same to that of $NO_2^-$ reduction. With regards to the impact of photogenerated carriers on the catalytic activity, the results demonstrate that NiO-Au-$TiO_2$ exhibits the most pronounced difference in the formation of ammonia and nitrite ions between illuminated and dark conditions, compared to other $TiO_2$-based counterparts. This trend is in accordance with the higher charge separation facilitated by the presence of a hole and electron acceptor in NiO-Au-$TiO_2$, as indicated by the transient spectroscopy measurements not reported in this abstract. Online measurement of generated gases revealed limited hydrogen gas production (a common competitor in nitrate reduction) at lower potentials and suppressed hydrogen production under light conditions at higher potentials. This indicates improved charge separation in the hybrid plasmonic nanocatalyst results in increased ammonia formation and decreased hydrogen production.

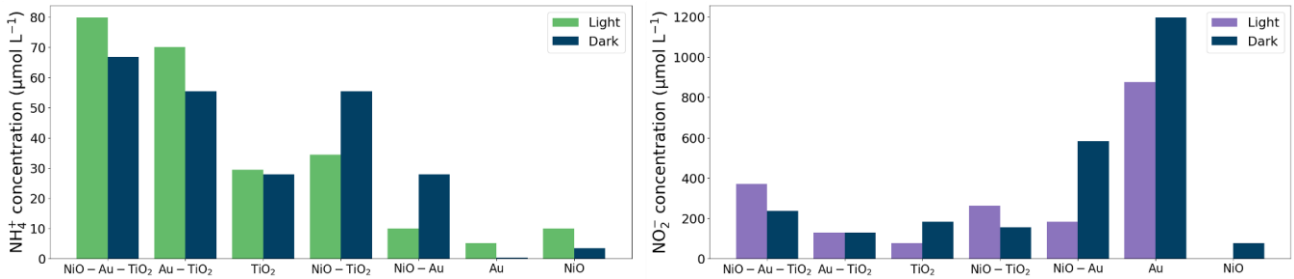

**Figure 1. Formation of ammonium (left) and nitrite ions (right) at -1.21 V vs Ag/AgCl in $KNO_3$ 0.2 mol $L^{-1}$ over a thirty-minute interval under both illuminated and dark conditions.**

**Keywords:** photocatalyst, photogenerated charge carriers, $CO_2$ conversion

**Introduction:** Photocatalytic conversion of $CO_2$ and water into fuel and commodity chemicals offers a potential green route towards a circular economy but is challenging due to the multi-proton-electron transfer steps involved and sluggish surface reaction kinetics.[1,2] Effective separation, migration, and capture of photogenerated charge carriers are key parameters to enhance the $CO_2$ conversion efficacy of photocatalysts.[3] Here, through computational simulations of $Cu_2O$ crystals with different facets, edge-truncated cubic $Cu_2O$ crystal was confirmed to enable efficient charge separation and experimental results revealed that the promotion of photocatalytic $CO_2$ reduction reaction and water oxidation reaction on the reduction {110} and oxidation {100} facets, respectively.

**Experimental/methodology**: Using standard precipitation and reduction techniques, two distinct $Cu_2O$ photocatalyst morphologies were synthesized, one with cubic crystals and the other with edge-truncated cubic crystals. The steady-state photoreduction reactions were carried out using a 300 W Xe lamp light source with AM 1.5 G filter. The morphologies and structures of photocatalysts were determined by transmission electron microscopy. The crystallinity and elemental compositions of photocatalysts were measured by powder X-rat diffraction patterns energy-dispersive X-ray photoelectron spectroscopy analysis. The photoresponse data were obtained through UV-vis spectra and photoluminescence spectroscopy.

**Results and discussion:** The photocatalytic activity toward the selective reduction of $CO_2$ to methanol on the edge-truncated cubic $Cu_2O$ with anisotropic {100} and {110} facets was found to be nearly 5.5-fold higher than that of cubic $Cu_2O$ with only {100} facets (**Figure 1a**) and were also stable for multiple photocatalytic cycles (**Figure 1b**). This observed difference is ascribed to the effective separation and migration of photogenerated charge carriers as well as the selective accumulation of electrons and holes on different facets of edge-truncated cubic $Cu_2O$ crystals (**Figure 1c**), which was confirmed through the optoelectronic simulations of modeled edge-truncated $Cu_2O$ crystal.

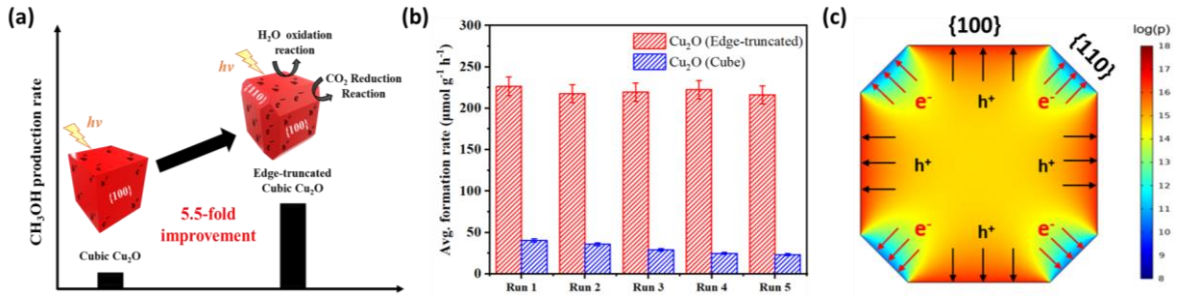

**Figure 1: (a) Photocatalytic $CO_2$ reduction performances of prepared samples in atmospheric conditions. (b) Stability test of both photocatalysts after five cycles. (c) A simulated 2D-surface plot of edge-truncated $Cu_2O$ crystal.**

**Introduction.** Arguably, few other methods have led to the type of scientific revolution as revealing the structure-function relationship between proteins and the mechanism of life and has been a staple of structural biology ever since. Technological advances in X-ray generation at synchrotrons and more recently X-ray free electron lasers (XFEL:S) has provided access to brilliant, short X-ray pulses which in conjunction with traditional pump-probe techniques have laid the foundation for time resolved (TR) diffraction-based experiments.[1] The scope of available proteins has been restricted to photo responsive proteins and to expand the scope of targets, new tools must be developed. The use of photolabile cage substrates has recently become a discussed topic within structural biology[2] and in our work we have employed (μ-peroxo)-(μ-hydroxo)bis[bis(bipyridyl)cobalt (HPBC) caged-oxygen complexes which can liberate millimolar concentrations of molecular oxygen upon a single laser pulse to study *ba*$_3$-type cytochrome c oxidase with the use of synchrotron and XFEL based diffraction studies.

**Results and discussion.** In this work we have synthesized and characterized several new caged oxygen compounds (Figure 1) and developed a protocol to enable reaction initiation between reduced microcrystals of *ba*$_3$-type cytochrome c oxidase and molecular oxygen liberated by a caged oxygen complex under conditions to enable further diffraction-based studies. With the developed protocol in hand, we were able to record room-temperature serial femtosecond crystallography (SFX) data of *ba*$_3$-type cytochrome c oxidase 10 ms after oxygen liberation with a 355 nm laser pulse which shows structural rearrangement of the proteins active site (Figure 2).

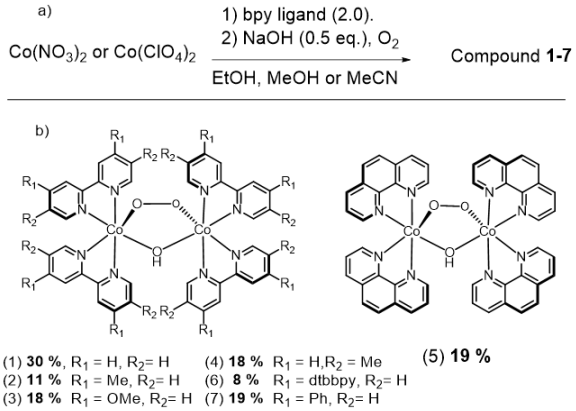

**Figure 1. a)** Overall reaction scheme for the synthesis of Compound **1**-**7**. **b)** Structure and isolated yields of the produced HPBC complexes.

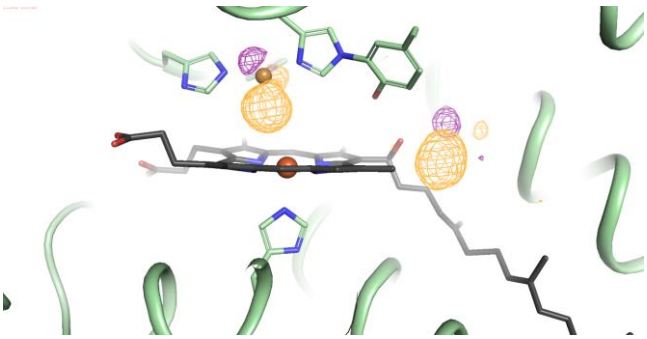

**Figure 2.** Preliminary $F^{obs}$ - $F^{obs}$ difference Fourier electron density map (yellow negative difference density, purple positive difference density, contoured at ± 5 σ) of *ba*$_3$-type cytochrome c oxidase at t = Δ10 ms after oxygen liberation with a 355 nm laser pulse of compound 1 mixed with microcrystals of reduced protein.

# A fundamental approach to the design and engineering of active photoelectrodes for solar water splitting

Taymaz Tabari[1*], Marcin Kobielusz[1], Wojciech Macyk[1]

*Faculty of Chemistry, Jagiellonian University, ul. Gronostajowa 2, 30-387, Kraków, Poland*

**Keywords:** rod architecture, hole consumption, mediator, photoelectrocatalysis

**Introduction.**

Water splitting is an uphill reaction, which needs 237 kJ to produce one mole of hydrogen. To provide it, solar energy can be used to oxidize/reduce water. Despite the numerous attempts to design efficient photoelectrodes in solar water splitting, the reported efficiency is far from reaching the expected theoretical values. This stems from the intrinsic slow charge transportation, and inefficient charge separation, along with poor oxidation kinetics of the photocatalysts such as $TiO_2$, $Fe_2O_3$, etc. Norskov et al. have shown that these photocatalytic systems are unable to efficiently produce oxygen, favoring the production of $H_2O_2$. This phenomenon points to the importance of employing active oxygen evolution reaction (OER) electrocatalysts to increase the efficiency of water splitting in a PEC system. On the other hand, an efficient charge separation at the bulk is a necessity for a photocatalytic system. In this context, 1D materials due to their directional charge transfer showed promising efficacy in charge separation. Herein, we have used a fundamental approach to design active photoelectrodes for solar water splitting constructed in a heterojunction architecture.

**Experimental/methodology.** The materials were synthesized employing hydrothermal, and sol-gel methods, while to build the heterojunction architecture a spin-coater was used. The photoelectrodes were studied using XRD, XPS, SEM, TEM, UPS, Kelvin probe, and electrochemical methods. The photoelectrochemical (PEC) activity is studied in a gas-tight reactor with an irradiation widow of 1 $cm^2$.

**Results and discussion.** In this collective study, we have shown that the most efficient 1D structure photoelectrodes are constructed from long rods with small diameters, which dramatically decreases charge recombination and increases charge separation. Such rods amounted to 0.24% "applied bias photon to current efficiency", which was among the highest activities reported for pristine and heterojunction $TiO_2$ [1]. However, the activity of the photoelectrodes correlates with the OER activity of the catalysts employed to oxidize water. In a series of $La_{1-x}Sr_xFeO_3$ (x = 0, 0.2, 0.4), we have shown that the catalytic activity and the overall PEC activity of the photoelectrodes are correlates with the length of Fe–O bond in these perovskites. The overall activity of the photoelectrodes in solar water splitting was a function of the band bending degree and hole consumption at the interface with electrolyte [2]. High solar to hydrogen efficiency can be obtained when both factors are designed to perform efficiently. However, the hole transfer at bulk and specifically at the interface of two semiconductors in a heterojunction design is hindered by the increased oxygen vacancies and decreased conductivity. Therefore, to improve the charge transfer at the bulk and diminish the back charge transfer, reduced graphene oxide is employed as a 2D mediator to direct the holes to the surface of the photoanode, while at the same time preventing back electron transfer. This architecture, constructed from 1D@2D@0D components, showed the highest activity reported for $Fe_2O_3$-based photoelectrodes, which are related to the optimized electronic and structural properties of it [3].

# Methane Oxidative Coupling on Au-$TiO_2$ Catalyst: DFT Studies

V. Kaipanchery, R. Tokarz-Sobieraj, D. Rutkowska-Zbik*

*Jerzy Haber Institute of Catalysis and Surface Chemistry PAS, Krakow, Poland*
** dorota.rutkowska-zbik@ikifp.edu.pl*

**Introduction.** Direct conversion of methane into fuels and platform molecules is hampered by its inertness, leading to the necessity of harsh reaction conditions to accelerate its reactivity. In recent years, a combined photo- and thermo-catalytic approach to activate mathane was proposed. Experimental studies show that Au-$TiO_2$ catalyst under UV/VIS light irradiation is selective in the oxidative coupling of methane to ethane [1]. The aim of the current contribution is to characterize the properties of the Au-$TiO_2$ catalyst and to study the mechanism of the methane coupling reaction under thermal and photocatalytic conditions.

**Experimental/methodology.** Quantum-chemical calculations were performed in the frame of Density Functional Theory (DFT) and Time-Dependent DFT (TD-DFT) with a PBE+D3 and B3LYP+D3 functionals and the def2-TZVP basis set. The geometry and electronic structure of the catalytic system was characterized by computing selected bond lengths, Mayer bond indices, ESP charges on the exposed surface sites, and the DOS plots.

**Results and discussion.** The system consisting of $Au_{13}$ metallic cluster deposited on $TiO_2$ was proposed as the model of the active site for the reaction (see Figure 1a) and was characterised with the DFT method. The deposition of the gold cluster resulted in the reduction of the HOMO-LUMO gap of the $TiO_2$ suppport, facilitating the charge transfer between the metallic cluster and the support. As a result of light absorption, the electron transfer is encountered and formation of the $TiO_2^{\delta+}$ and $Au^{\delta-}$ is observed.

Then, methane interaction with various sites on the Au-$TiO_2$ catalyst was considered to find the most probable active site for the reaction. The interface between the gold particle and the support or the vacant site at the titanium dioxide are the two preferred sites for the $CH_4$ adsorption. The C-H bond activation of methane requires 146 kJ/mol when occurring at the $TiO_2^{\delta+}$ phase. This energy, however, is lowered to 67 kJ/mol when occurring at the gold – titania interface (see Figure 1b). During the reaction, gold cluster undergoes significant reorganization. Most probably, the coupling between two methyl groups and formation of ethane takes place at the surface of the catalyst.

**Keywords:** photocatalyst, heteropolyacid, $TiO_2$, photo-termo-catalysis, n-butanol dehydration

**Introduction.** The $TiO_2$ is widely used as a photocatalyst. This fact motivated us to irradiate the solid heteropolyacid-$TiO_2$ catalysts by UV light during the gaseous alcohol conversion. The n-butanol conversion was carried out comparatively in both the thermo-catalytic and the photo-themo-catalytic modes as innovative approach (Fig. 1). The application of this reaction has a twofold motivation. First this reaction is of practical relevance, being related to biomass processing, which is a potential source of n-butanol, readily acquired from sugars using Clostridium bacteria. Secondly, the alcohol dehydration over heteropolyacid-$TiO_2$ (HPA/$TiO_2$) catalysts uses their acidic protons and thus allows to establish their order of acidity. Moreover our recent research has showed that the catalytic activity of HPA/$TiO_2$ nanocomposites strongly depends on the used $TiO_2$ polymorph [1].

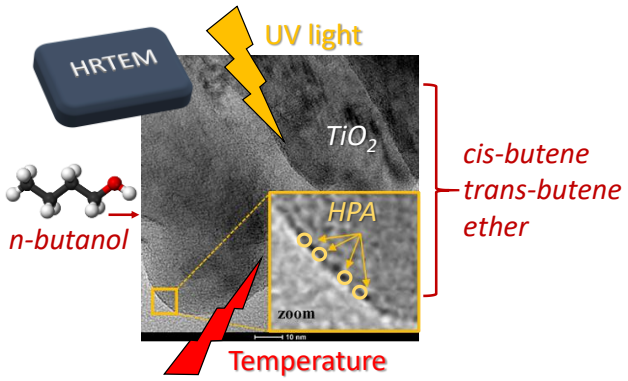

**Fig.1. Schematic illustration of reaction**

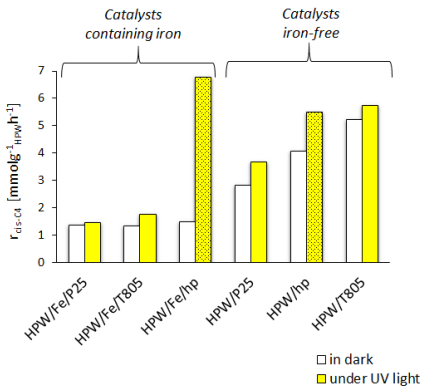

**Fig. 2.Rate of cis-C4 formation over solid catalysts upon UV light**

**Experimental/methodology.** As an active phase $H_3PW_{12}O_{40}$ (HPW) heteropolyacid was applied. In turn the photocatalytic oxides: $Fe_2O_3$ and $TiO_2$ were tested as the additive and support, respectively. In the case of $TiO_2$ such as home-prepared (hp) and commercial, hydrophobic T805 and the hydrophilic P25 oxides, with different morphological forms like cubes, nanobars and tiles were applied. Two series of catalysts were synthesised: HPW/$TiO_2$ and HPW/$Fe_2O_3$/$TiO_2$. The authors constructed special photocatalytic chamber with UV light which was connected on-line with GC. Such way allows to monitor this gaseous reaction without or with light. The broad spectrum of techniques such as XRD, HRTEM, UV-vis, FTIR and Raman spectroscopies, XPS, BET analysis and GC were used to characterize the physicochemical (including optical) properties of these photocatalysts. The electronic and geometry structure of heteropolyacid-$TiO_2$ systems was determined within DFT (PBE+D3/def2-TZVP) and their theoretical spectra simulated within TD-DFT.

**Results and discussion.** Four main factors to be of critical importance for achieving high catalytic activity of HPA/$TiO_2$ nanocomposites were identified: type of $TiO_2$ polymorphs, their surface area, hydrophobic properties, and acid strength [2]. The best performance was observed for HPW/$Fe_2O_3$/hp and HPW/T805 catalysts. The last one is active most likely as a result of hydrophobic nature of T805 support, that protects the proton sites from competing effect of $H_2O$ molecules with respect to alcohol molecules. The iron addition into HPA/$Fe_2O_3$/$TiO_2$ nanostructures caused the increase of selectivity to di-n-butyl ether. The UV light use is mainly manifested by significant increase of cis-butene rate formation (Fig. 2).

# Improvement of Photoelectrocatalytic Activity and Stability of $WO_3$ for Oxygen Evolution by Loading Brownmillerite $Ca_2FeCoO_5$ as a Cocatalyst

E. Tsuji, Y. Degami, H. Okada, S. Suganuma and N. Katada

*Center for Research on Green Sustainable Chemistry, Tottori University, Tottori, Japan*
*e-tsuji@tottori-u.ac.jp*

**Keywords:** cocatalyst, $WO_3$, water splitting

**Introduction.** The increasing demand of hydrogen as a clean energy resource and a chemical feed stock has promoted the development of photocatalysts for water splitting. $WO_3$ is one of the most promising photocatalysts acted under visible light illumination. However, there are mainly two problems; (i) oxygen evolution reaction (OER) on $WO_3$ is kinetically slow, and (ii) peroxide species is also formed during photooxidation of water, inducing rapidly photocorrosion of $WO_3$. One of the effective strategies to improve OER activity and stability of $WO_3$ is loading of OER cocatalysts. In this study, we report improvement of photoelectrocatalytic activity and stability of $WO_3$ for OER by loading brownmillerite-type $Ca_2FeCoO_5$ (CFCO) [1], which showed higher OER activity than noble metal oxides in alkaline solutions [2].

**Experimental/methodology.** CFCO was synthesized by a sol-gel method containing a calcination procedure at 873 K [1]. Photoanodes were prepared by an electrophoretic deposition method (EPD). $WO_3$ was loaded on FTO substrates at 10 V and calcined at 723 K, then, CFCO was loaded on them at 2 - 5 V. Finally, the resultant CFCO/$WO_3$ were calcined at 873 K. The photoelectrochemical performances were investigated by using a normal three electrode system using the CFCO/$WO_3$, a Pt and a Ag/AgCl/KCl (satd.) electrode as the working, counter and reference electrodes, respectively. The solar simulated light was irradiated from the back side of the FTO glass. An aqueous solution was a neutral electrolyte containing phosphate.

**Results and discussion.** The amounts of CFCO gradually increased with increasing applied EPD voltage between 2 and 4 V, and drastically increased at 5 V. The photocurrent increased with increasing CFCO up to 3 V and decreased at more than 4 V. The saturated photocurrent density of CFCO/$WO_3$ loaded at 3 V came close to those of $WO_3$ with $RuO_2$. From cyclic voltammograms, saturated photocurrent of CFCO/$WO_3$ formed at 3 V was almost constant during cycling test for 10 cycles (Fig. 1a), whereas that of bare $WO_3$ rapidly decreased with increasing the cycles (Fig. 1b). From SEM images after the photoelectrochemical water splitting, the surfaces of $WO_3$ particles were maintained smooth by loading CFCO (Fig. 1c), whereas those of bare $WO_3$ particles became uneven and a lot of pits were formed (Fig. 1d). These results suggest that photocorrosion of $WO_3$ was suppressed by loading of CFCO, leading to improvement of stability.

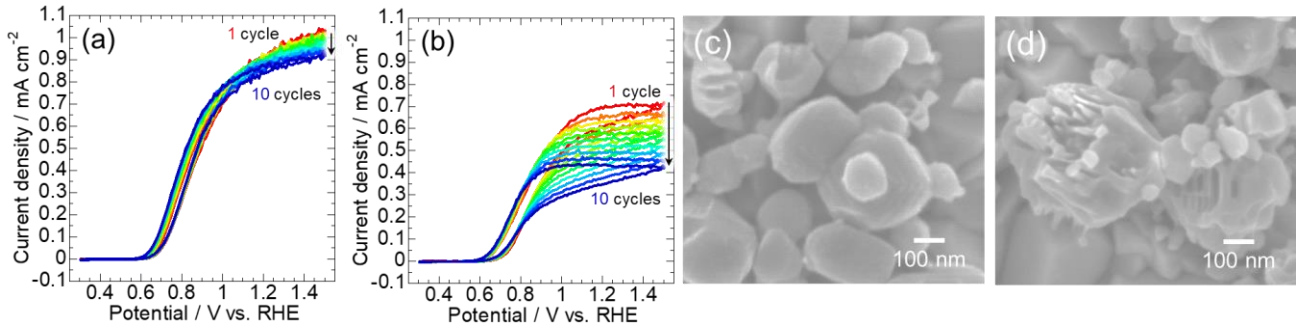

**Fig. 1. Cyclic voltammograms of (a) CFCO/$WO_3$ prepared by the EPD method at 3 V and (b) bare $WO_3$. (c) and (d) shows SEM images of the CFCO/$WO_3$ and bare $WO_3$ after the stability tests.**

**Introduction**

Water molecules close to a charged solid surface play a crucial role in electrochemical processes. Indeed, the organization of interfacial water, which depends on the chemical composition and geometry of the catalyst surface, controls: i) the transport of ions and other molecular species and ii) the thermodynamics and kinetics of reactions (such as catalyst performances, activation energy and reaction rate) [1,2]. Thus, unravelling the structural and electrical organization of the electric double layer (EDL), *i.e.,* the region of water in the proximity of a solid surface, is fundamental for a deep knowledge of electrochemical processes and for the development of new and efficient catalysts [1,2]. Motivated by these reasons, in this work, by combining experimental and theoretical approaches, we provide new insights into the water network at solid interfaces and relate it to the electrochemical water splitting.

**Experimental**

Different $TiO_2$ (undoped and boron-doped) powders were synthesized. X ray diffraction (XRD), UV-vis, Raman and photoluminescence techniques were used to characterize the catalysts. The samples were tested for hydrogen production, and molecular dynamics simulations and highly accurate FTIR spectroscopic measurements were performed to obtain information about the arrangement of interfacial water.

**Results and discussion**

The rate of $H_2$ production over the B-doped $TiO_2$ is about 4.5 times higher than that of the other $TiO_2$ catalysts (Figure 1a). This result is related to the specific hydrogen-bond network of the water molecules which is strongly influenced by the morphology of the solid surface. Through the analysis of the FTIR spectra and, in particular, by probing the vibrational modes of water (OH stretching and HOH bending modes), we found five different water populations (an example is reported in Figure 1b) that change at varying the interface. The experimental results agree with the theoretical ones that suggest that the boron atoms never act as water-adsorption sites or as available surface sites for hydrogen-bonds formation. In addition, the boron atoms can tune the surface work function of $TiO_2$, enhancing interfacial reactions with the aqueous environment.

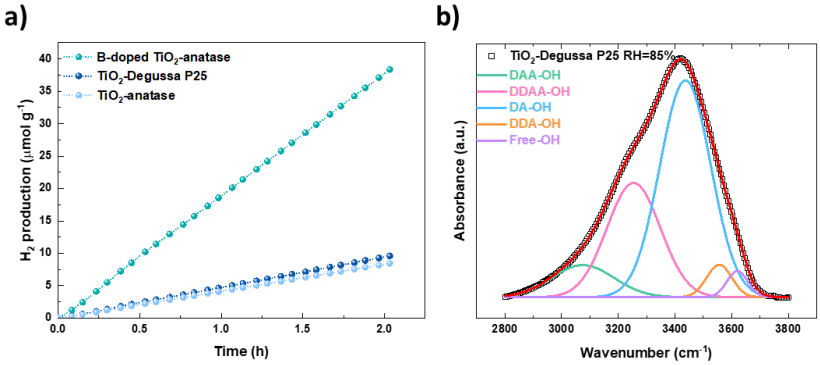

**Figure 1: a) Hydrogen production (in µmol per gram of catalyst) versus time over the investigated $TiO_2$ catalysts, b) example of Gaussian deconvolution of the OH stretch band of $TiO_2$-Degussa P25/water system at RH=85%.**

# Valorisation of glycerol wastewater for hydrogen production at pilot scale under natural radiation

J. G. Villachica Llamosas [1], A. Ruiz-Aguirre[1], S. Malato[1]
[1] *CIEMAT – Plataforma Solar de Almería, Ctra. De Senés s/n, 04200 Tabernas, Almería, Spain*
[*] *jgvillachica@psa.es.*

Hydrogen, as energy carrier, is gaining renewed and rapid attention in the world. However, hydrogen is still largely produced from fossil fuel. A renewable way for its production is photocatalytic water splitting, but the efficiency of this process is extremely low. An alternative is photoreforming of organic compounds, being glycerol, an abundant byproduct of biodiesel wastewater that allows wastewater revalorization[1]. To date, the maximum efficiency (Solar To Hydrogen efficiency (STH)) reached has been 5 % but with an unstable photocatalyst[2]. For that, great efforts in finding an efficient and stable photocatalyst is one of the major targets in this field. In this work, glycerol photoreforming was carried out in a pilot photoreactor (25 L) under natural solar radiation conditions. The photoreactor consisted of a stainless steel tank (10 L) coupled to a solar compound parabolic collector (CPC) (14.25 L of illuminated volume, 2.1 $m^2$ of illumined surface) in continuous recirculation (20 $L \cdot min^{-1}$ ). $N_2$ gas was bubbled in the system (max. flow rate of 500 $mL \cdot min^{-1}$) to keep anoxic conditions and also to entrain continuously the $H_2$ produced, from the head-space of the tank to the on-line gas chromatograph for quantification.

Different commercial and synthesis photocatalysts ($NiO:TiO_2$, $CuO:TiO_2$, $gC_3N_4$-urea, $gC_3N_4$-urea- CuO, $gC_3N_4$-melamine, $gC_3N_4$-Ru, C-Ru) were tested trying to reach the most efficient one varying the operating conditions (glycerol concentrations, catalyst concentrations, proportion of cocatalysts and soft calcination) in different water matrixes (demineralized water, natural water and artificial wastewater). Best results (1.44 % of STH) were achieved with $TiO_2$ mixed with metal oxides in a proportion of 10:1 respectively (Fig. 1). Tests performed under different irradiation conditions and different seasons of the year produced consistent results. Decontamination and disinfection in anoxic conditions, was achieved after 180 min and 10 min respectively. A soft calcination at different temperatures (200 ◦C and 400 ◦C) and times (1 h, 3 h and 6 h), was applied to the catalyst mixture ($CuO:TiO_2$) to increase its efficiency, achieving at 200°C temperature and 3 h calcination the best results (Fig.2). In natural water, the presence of salts reduced process efficiency requiring a higher concentration of photocatalyst .

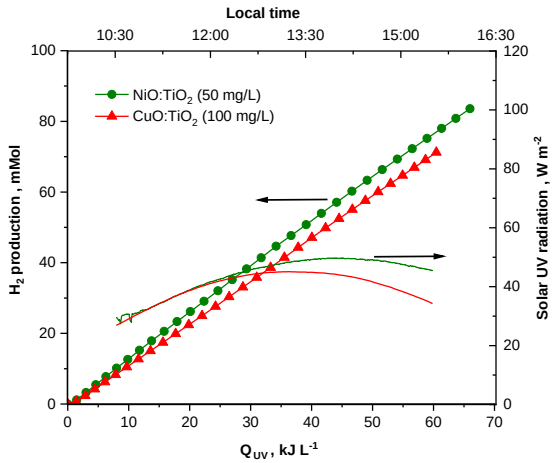

Fig.1. Hydrogen production with different commercial photocatalyst.

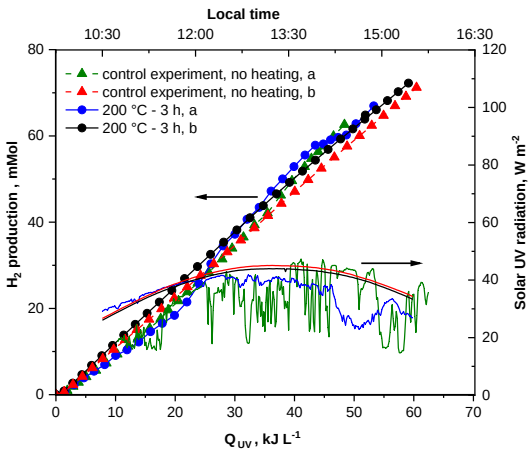

Fig.2. Evaluation of the application of soft calcination in the efficiency of $CuO:TiO_2$.

**Introduction.**
It is urgent to develop alternative energy sources to fossil fuels because of global warming and the energy shortage. Hydrogen has been widely studied as sustainable energy with broad application potential. Moreover, hydrogen production by photocatalytic water splitting is known as green hydrogen with zero-carbon emissions. However, the separation of H2 and O2 requires extra energy. This study provides an alternative to separate H2 during water splitting by a novel photo twin reactor [1].

**Experimental/methodology.**
$SrTiO_3$ was synthesized by the flux molten-salt method. $BiVO_4$ was prepared by the hydrothermal method [2]. In the twin photoreactor, $Rh_xCr_{2-x}O_3/SrTiO_3$ was used as the hydrogen-evolution photocatalyst, and $BiVO_4$ was used as the oxygen-evolution photocatalyst. Ferric/Ferrous ions served as electron media, and a cation-exchanged Nafion membrane divided the two photocatalysts in the twin photoreactor.

**Results and discussion.**
As shown in Figure, The rate of $H_2$ and $O_2$ were 204 and 110 μmol $g^{-1}$ $h^{-1}$, respectively. The Z-system of the twin photoreactor can separate hydrogen and oxygen simultaneously during photocatalytic water splitting, thus not only avoiding the recombination of hydrogen and oxygen but also reducing additional separation costs and explosion risk. This research brings in the value of photocatalysts in practical applications.

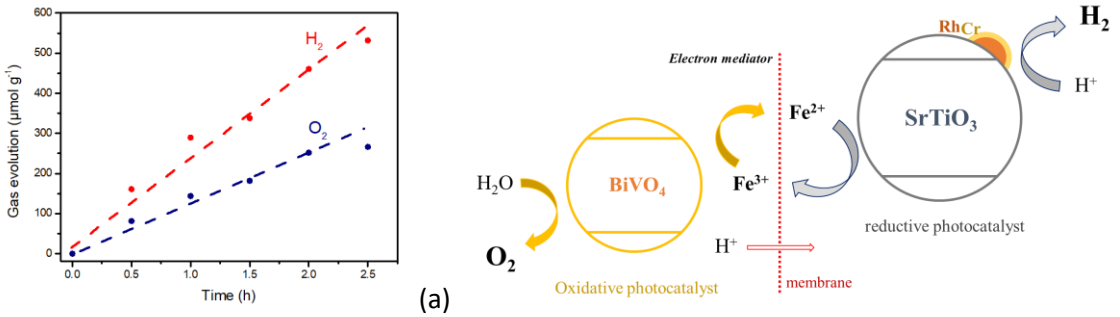

Figure: (a) $H_2$ and $O_2$ yields (b) Z-Scheme of photocatalytic water splitting

**Keywords:** photocatalytic $H_2$ evolution, electrostatic attraction, $Cd_{0.1}Zn_{0.9}S$ solid solution, energy barrier.

**Introduction.** Currently, the efficiency of solar energy conversion to $H_2$ is still far below the requirements of potential applications. To improve the photocatalytic activity of $H_2$ production, a novel $Co_2P$/ZCS shell-core photocatalyst were successfully synthesized by electrostatic attraction, with $Co_2P$ layer covering on the surface of CZS sphere. This study focuses on the material design and strategies for improving the anti-photocorrosion of CdS-based photocatalysts, which provides an important reference basis for new catalyst design and wide prospects for further application in photocatalytic $H_2$ evolution.

**Experimental/methodology.** $Co_2P$ decorated $Cd_{0.9}Zn_{0.1}S$ (CZS) nanocomposites was synthesized via a self-assembly method. A certain amount of $Co_2P$ was added into absolute ethanol and ultrasonic treatment for 30 min. Subsequently, CZS was added into the above solution, and continuous ultrasonic treatment for another 30 min. To remove ethanol, the solution was directly dried at 60 ℃ for 12 h in a vacuum oven.

**Results and discussion.** A novel $Co_2P$/ZCS shell-core photocatalyst were successfully synthesized by self-assembly method, in which properly loading of $Co_2P$ layer on CZS can improve the photocatalytic activity of $H_2$ production. Under visible light irradiation, CP-4/CZS achieves a $H_2$ yield of 16.5 mmol $g^{-1}$ $h^{-1}$ in $PhCH_2OH$ solution, much higher than CZS. The coating $Co_2P$ layer can promote charge separation and transfer, and reduce the CZS oxidation caused by the aggregation of photogenerated $h^+$ on the CZS surface. Moreover, S-scheme heterojunction formed between $Co_2P$ layer and CZS sphere effectively promotes the separation of photogenerated electrons and holes, improving the efficiency of photocatalytic hydrogen precipitation (**Figure 1**).

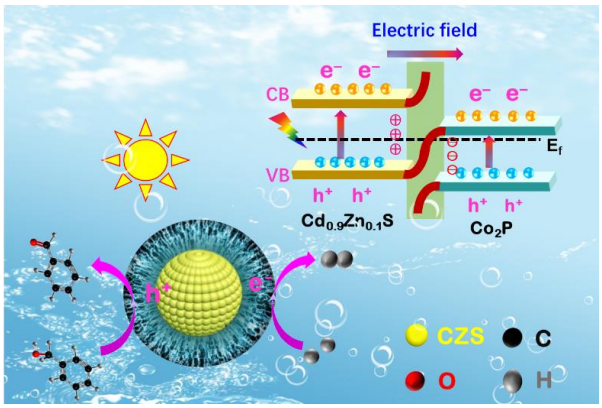

**Figure 1.** The S-scheme transfer mechanism of $H_2$ evolution on CP-4/CZS composite under the visible light.

**Keywords:** Ball mill, Plastics upcycling, Ammonia synthesis, Reactor design

**Introduction.** Mechanochemical processes use collisions in a ball mill or similar device to drive chemical reactions. The collisions can create transient surface sites with extraordinary catalytic activity and hot spots with rapid local temperature rises followed by dissipation of heat to the environment. Mechanically induced charge separation (i.e., triboelectric effect) and mechanoradicals formed by homolytic cleavage of polymers can also initiate reactions. In addition, mechanical forces can create intimate contact between two solids through shearing, so that the conversion of a solid reactant over a solid catalyst becomes viable.

**Experimental/methodology.** Milling experiments were performed in a Retsch MM400 vibratory ball mill with stainless steel vessels and balls. Milling vessels were modified to allow for continuous gas flow through the vessel. Gas flows were regulated with mass flow controllers. $CO_2$ formation was monitored by online MS analysis using a Hidden HPR-20. Monomers from plastics depolymerization reactions were analyzed by GC or HPLC, whereas GPC was used to measure the molecular mass distributions of the residual polymers.

**Results and discussion.** A fundamental study of hot spots on $CaCO_3$ showed that the impact of a 20 mm steel ball with a net velocity of 3 m/s results in a hot spot above 800 °C, which decays in 10s of ms. [1]. While the exact temperature profile depends on the impacted material, this illustrates reactive environments in mechanocatalytic processes.

The ability to shear different solids against each other opens new possibilities for converting solid feedstocks like waste plastics. The depolymerization of poly(ethylene terephthalate) (PET) occurred readily when the polymer was milled with NaOH [2]. After a short induction period in which particle size reduction dominated, monomers were produced at a constant rate up to a milling time of 12.5 min (Figure 1). At this point, the reaction mixture was converted from a powder into a wax that coated the milling balls or was pressed into the sites of the milling vessel (inserts in Figure 1). After wax formation, the remaining polymer was converted much faster. The molecular mass distribution of the residual polymer barely changed indicating that polymer domains are either entirely depolymerized or not affected at all. The reaction kinetics are consistent with a modified shrinking core model.

Mechanocatalytic depolymerization of poly(styrene) (PS) follows a radical mechanism. The presence of $O_2$ and certain metal catalysts increased the formation of active radical species. When the concentration of monomeric styrene in the milling vessel reached a threshold repolymerization to a more stable polymer occurred. However, when styrene was continuously purged from the reactor in an inert gas stream the rate of styrene production remained approximately constant with respect to milling time. The selection of suitable catalysts for this reaction will be discussed.

Poly(ethylene) is effectively depolymerized in a mechanocatytic process, in which some carbon atoms in the polymer chain are oxidized over an $Fe_2O_3$ catalyst to facilitate chain cleavage.

**Keywords:** Plastic waste, pyrolysis, dechlorination, iron

**Introduction.** The dechlorination of Cl containing hydrocarbons derived from the pyrolysis of plastic waste is a big challenge to overcome due to the strict requirement of Cl content permitted in the steam crackers (10 ppmw). Several strategies have been proposed to decrease the Cl content throughout the process. These include, stepwise pyrolysis, hydrodechlorination, "in-situ" dechlorination as well as the use of a subsequent gas cleaning step by different catalysts and/or sorbents. However, in most cases, a combination of different steps is required [1]. Among the studied materials for dechlorination step, Fe has been reported as very promising catalyst/sorbent to remove the Cl to the targeted values. Different Fe-based materials have been used including α-$Fe_2O_3$, γ-$Fe_2O_3$, Fe/C, α-FeOOH, Fe/$SiO_2$ or red mud [2]. It is known that the activity of the different phases and reduction state of Fe have a big influence in the dechlorination behavior. However, this has not been studied in depth in the literature. In addition, the dechlorination mechanism is still not clear. In this work, a synthetic $Fe_2O_3$/$SiO_2$ has been employed to investigate the effect of the reduction state, as well as try to clarify the reaction mechanism of Fe in the dechlorination using chlorobenzene (CB) as model compound.

**Experimental/methodology**. An Fe-based material supported on $SiO_2$ has been prepared by incipient wetness impregnation. To elucidate the reduction effect in the reaction, different reduction conditions, including different temperatures and reduction times have been studied. The reaction has been carried out in a quartz reactor using a 50 ppm CB/$N_2$ at 350 °C. Furthermore, to find the reduction state of iron in the different conditions, the materials have been characterized by TPR, "in-situ" UV-Vis spectroscopy and XRD before and after the reaction.

**Results and discussion.** The activity results showed a clear effect of the reduction temperature in the CB conversion (Fig 1 A), demonstrating that the most favorable reduction state appear with the reduction done at 350 °C for 2h. On the other hand, by XRD analysis of the fresh and spent samples (Fig 1 B), it was found different Fe crystal phases when different reduction treatment were employed. The fresh and unreduced spent samples contained $Fe_2O_3$. The spent sample reduced at 500 °C presented crystalline $Fe^0$ and the spent sample reduced at 350 °C appeared as an intermediate reduction mixture ($Fe^0$/$Fe_3O_4$) difficult to identify by XRD. These results suggest that the oxygen vacancies generated by the incomplete reduction may have an important effect in the dehlorination mechanism. Hence, "in-situ" characterization such as UV-Vis spectroscopy is clue to determine the Fe reduction degree in the reaction conditions.

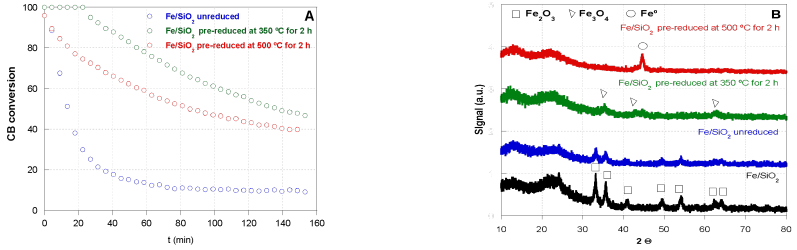

**Fig 1. Chlorobenzene conversion during 150 min on stream with Fe/$SiO_2$ unreduced, reduced at 350 °C for 2 h and reduced at 500 °C for 2 hour (A), XRD diffractograms of fresh Fe/$SiO_2$ and after reaction (B)**

**Keywords:** Electrocatalysis, Decarboxylation, Sustainable olefin production

**Introduction.** Ethylene is an important feedstock in the chemical industry that is currently produced from fossil resources. The electrochemical oxidative decarboxylation of carboxylic acids, such as succinic acid, can offer an environmentally friendly route to generate ethylene provided the electrolysis uses renewable electricity and the succinic acid is obtained from waste streams. We have developed two different approaches for this task. Firstly, a two-step process that can convert plastic waste into gaseous products, with ethylene as main product, that can be even used to resynthesize Polyethylene and offer a genuine chemical recycling route for plastics. Secondly, a bio-electrochemical approach allowing the conversion of food waste into ethylene. In both processes, succinic acid is a central intermediate that undergoes an electrochemical reaction to form the valuable ethylene product. With spectroscopical and electroanalytical approaches as well as quantum mechanical calculations, insights into the reaction mechanism could be gained as well. Furthermore, different electrocatalysts were tested and material characteristics, beneficial for the ethylene formation could be determined. The developed processes offer great potential for sustainable and the fossil resource free production of ethylene.[1]

**Experimental/methodology.** A range of electrochemical and spectroscopic approaches such as Koutecky–Levich analysis, rotating ring-disk electrode (RRDE) studies, and Tafel analysis as well as quantum chemical calculations, electron paramagnetic resonance (EPR), and in situ infrared (IR) spectroscopy generated further insights into the reaction mechansism. Different pre-treatment procedures (thermal and biocatalytic) were applied to make the heterogeneous substrates such as plastic waste or food waste accessible for electrochemistry. Finally, electrocatalytic tests in batch and flow cells were performed to convert the waste streams into alkenes.

**Results and discussion.** It was found that the nature of the carbon material significantly influences the reaction outcome and well-ordered, two-dimensional electrode materials are preferred, such as flat graphite. Electrochemical experiments and in situ IR spectroscopic measurements support the determination of the onset potential for the decarboxylation reaction ranging between 2.2 and 2.3 V vs. RHE. Insights into the reaction network were gained using quantum chemical calculations, and the presence of a monoalkyl radical as a reaction intermediate was confirmed by EPR spectroscopy. Finally, the utility of succinic acid to ethylene decarboxylation was exemplified by demonstrating a combined bio-electrocatalytic approach converting food waste into succinic acid and subsequently into ethylene (0.4 µmol ethylene $cm^{-2}$ $h^{-1}$) and a thermal-electrocatalytic process converting plastic waste into ethylene.[2}

**Keywords:** Olefin metathesis, ISOMET, sustainable catalysis

**Introduction.** The rising concerns of plastic waste management require a variety of strategies and technologies to move towards sustainable and circular materials. One such strategy to address the challenge of persistent fossil-based plastics is new catalytic processes being developed to convert domestic plastic waste, such as polyethylene, to produce propylene. Morover, the propylene – the petrochemical produced in the second largest volume – can be an important precursor also to high-performance polymers that are biodegradable on-demand.

**Results and discussion.** Olefin metathesis is one of the most versatile methods in synthetic organic chemistry. Since the discovery of stable and functional group-tolerant catalyst systems, their industrial application has been steadily increasing. The isomerization metathesis (ISOMET) is a special case of olefin metathesis. [1] It is a one-pot, tandem reaction using a dual catalyst system. During ISOMET, the olefinic bonds migrate along the hydrocarbon chain (isomerization), which is followed by a metathesis reaction. Such simultaneous olefin isomerization and metathesis enables for example propylene synthesis from polyethylene waste or even from renewable feedstocks (vegetable oils, phospholipids). The presented method is based on the principles of sustainable development – in the same time, it lays the foundations for a unique, future-oriented research direction.[2]

# Wet air oxidation of a refinery wastewater using catalytic materials synthesized from an oily sludge.

S. Jerez[1*], M. Ventura[1], M.I. Pariente[1], J.A. Melero[1]

[1]*Department of Chemical and Environmental Engineering, University Rey Juan Carlos, Madrid, 28933, Spain*
[*]*sara.jerez@urjc.es*

**Introduction.** A significant amount of residues are generated by the refinery industry that are highly toxic to human health. Refinery wastewater and oily sludge are considered environmentally hazardous and cost prohibitive in terms of management. Thus, valorising strategies should be developed to minimize their impact and enhance their reuse. The solid content in oily sludge is approximately 40 wt.%, with a high concentration of carbon material (45 wt.%). Several authors have reported promising results in the synthesis of porous materials using refinery residues, which can be used for several applications [1]. At the same time, some refinery wastewaters typically present a non-biodegradable and high organic content, and oxidative processes are commonly applied for pollutant removal. In the present work, the synthesis of a new class of materials using the solid particles of oily sludge, and its application in catalytic wet air oxidation (CWAO) reactions to treat a non-biodegradable refinery wastewater is proposed.

**Experimental.** The refinery wastewater and oily sludge come from the spent caustic effluent and API separator, respectively, of a refinery treatment plant in Spain. The solid fraction from oily sludge was mixed with KOH as an activating agent with 0:1 (ACT-0.1) and 1:1 (ACT-1.1) mass ratio and applied a carbonization (400 $^{0}$C, 4 $^{0}$C/min and 30 min) and activation (850 $^{0}$C, 4 $^{0}$C/min and 80 min) steps, both in $N_2$ atmosphere. CWAO reactions were carried out in an autoclave reactor, at 200 $^{0}$C and 50 bar of air pressure for 4 hours, using 1 g/L of catalyst, and analysing the removal of chemical oxygen demand (COD) concentration of the refinery wastewater with the reaction time.

**Results and discussion.** The results obtained for the synthesis of these new materials have proved the feasibility of obtaining interesting materials with high carbon content (40 and 30 wt.%), metals (39 and 31 wt.%), and specific surface area ($S_{BET}$) ranging from 55 to 637 $m^2/g$ for ACT-0.1 and 1.1 respectively. The use of KOH during the synthesis clearly increases the textural properties of the solids which implies an improvement of the catalytic activity up to 60 % of COD removal for the material ACT-1.1, compared with a 45% for the material ACT-0.1 (Figure 1). This catalytic performance was benchmarked with a commercial activated carbon (ACT-NORIT), with higher $S_{BET}$ (1000 $m^2/g$). This material shows lower COD removal than ACT-1.1 despite its higher $S_{BET}$ which is an indication of the significant contribution of metals in the catalytic abatement (mainly Fe with a 15 wt. %). Furthermore, a thermal WAO assay was carried out reaching less than 40 % of COD removal. This fact evidences the important role of synthesized materials in the COD removal. Moreover, the raw solid particles coming from the sludge were used as catalyst (ACT-Raw) showing a COD removal even lower than WAO reaction, probably due to the leaching of organic matter in the untreated solid. ACT-1.1. sample was reused in three catalytic cycles keeping the catalytic activity and without leaching of metallic species.

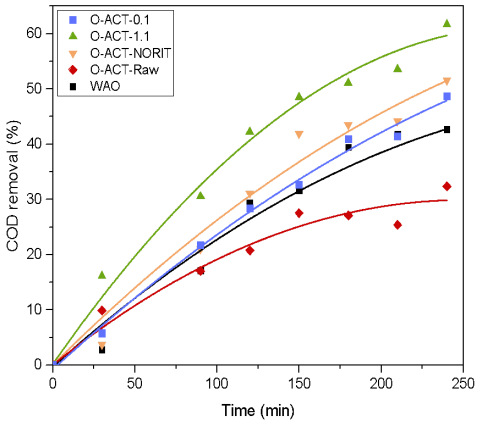

Figure 1: CWAO reactions using the synthetized catalysts (ACT-NP 0.1 and 1.1), a commercial activated carbon (ACT-NORIT), the raw solid particles (ACT-Raw) and a thermal wet air oxidation reaction without catalyst (WAO).

# Self-decontaminating protective clothes: Layer-by-Layer $TiO_2$ deposition for photocatalytic decontamination of Chemical Warfare Agents

Morguen Maël[1,2], Bacoup Stéphane[1], Vaure Louis[1], Keller Valérie[2*]

[1] *Paul Boyé Technologies, Labarthe-sur-Lèze, France*
[2] *ICPEES, Strasbourg, France*

**Keywords:** Photocatalysis, Decontamination, $TiO_2$, Layer-by-layer, Textiles

The different challenges of the next decades may bring an increase in geopolitical tensions and thus a risk of conflicts accompanied by an eventual use of Chemical Warfare Agents (CWA). As a result, protections against CWA need to be improved and the addition of self-decontaminating properties to military clothes is a promising tool to avoid (cross-)contamination issues. The purpose of this work is to develop photocatalytic textiles capable of degrading CWA and more specifically organophosphorus compounds under light activation. For this purpose, $TiO_2$ has proved to be an efficient photocatalyst for CWAs degradation under UV-A irradiation [1]. However, its immobilization on textiles remains a challenge due to its poor adhesion on fibers for more convenient post-synthesis functionalization. For this reason, we decided to use a layer-by-layer deposition method consisting in an alternative deposition of positively charged particles (pH below isoelectric point) and negatively charged polymers (intrinsic properties) [2]. This method enables both a control of the thickness of the photocatalytic layer, as well as a strong adhesion on fibers.

Many parameters of this deposition method can influence the overall activity through the amount of deposited $TiO_2$, such as the number of layers, and the concentration and pH of the $TiO_2$-based precursor suspension. A parametric study was performed to find the optimal conditions for a compromise between a good adhesion and a high photocatalytic activity. The nature of $TiO_2$ can also largely influence the activity with differences in some key properties such as specific surface area, surface properties, structure, band-gap, and efficiency of charge carriers generation [3]. For this reason, different commercially available $TiO_2$ were used for textiles functionalization and assessed towards DMMP (analog of organophosphorus agent) elimination for similar deposition conditions.

As expected, the quantity of $TiO_2$ deposited onto the micrometric fibers has a clear influence on the photocatalytic activity **(Fig. 1)**. Another impacting parameter lies also in homogeneity of $TiO_2$ deposition and adhesion onto the fibers **(Fig. 2)**. Differences in terms of resulting photocatalytic activities were also observed between the different commercial $TiO_2$ studies and will be explained and discussed. As new perspectives for the elaboration of self-decontaminating textiles, some examples relating the combination of $TiO_2$ with adsorbent materials, enhancing overall decontamination properties will also be shown.

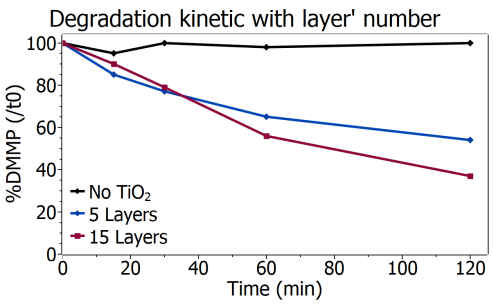

**Fig. 1:** Kinetics of DMMP elimination as a function of the number of deposited $TiO_2$ layers

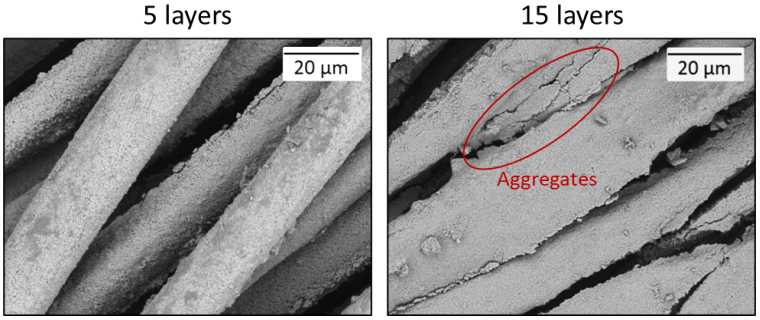

**Fig. 2:** SEM images of functionalized textiles with 5 and 15 $TiO_2$ layers.

**Keywords:** photocatalysis, microslit reactor, parallel reactor, $TiO_2$, hormone, degradation

**Introduction.** In modern water management endocrine disrupting chemicals (EDCs) like pharmaceutical products or biocides are more and more in the focus of interest. This is, because in common three-stage sewage treatment plants these chemicals are not degraded in a sufficient degree or manner. Therefore, the German Federal Environmental Agency demands of a fourth cleaning stage to eliminate these substances. Existing solutions for the problem are taint with diverse disadvantages, e.g. that resulting decomposition products are sometimes more toxic than the pollution educts [1]. An alternative concept will be the catalytically supported degradation of these substances by UVA light. Here we present the photocatalytic degradation of artificial female hormones (EE2 = 17α-ethinyl estradiol) in aqueous model solution using two different reactor concepts. The objective is to invent a modular UVA-LED photoreactor system in combination with a special catalyst material having a tailored band gap according to the used UV wavelength of 365 nm [2,3,4]. The modularity of the concept allows adaptation to local wastewater qualities and quantities of small polluters and is not intended for application in municipal wastewater treatment plants.

**Experimental/methodology.** For high-throughput catalyst screening a 60-fold parallel UVA-LED reactor device was build up to simultaneously investigate the performance of different catalyst materials according to EE2 degradation. The syntheses of catalysts were performed either by sol-gel route or by wet-impregnation. All investigated ternary catalyst compositions are oxides with main component Ti and different amounts of doping elements. The catalysts were characterized by BET, IR and XRD-measurements. After catalyst screening the most promising catalyst candidates were processed as wall-catalyst for the useage in a modular designed microslit photoreactor with exchangable catalyst substrates. Degradation processes were tracked by SPE-GC-MS or UHPLC-TQ-MS.

**Results and discussion.** The selection of metal ions for the $TiO_2$ doping was made by looking at the band-gaps of the metal oxides. According to this Zn, Sn, Zr, Nb, Ce, W, Bi and Fe were chosen as doping metal candidates. Additionally g-$C_3N_4$ has been prepared and used as dopant. Compared to the benchmark of $TiO_2$ (P25) only Zn- or g-$C_3N_4$-doped $TiO_2$ lead to a higher degradation conversion. The performance was strongly depending on the preparation of catalyst material as particles for the parallel reactor or as coating in the microslit reactor, where the modified residence time plays an important role. The extensive testing of catalysts led to the conclusion that the photocatalytic conversion in the microslit reactor is limited by mass transport and thus rather a function of residence time than a function of the materials utilized. This makes adequate process development seem more important than material development. The novelty of this contribution lies in the unique combination of testing a wide range of composite catalysts in a unique microreactor geometry.

**Keywords:** Advanced oxidation processes, reactive oxygen species, organic dyes, antibiotics

**Introduction.** For the last decades, $Nb_2O_5$ has been attracting attention as a promising heterogeneous catalyst dedicated to the elimination of organic pollutants through advanced oxidation processes (AOPs) [1]. Nowadays, the interest in the application of this metal oxide for wastewater remediation is still increasing and focuses on improving niobia reactivity by designing novel heterostructure catalysts and/or modifying its surface properties by post-synthetic modification or metal doping [1]. This work will summarize our recent studies aiming at understanding and improving reactivity of niobia-based catalysts in the catalytic activation of hydrogen peroxide and degradation of selected organic compounds. Particular attention will be paid to unraveling the role of niobia crystallinity [2] and the presence of metal [3,4] or nonmetal [5] dopants in controlling the efficiency of $Nb_2O_5$ in activating of $H_2O_2$ toward the formation of various reactive oxygen species (ROS). The reactivity of these strongly oxidizing species in the degradation of model organic pollutants (organic dyes and antibiotics) will be discussed.

**Experimental/methodology.** The studied oxidation catalysts were synthesized using co-precipitation or hydrothermal methods. The catalysts were fully characterized using XRD, FT-IR, UV-vis, XPS, TEM/EDS, $N_2$ physisorption, elemental analysis, and Zeta potential measurements. ROS formed *in situ* in the presence of hydrogen peroxide were identified with Raman and EPR techniques. The contribution of selected ROS to the degradation of organic compounds was estimated with the use of ROS scavengers. The degradation pathways and products were identified using ESI-MS and LC-MS analyses, while the mineralization efficiency was estimated based on Total Organic Carbon analyses.

**Results and discussion.** Our study revealed that the reactivity of $Nb_2O_5$ in $H_2O_2$ activation is strongly affected by the phase composition of the metal oxide. The highest efficiency in ROS formation is observed for amorphous niobia under acidic conditions [2]. We have also revealed that the catalytic decomposition of $H_2O_2$ proceeds via an electroprotic mechanism, resulting in the formation of $HO^{\bullet}$ radicals and $O_2^{\bullet-}$ radical anions. The latter can be adsorbed and stabilized on the niobia surface improving the efficiency of $HO^{\bullet}$ formation. We have also shown that ROS formed and adsorbed on the surface of niobia are responsible not only for the efficient degradation of pollutants but also for significant improvement of the adsorption properties, which has been overlooked so far. In a short reaction time, the contribution of surface ROS to the adsorption was found to be much higher than that to degradation [6]. We have also revealed that the reactivity of $Nb_2O_5$ in the degradation of organic pollutants (model dyes and antibiotics) via AOPs may be significantly enhanced by doping with Ce [3], Co [4], and P [5]. Electronic and structural factors resulting in the enhanced reactivity of these mixed systems have been discussed in detail.

# Lignin Oxidation towards High-Added-Value carboxylic acids under mild hydrothermal conditions using MgO-based catalysts

N. Vidal*, M. Ventura, F. Martínez, J.A. Melero

*Chemical & Environmental Engineering Group, Universidad Rey Juan Carlos, Mostoles (Spain)*
**nora.vidal@urjc.es*

**Introduction.** Lignocellulosic biomass mainly consists of cellulose, lignin, and hemicellulose but lignin is the only sustainable aromatic resource in nature. Oxidation is one of the promising strategies that can convert lignin into a range of high-added-value platform chemicals. Because of the intrinsic complexity of the lignin polymer its oxidation is largely influenced by operation conditions, catalyst types, presence of oxidants, and solvent species.[1] One of the high-value-added products potentially obtained from this oxidation are the dicarboxylic acids (e.g., fumaric and succinic acids), which can be used as polymer building blocks [2]. Recently, in our research group, we have explored the catalytic oxidative-depolymerization of lignocellulosic wastes by using cheap and earth-abundant metals based on Ca-Mg [3] being not selective in the oxidation of the polymers. This work, explore the selective depolymerization of lignocellulosic wastes by using mixed oxides based only on Mg with improved properties that gives to a selective depolymerization of lignin to carboxylic acids.

**Experimental/methodology.** Different MgO catalysts were synthesized from different techniques and precursors: by co-precipitation method with $Mg(NO_3)_2$, by rehydrated $Mg(OH)_2$ and by xerogel and aerogel method using $Mg(C_2H_5O)_2$ as precursor To modulate the behavior of MgO the incorporation of MgO to SBA-15 was studied by two methods: adding Mg precursor during the SBA-15 synthesis (MgO-SBA-15) and by wet-impregnation of MgO over SBA-15 (MgO/SBA-15). The reactions were performed in a 15 mL ace pressure glass tube stirred with a magnetic bar; 0.1 g of the lignocellulose material, 20% wt. /wt. of catalyst and 5 mL of $H_2O$ at 120 $^0$C. The liquid phase was analyzed by HPLC to determine the catalytic performance and reaction products, whereas the remaining solid phase was characterized by elemental analysis and TGA to assess the conversion of the three polymers.

**Results and discussion.** All of the MgO catalysts are obtained with a crystalline structure (100), while for aerogel production from $Mg(C_2H_5O)_2$, the structure is (111). The total solid conversion results do not differ much between different catalysts being between 23 % and 38 %. However there are significant differences on the individual conversion of the three polymers, (Fig.1). The highest and most selective conversion of lignin was obtained with the catalysts synthesized from $Mg(NO_3)_2$, achieving over 1 g/L of dicarboxylic acids. MgO/SBA-15, was also very selective to convert lignin but not in a selective manner. Therefore, the catalyst that provides better results would be the MgO obtained by co-precipitation method from $Mg(NO_3)_2$, giving a residual solid mostly composed of cellulose and hemicellulose. The catalyst leaching was also analyzed during the reaction by ICP-AES and no loss of magnesium was observed. Catalyst showed a good catalytic performance after several catalytic cycles. Catalysts were fully characterized by XRD, SEM, ICP-AES and $CO_2$/$NH_3$-TPD.

# Dechlorination of PVC to HDPE: Effects of Catalysts and Bases

S. Svadlenak[1], Dorthe Wildenschild[1], K. Goulas[1*]

[1]*Oregon State University, Corvallis, OR, United States of America*

**Keywords:** upcycling, polymers

**Introduction.** Polymer upcycling to value-added products is a necessary step for the reduction of pollution from waste polymers. While significant advances have been made towards successful upcycling of polyolefins to monomers and to liquid fuels and chemicals, processes to upcycle polyvinyl chloride (PVC) to useful chemicals are still largely elusive. The need for such a process is particularly important, as PVC represents a significant portion of the total mass of polymer that is landfilled around the world. Moreover, the presence of PVC in polyolefin waste streams complicates the upcycling of these waste streams, as residual chloride poisons catalysts and generates HCl and toxic chlorinated hydrocarbons. We propose to upcycle PVC to HDPE (high-density polyethylene), appropriate for use in hot melt adhesives, via a hydrothermal tandem dechlorination and hydrogenation process.[1]

**Experimental/methodology.** PVC resins and PVC-containing wastes are mixed with aqueous solutions of organic bases and a heterogeneous catalyst. The system is pressurized with hydrogen gas and heated to the reaction temperature. The product is analyzed by differential scanning calorimetry (DSC), FT-IR spectroscopy and NMR to obtain its yield and melting point. The reacted system is also analyzed by X-ray tomography, to understand how the gaseous, liquid and solid phases interact.

**Results and discussion.** We show that the yield of polyethylene increases with the Kow of the amine base used in the reaction. We attribute this increase to the increased partition of amine into the PVC phase, enabling homogeneous dechlorination. The resulting poly-ene molecule then undergoes hydrogenation over the Pt-based catalyst. This hydrogenation reaction competes with the hydrogenolysis of the product to short-chain hydrocarbons. Screening of multiple heterogeneous catalysts shows that Pt is the optimal catalyst, showing the highest yield and a satisfactory melting point. Hot melt adhesives require waxes with melting points between 80 and 130 °C. Further improvements in yield and melting point can be achieved by using alloy catalysts.

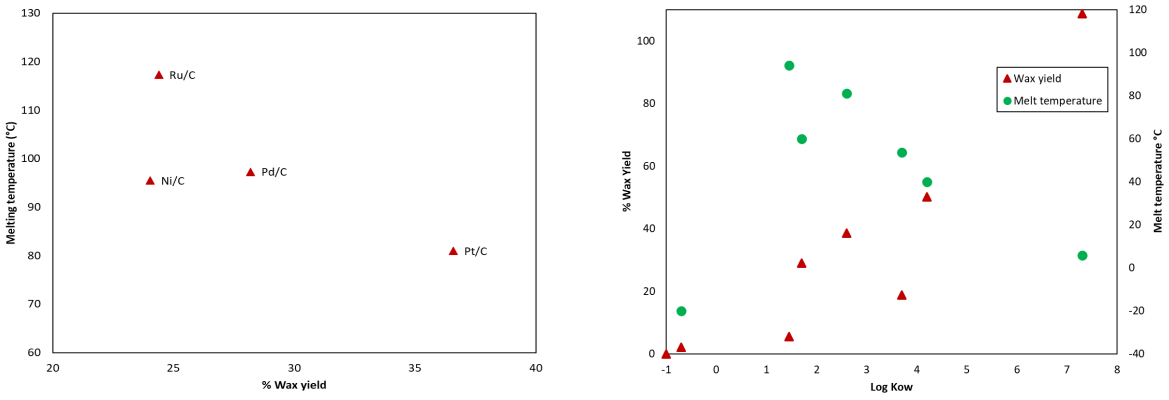

Figure 1: Effects of the amine base (left – Pt/C catalyst) and of the metal catalyst (right – N,N-dimethylhexylamine base) on the yield and wax melt temperature. 200 °C, 33:1 PVC:metal (by mass). 24 hr, 5.5 bar $H_2$, 200 °C 3:1 N:Cl ratio

# Acidic carbocatalyst for the conversion of polyethylene waste to hydrocarbons

M. Al-Naji[1*], M. Antonietti[1]

[1]*Max Plank Institute of Colloids and Interfaces, Colloid Chemistry, Am Mühlenberg 1, 14476 Potsdam, Germany,*
**majd.al-naji@mpikg.mpg.de*

**Introduction.** In 2021 it was estimated the European Union's production and consumption of plastics (fossil-based plastic, post-consumer recycled plastics, and bio-based plastics) to be 57.2 Mtons.[1] Of these large amounts of plastics, only ~12% are recycled, mainly mechanically.[1] Thus, there is a great demand in implementing new chemiocatalytic technologies to increase the number of recycled plastics. Recently, several chemical recycling techniques have been reported, *i.e.*, pyrolysis, hydrocracking, dissolution (mainly with sorted polymers), and gasification (energy intensive with low atom efficiency).[1] Of these, pyrolysis and hydrocracking are largely studied as they are promising approaches for non-sorted plastic waste composed of different polymer types and impurities.[1,2] Usually these methods describe the use of expensive bifunctional catalysts based on noble metal catalysts and acidic support materials, e.g., zeolites. Additionally, most of the recent publications use clean polymers, with a high catalyst/feed ratio.[1,2] All ordinary catalysts used in plastic waste recycling are suffering from rapid deactivation under these harsh conditions.[2] Therefore, we present a highly acidic carbocatalyst (AC) for polyethylene fragmentation to liquid hydrocarbons (C7-C20) that can be converted to olefins in a steam cracker for further processing.[2]

**Experimental/methodology.** This AC is synthesized by condensing a mixture of Na-lignosulfonate (sulfur-rich carbon source) and a hard template (ZnO) to generate porosity. All catalytic experiments in an inert atmosphere were performed in a 250 $cm^3$ round bottom flask connected to a condenser. The fragmentation of HDPE in the presence of 20 bar ($H_2$) was conducted in a 300 $cm^3$ stainless-steel batch reactor.

**Results and discussion.** The synthesized AC exhibits a high specific surface area ($A_{BET}$ = 664 $m^2$ $g^{-1}$), as well as a high density of acid sites (1.6 µmol $g^{-1}$) that is attributed to the presence of an oxidized sulfur species, similar to electron-poor sulfones. Furthermore, this AC possesses high thermal stability due to the high content of (oxidized) sulfur (7.9 wt.-%) with oxygen edge terminations, which changes the electron density of the carbonized material and creates a “nobility”. For polymer fragmentation, the AC was then contacted with commercially available high-density polyethylenes (HDPE), as well as with a real waste plastic consisting of (LDPE and HDPE) from a sorting plant. In this context, the AC showed a high activity in HDPE fragmentation to (C7-C20) of n-alkane (348 mg $g^{-1}_{HDPE}$) and n-alkene (110 mg $g^{-1}_{HDPE}$) at 653 K and after 24 h of reaction time under $N_2$ atmosphere (Fig. 1). This indicates that the AC possesses dual functionalities namely acid sites for cracking C-C bonds and hydrogenation function. For stronger evidence of the superior activity of the AC and the existence of the dual functionalities, an experiment with externally supplied 20 bar of $H_2$ for 24 h was performed. The n-alkane yield was found to be 1302 mg $g^{-1}_{HDPE}$, while the n-alkene yield was suppressed and corresponded to 188 mg $g^{-1}_{HDPE}$. Additionally, the presence of external $H_2$ resulted in gas and oil fractions with product distribution rich in shorter n-alkanes in the range of C7-C14, with respect to $H_2$-free experiments (C11-C17), *viz.* Fig.1.

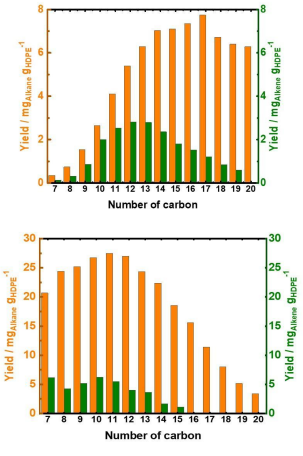

Fig. 1. Product distribution in the oil phase at from HDPE fragmentation for 24 h; Reaction conditions: $m_{HDPE}$ = 5 g, $m_{catalyst}$ = 0.5 g, T = 653 K, n = 600 rpm, under $N_2$ (top) and 20 bar $H_2$ (bottom).

**Introduction.** One of the urgent currently ecological issues are related to the environmental concerns arise from polymer recycling that thrown a shadow over the importance of these materials that have an important role in our economy and daily lives. Heterogeneous catalysis plays a critical role recycling of waste plastics, but to date, none of these have demonstrated outstanding performance and this is why for this process, a viable industrial approach has not yet been developed [1,2]. Consequently, the ultimate goal of this study is to find new solid acids able to depolymerize PET to the raw materials. A potentially useful approach to control MXenes' catalytic activity [2,3] is to handle their surface chemistry. Therefore, during this study we intend to increase the MXenes acidity by modifying the surface with acidic moiety to have –$SO_3H$–MXene capable to depolymerize the polyethylene terephthalate (PET) by hydrolysis route.

**Experimental/methodology.** The goal of this study is to find new solid acids able to depolymerize PET to the raw materials. Among newly discovered materials, MXenes, a novel family of two-dimensional (2D) metal carbides-nitrides, with graphene-like structures, produced by etching of A element from MAX phase [2,3] has drawn our attention. A potentially useful approach to control MXenes' catalytic activity is to manipulate their surface chemistry. Therefore, during this study we extended the material acidity by modifying the surface with acidic moiety to have –$SO_3H$ modified MXene (Figure 1) capable to depolymerize PET by hydrolysis.

**Results and discussion.** Modified MXene with sulfonated groups was realized by grafting –$SO_3H$ groups using sulfonated aryl diazonium salt of sulfanilic acid. Different amounts of sulfanilic acid salt were used, in order to establish the influence of the sulfonic group concentration on the surface, denominated as $Ti_3C_2T_x$–$SO_3H$–y, where y=(1, 3, 5, 7). The as-modified MXenes were investigated by different techniques (XRD, DRIFT, RAMAN, SEM, TEM) and demonstrate that the MXene structure remains lamellar and did not collapse during sulfonation reaction. The distance between sheets increases after modification (see Figure 2) due to the aryl sulfonate groups anchored between the MXene layers. EDX (SEM) and XPS result have confirmed the presence of –$SO_3H$ groups on the MXene surface. The use of these materials in PET hydrolysis depolymerization showed complete conversion and a yield of 75% terephthalic acid, with terephthalic acid as only reaction product. The influence of the reaction parameters (*i.e.,* temperature, pressure and amount of catalyst) was also studied and indicated that $Ti_3C_2Tx$–$SO_3H$-y are promising candidates for processing efficiently PET in environmentally friendly conditions.

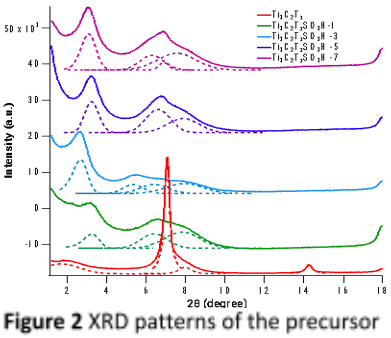

**Figure 2** XRD patterns of the precursor MXene and sulfonated MXene

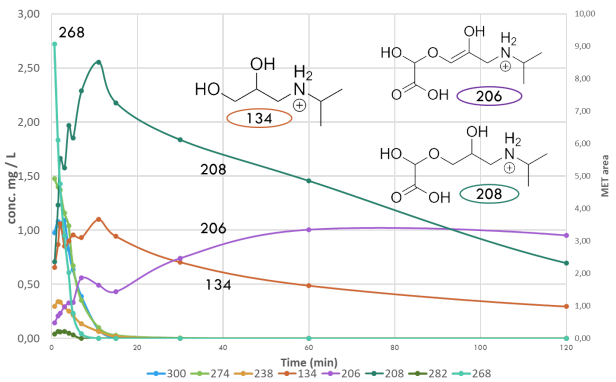
**Keywords:** wastewater treatment, metoprolol, ozonation, heterogeneous catalyst

**Introduction.** Among emerging contaminants, pharmaceuticals represent a significant concern due to their toxicity and potential to harm aquatic species and humans. Biomagnification, bioaccumulation, and antibiotic resistance are the major negative effects of these contaminants [1]. As the water contamination steadily increases, scientists are searching for methods to improve wastewater treatment. A variety of chemical, physical, and biological wastewater treatment methods are used to remove pharmaceutical pollutants. However, the majority of these methods are expensive, have low effciency, and can even produce toxic waste products [2]. Using solid catalysts in advanced catalytic ozonation enhances the breakdown of ozone molecules, producing highly reactive free radicals. As a result, various organic compounds are degraded and mineralized quickly and efficiently [3]. Metoprolol is a beta blocker which is used in large amounts for heart and blood circulation diseases. Recent research has revealed that metoprolol medication can reach up to µg/L levels in surface waters, since conventional water and wastewater treatment processes have a very limited removal efficiency of less than 10%, posing a risk to human health and the aquatic environment [4]. We have developed a combined ozonation and catalytic method to effectively and completely eliminate this pollutant and several other pharmaceutical pollutants.

**Experimental/methodology.** We investigated the effects of some of our in-house, fully characterized Iron modified catalyts (Fe-H-Beta-25-EIM, Fe-H-Beta-75-SSIE, Fe-$SiO_2$-EIM and Fe-$Al_2O_3$-EIM) on the ozonation of metoprolol (MET). In order to perform the experiments, a new type of a gas-liquid reactor system was designed and constructed. By applying an ozone generator, ozone is created and fed into the liquid phase at the bottom of the reactor. The pharmaceutical solution is stirred vigorously while ozone-rich gas continuously bubbles through it. A special rotating bed device was used for the catalyst. The method allows for a very precise measurement of the decomposition kinetics of MET and its by-products.

**Results and discussion.** Ion trap mass spectrometry can identify MET by-products formed during ozonation. Seven different by-products are produced as a result of the ozonation of MET (Figure 1). In most cases, the catalysts enhanced the complete degradation of MET as well as its harmful by-products. For instance, Figure 2 demonstrates the degradation of the by-product 208 through catalytic vs. non-catalytic ozonation.

**Figure 1:** Noncatalytic Decomposition of metoprolol



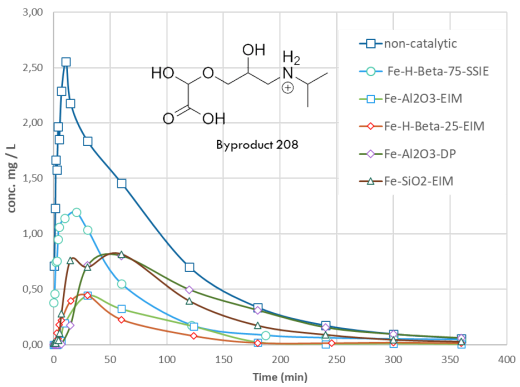


**Figure 2:** Decomposition of by-product m/z 208

**Keywords:** Advanced oxidation processes, reactive oxygen species, oxides,

**Introduction.** Advanced oxidation processes (AOP) are a group of wastewater treatment techniques based on the generation of reactive oxygen species (ROS). ROS are highly active oxidizing agents that can be used for the degradation and mineralization of emerging organic pollutants. The most efficient ways to produce ROS are the decomposition of $H_2O_2$ or peroxosulphate anion in the presence of redox-active transition-metal oxides (through the Fenton-like mechanism) or the $d^0$ group of transition-metal oxides, which are redox-inactive under ambient conditions, yet are capable of activation of the peroxo bond via the electroprotic mechanism [1]. In this work, the reactivity of selected one-phase crystalline and amorphous oxides, binary crystalline-amorphous composites of these oxides, and resulting mixed oxides have been studied in the generation of ROS and sulphate radicals. Particular attention has been paid to the elucidation of the reaction mechanisms of the formation of reactive species and its role in the degradation of model organic pollutants (organic dyes and antibiotics).

**Experimental/methodology.** The materials obtained were synthesized using co-precipitation or hydrothermal methods and thoroughly characterized using XRD, FT-IR, UV-vis, XPS, TEM/EDS, $N_2$ physisorption, elemental analysis, and Zeta potential measurements. Various active species such as hydroxyl radicals ($^{\bullet}OH$), superoxide radicals ($O_2^{-\bullet}$), peroxide anions ($O_2^{2-}$), and singlet oxygen ($^1O_2$) were detected by EPR, Raman, and UV-vis spectroscopic techniques. In the case of EPR measurements, radicals were detected directly or indirectly using DMPO as a spin trap.

**Results and discussion.** The applied characterization techniques revealed that the obtained materials can be categorized into three generic groups: (1) amorphous-crystalline composites (e.g. $CuO@Nb_2O_5$, $Co_3O_4@ZrO_2$), for which the component phases preserve their initial nature (amorphous $ZrO_2$ and $Nb_2O_5$ supports and crystalline nanosized oxides of redox activity CuO, $Co_3O_4$, $Fe_2O_3$), (2) binary mixed oxides forming new crystalline phases ($CeO_x@Nb_2O_5$ forming the $NbCeO_4$ crystal phase), (3) dopped binary oxides ($NbCeO_x$-$CuO_x$, $NbVO_x$-$PO_x$). Spin-trapping studies proved that all investigated systems are active in the generation of hydroxy radicals and superoxide anion radicals (including pristine amorphous phases), while groups (2) and (3) participate in the generation of the hydroxyl and $SO_4^{-\bullet}$ radicals. This observation was confirmed by UV-vis studies of OPD oxidation. The presence of singlet oxygen was detected particularly in the case of phosphate-dopped systems [2]. Finally, the catalytic activity of the investigated oxides in methylene blue (MB) discolorations and ciprofloxacin (CIP) degradation was tested. The observed activity was accounted for by the concerted action of adsorption and oxidative degradation by reactive species (the competing impact of radicals and $^1O_2$ was unraveled in this case). In most cases, the catalysts make use of both electroprotic and Fenton-like mechanisms for the generation of reactive species. It is noteworthy that the $NbCeO_x$ mixed oxide is also active in the generation of $SO_4^{-\bullet}$ species with activity smaller than in the case of the amorphous $Nb_2O_5$, suggesting that the electroprotic mechanism of peroxo bond rupture is possible not only for $H_2O_2$ [1] but also for peroxosulphate substrate.

*[*]david.serrano@imdea.org*

**Introduction.** Zeolites with high accessibilty play a fundamental role during the catalytic pyrolysis of wastes/residues as they are formed by bulky molecules. In particular, the MFI structure is one of the most employed zeolites in this type of reactions due to their unique combination of molecular sieve effect and acid properties. Likewise, the substitution of framework Al species for other heteroatoms allows tailoring the acid properties, thus varying the pyrolysis product distribution. In this work, we have synthesized highly accessible MFI zeolitic materials in the form of nanosponges (nSP) and nanosheets (nSH) with the incorporation of Al and Ga in the zeolitic framework. These materials have been tested as catalysts in the pyrolysis of oak wood and low density polyethylene (LDPE), which can be of interest for the productions of advanced fuels from biomass residues and plastic wastes.

**Experimental/methodology.** Aluminosilicate and gallosilicate in nanosponge and nanosheet samples (denoted as Al-MFI-nSP and Ga-MFI-nSP, Al-MFI-nSH, and Ga-MFI-nSH, respectively) were synthesized according to literature procedures[1,2]. The catalytic pyrolysis of LDPE was performed as described elsewere[3] at 350 °C for 2 h, with LDPE/catalyst mass ratios between 50 and 75. The oak wood pyrolysis set up is also decribed in a previous work[4], being operated with a catalyst to biomass ratio of 0.15, at 10 bar and temperatures of 500 / 450 °C for the thermal and catalytic zones, respectively.

**Results and discussion.** Both MFI-nSP and MFI-nSH samples display sharp variations, not only regarding morphology (Figure 1) and textural properties, but also in terms of acidic features. MFI-nSH samples exhibit a lower Bronsted/Lewis acid sites ratio than their analogous MFI-nSP samples. In addition, the presence of Ga in the zeolite framework, instead of Al atoms, enhances the Lewis acidity.

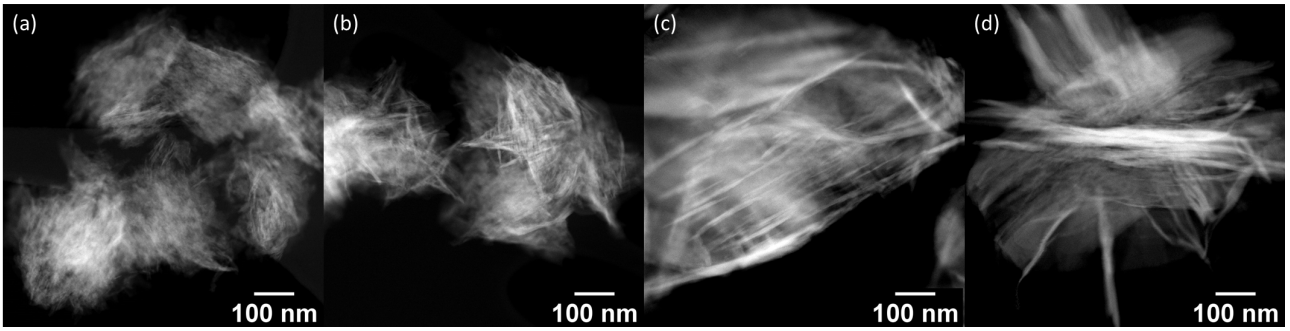

**Figure 1. DF-STEM images of Al-MFI-nSP (a), Ga-MFI-nSP (b), Al-MFI-nSH (c), and Ga-MFI-nSH (d) samples.**

These variations have a direct impact on the catalytic pyrolysis of LDPE and oak wood. Al/Ga-MFI-nSP display a superior activity than the Al/Ga-MFI-nSH for both LDPE and oak wood pyrolysis processes. In overall, an optimum combination of accessibility and a balanced Bronsted/Lewis acid concentration ratio has been found for the Ga-MFI-nSP sample, that leads to the best catalytic performance in the LDPE and oak wood pyrolysis.

# Chemical Recycling of thermoplastic Polymers with solid Catalysts

Marcus S. Lehnertz[1], Regina Palkovits[1*]

[1] *Institute for Technical and Macromolecular Chemistry at RWTH Aachen, Aachen, Germany*
[*] *palkovits@itmc.rwth-aachen.de*

**Keywords:** Chemical recycling, Heterogeneous catalysis, Biopolymers

**Introduction.** Being essential to our daily life, polymers have been produced in ever increasing amounts since the 1950's.[1] Especially within the last years, it became obvious that the development of recycling concepts for these indispensable substances could not keep up. Significant progress has been made towards mechanical recycling and the pyrolysis of polymers.[2] However, mechanical recycling cannot be repeated infinitively due to decreasing polymer quality over each cycle. Pyrolysis is usually carried out at high temperatures leading to an increased energy consumption. We therefore aim to implement solid catalysts in chemolytic recycling approaches to demonstrate the efficient conversion towards monomers and value-added products.

**Experimental/methodology.** The experimental setup features autoclaves in different volumes ranging from 5 to 975 ml. Majority of the catalysts is produced via wet impregnation and subsequent reduction under hydrogen atmosphere at elevated temperatures. To investigate the underlying catalytic phenomena, extensive analysis has been carried out, including nitrogen physisoprtion, temperature programmed reduction (TPR), CO-pulse, X-ray photoelectron spectroscopy (XPS) and IR-spectroscopy. Product analysis is carried out via HPLC, NMR, GC and GC-MS.

**Results and discussion.** The substrate scope covers bio-polyesters with rising markets such as polyhydroxy butyrate (PHB) and polylactic acid (PLA)[3-4] as well as established polymers, e.g. Nylon-66 and Poly(bisphenol A)carbonate (PC). It is demonstrated that pressures as low as 1 bar hydrogen are sufficient to activate the Ru-based catalyst. The required reaction temperature correlates with the melting point of the respective polymer, ranging from 160°C for PLA up to 250°C for Nylon-66. Water can often be used as a sustainable solvent, although methanol or dioxane are applied in special cases, e.g. for Nylon-66 and PC, respectively.[5] Due to their leading role for the reaction, a variety of supports for the Ru-based catalysts have been tested for their suitability, ranging from carbon to spinels and ceria. The performance of cerium oxide, either as a full catalyst or support material, stood out. One successful example is the conversion from PHB to its monomer 3-hydroxybutyric acid (3-HBA) with a yield of 79% and butyric acid (21%) as the solely side product.[3] Among other reasons, the activity of the catalyst system consisting of 0.5 - 5 wt% Ru on ceria is found to originate from weak Brønsted acid sites analysed by Pyridine-IR. Finally, the system is tested for its practical applicability by using all investigated polymers as substrates in a one-pot recycling approach.[5]

**Keywords:** catalytic debromination, plastic waste, supported metal catalyst

**Introduction.** Plastic waste is suggested as one of the geological indicators of the so-called Anthropocene era. The exponential growth of plastics use together with their ubiquitous nature has resulted in plastic waste being now present in most terrestrial and marine environments followed by near-permanent contamination and serious environmental challenges (1,2). Many plastics based consumer goods contain flame retardants that inhibit combustion and propagation of fire. These often halogenated chemicals have been listed as persistent organic pollutants (POPs), and their use in consumer products is regulated by the Stockholm Convention due to their possible toxicity to humans and the environment (3). However, concentrations of flame retardants have been studied mainly in natural waters in wastewater treatment plants with modest concentrations (4) whereas in plastic recycling it is pivotal to study debromination at much higher concentrations. Thus, specific pre-treatments for plastic waste material is needed for improved recycling process to remove halogenated additives. Here we show that supported transition metal catalysts can provide a potential pathway for debromination of waste plastic feedstocks.

**Experimental/methodology.** Here catalytic debromination of brominated flame retardants was studied by using supported transition metal catalysts. Supported metal catalysts were prepared by strong electrostatic adsorption method (SEA) and studied in moderate conditions for debromination of tetrabromobisphenol A (TBBPA) in an organic solvent. Hydrodebromination reactions were carried out in a teflon sealed autoclave reactor under hydrogen atmosphere (210°C, 80 bar $H_2$). The initial bromine content of the solvent was set to 2 500 ppm. The debromination products were analyzed by using GC-FID, GC-MS (Bruker, DE) and 500 MHz NMR (JEOL, JP). Organic solvents were used for a higher initial flame retardant concentrations without diffusion problems that are relevant when dealing with recycled plastic waste streams.

**Results and discussion.** In this study we confirmed that supported transition metal catalysts have activity in reducing bromine content and converting TBBPA into less brominated compounds. Propagation of debromination was examined by GC-MS and NMR. Our experiments revealed that well dispersed Ni/$TiO_2$ catalysts prepared by SEA method were active in removing bromine from brominated flame retardants under reductive atmosphere in laboratory scale. According to our experiments, economically feasible catalytic debromination of plastic waste streams can be realized, especially by using Ni/$TiO_2$ catalyst prepared by SEA method. Such transition metal catalysts make it possible to lower the bromine content in recycled plastic waste to reach the bromine levels set by EU regulation. The findings of this study can be used to further develop new, environmentally more viable plastic recycling processes.

**Introduction.** Plastic pollution has become a serious issue that is causing a threat to the environment and human health without proper recycling management [1]. Several technologies have been studied to convert plastic wastes into value-added products like fuel oil, diesel oil, and gasoline, with significant drawbacks such as high energy consumption and the production of lower-value-added compounds with poor quality [2,3]. The conversion of polyolefins to naphtha like compounds is of particular importance because naphtha can be used in commercial steam crackers to produce olefins, and subsequently virgin polyolefins, closing the gap in circularity of polyolefins. Herein, we investigate (i) whether naphtha-like liquid products can be obtained with pyrolysis (PYR) or hydrogenolysis (HYD) at high efficiency and (ii) performance of Ni-based catalysts as a replacement to their precious-metal containing counterparts.

**Experimental/methodology.** Ni-based catalysts were synthesized and reduced prior to use under $H_2$ at 700 °C. Catalytic activity experiments were performed in a Parr reactor at 20 bar and at a temperature range of 300-400 °C. Virgin PE ($M_n$=1700 Da & $M_w$=4000 Da) was used as a feedstock. Experiments were first performed to determine the conditions at which yield of liquid products was the highest. The liquid product was first distilled to obtain a liquid fraction having a boiling point less than 210 °C and analyzed using GC-MS as well as PIONA method to obtain n-paraffins, iso-paraffins, olefins, napthenes, and aromatics. Fresh and used catalysts were characterized by Scanning electron microscope (SEM), Brunauer-Emmett-Teller (BET), X-ray photoelectron diffraction (XRD), energy dispersive X-ray analysis (EDX), desorption of CO with diffuse reflectance infrared Fourier transforms spectroscopy (DRIFTS), and DRIFTS of adsorbed pyridine to gain knowledge about physical and chemical properties of the catalysts.

**Results and discussion.** The 1st part of the investigations focused on whether naphtha-like compounds can be obtained by PYR. Chromatography as well as chemical and physicals tests pointed out that liquid products obtained by PYR (yellow and orange liquids in Fig1) exhibit distinct differences than naphtha (colorless liquids in Fig1) and cannot be used as a feedstock for steam crackers. The 2nd part of the investigations focused HYD and PYR performance of catalysts. The activity testing on HYD of PE to produce linear saturated alkanes was performed with Ni-$Cat_1$ and Ni-$Cat_2$ under reaction conditions of $g_{feedstock}/g_{catalyst}$=3, 400 ºC, 20 bar $H_2$ and 5 h. It is found that the obtained distillates ranged from $C_5$-$C_{12}$ as a colorless liquid containing mostly saturates *(*linear and cyclic alkanes) (Table 1). The thermal cracking of PE by Ni-$Cat_1$ and Ni-$Cat_2$ was yielded in 92% and 94% saturated compounds with a negligible amount of olefin and aromatics after distillation. When the reduced catalysts (Ni-$Cat_{1R}$ and Ni-$Cat_{2R}$) were used, the yield of saturates was slightly decreased. Results indicate that the catalyst surface has a significant role in the selective formation of paraffinic naphtha-like high-valued chemicals through the deconstruction mechanism.

**Keywords:** antibiotics, laccase, syringaldehyde, water and wastewater treatment

**Introduction.** The increasing presence of different classes of antibiotics in water bodies generates great health and environmental concerns due to the microbial-resistance issue [1]. As a result, different methods are being investigated to remove antibiotics from wastewater. Some enzymes, including laccase, are receiving increasing attention as biocatalysts for this environmental application [2]. Because of its low redox potential (0.42-0.79 V), laccase has limited ability to oxidize organic compounds. However, in the presence of a specific redox-mediator (e.g., ABTS) laccase-driven degradation of antibiotics may be observed [3]. In this work, laccase from *Trametes versicolor* has been used for the removal of antibiotics belonging to different classes (e.g., tetracyclines, fluoroquinolones, sulfonamides, etc.) in the presence of redox mediators.

**Experimental/methodology.** Laccase from *Trametes versicolor* (activity ≥ 0.5 U/mg) was obtained from Sigma-Aldrich. ABTS and syringladehyde (SYR) were used as redox mediators. Experiments were carried out in ultrapure water (UP) and primary and secondary effluents from a municipal wastewater treatment plant (PE and SE, respectively) at pH ranged from 6.5 to 7.5. The following antibiotics were used: metronidazole, tetracycline (TET), oxytetracycline (OTET), sulfamethoxazole (SFX), sulfadimethoxine (SFM), ofloxacin, ciprofloxacin, flumequine and trimethoprim. Degradation of antibiotics was followed by HPLC-DAD. The ABTS assay was used for routine laccase activity determination.

**Results and discussion.** First, screnning experiments were carried out in UP to rank the antibiotics according to their enzymatic degradation rate. At pH 6.5 using ABTS as mediator, TET and OTET were completely degraded in less than 1 h while more than 90% SFM and 70% SFX were removed in 10 h (see Fig.1). The rest of the antibiotics tested were less prone to enzymatic biodegradation. SYR was demonstrated as an effective redox mediator for SFX degradation. The presence of organic matter in SE inhibited the enzymatic degradation of SFX to some extent and cause some enzyme deactivation. Also, simulataneous microbial (i.e., activated sludge) – enzymatic (laccase) biodegradation of SFX in PE was investigated.

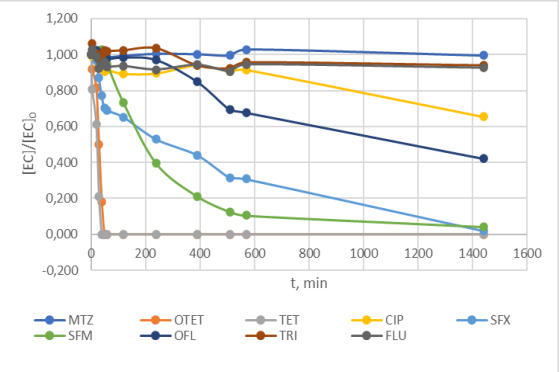

*Fig.1. Laccase-mediated degradation of antibiotics. T=25ºC; pH=6.5; [Laccase]=100 mgL$^{-1}$; [ABTS]=0.036 mM; [EC]$_0$=0.5 mgL$^{-1}$*

**Keywords:** Hydrogen peroxide, greywater remediation, bimetallic catalysts.

**Introduction.** Water sustainability is one of the most important challenges of the 21st century. Loss of water depletes energy reserves and undermines ecosystem health and human water security[1]. Current remediation of wastewater is heavily reliant on chlorination. One major downside to this method is the accumulation of toxic chemical residues in potable water. Hydrogen peroxide ($H_2O_2$) has the potential to replace chlorine-containing compounds for water remediation. It has a broad spectrum of bactericidal activity and water is the only by-product of its use, avoiding the by-products associated with chlorination. Commercial $H_2O_2$ has drawbacks, including the need to store large volumes of highly concentrated $H_2O_2$ on site and the need to remove propriety stabilizing agents prior to use. The in-situ production of $H_2O_2$ from $H_2$ and $O_2$ would avoid the drawbacks associated with the use of commercial $H_2O_2$ and allow for the decentralised treatment of greywater on a local level.

**Experimental/methodology.** A series of 1 wt% AuPd/$TiO_2$ catalysts was prepared by an excess-chloride co-impregnation procedure[2]**.** Catalyst testing was conducted in a continuous fixed-bed reactor to evaluate performance towards $H_2O_2$ synthesis and the remediation of model greywater.

**Results and discussion.** A synergistic effect was observed upon the alloying Au and Pd, leading to enhanced $H_2O_2$ productivity compared to the monometallic catalysts (Figure 1, left). The optimal 0.5%Au-0.5%Pd/$TiO_2$ catalyst displayed exceptionally high biocidal efficacy achieving an 8.1 $\log_{10}$ reduction (i.e. 99.999999%) in *E. coli* at a contact time of 1 minute, which was $10^7$ times more effective than using an equivalent amount of preformed $H_2O_2$ and $10^8$ times more effective than chlorination under equivalent conditions (Figure 1, right). EPR spectroscopy revealed the alloying of Au and Pd was essential in the production of several reactive oxygen species, which subsequently were responsible for the observed bactericidal efficacy.

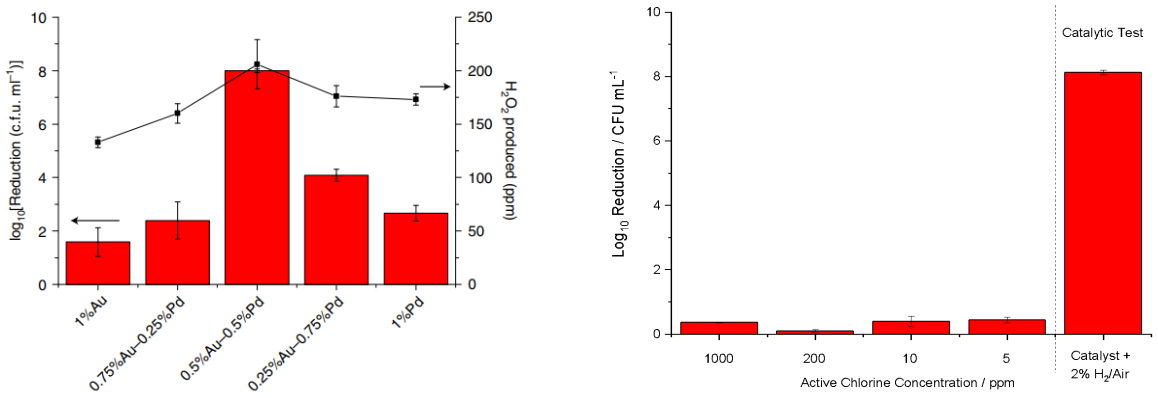

**Figure 1.** Left: Biocidal efficacy and $H_2O_2$ productivity of the 1% AuPd/$TiO_2$ catalyst series under flow conditions. Right: Biocidal efficacy of the optimal 0.5Au-0.5%Pd/$TiO_2$ catalyst compared to aqueous NaOCl under flow conditions.

**Keywords:** Bimetallic Catalysis, Multiphase Catalysis, Environmental Catalysis

**Introduction:** The development of a zero-emission ship engine system can reduce substantially the emissions generated from freight transport. This is very attractive in liquified natural gas (LNG) powered ships as the captured $CO_2$ can be converted back to methane using green hydrogen, enabling the circular use of carbon-based fuels. Unfortunately, the combustion of LNG emits a so-called "methane slip" as well as $NO_x$ gases. To capture all the emissions, methane can be catalytically oxidized to $CO_2$ and the $NO_x$ emissions can be scrubbed into liquid phase resulting in a nitrate and nitrite containing solution.[1] Converting these oxidized nitrogen species back to $N_2$ is key to prevent the disposal of these waters into the harbors as the high concentration of nitrates and nitrites will promote eutrophication of the water bodies and aquifers near the area.

**Experimental/methodology:** While monometallic catalysts suffice for the reduction of nitrites, bimetallic catalysts such as Pd-Sn, Pd-Cu or Pd-In are required for nitrate conversion (Figure 1).[2] For their reactivity, not only the metal combination but also the microscopic arrangements of the active sites are of importance. Therefore, bimetallic Pd-Sn catalysts are synthesized *via* sequential wet impregnation and controlled surface deposition resulting in random Sn-Pd or defined Sn-Pd structures, respectively. The catalysts are characterized and applied in rigorous reaction kinetic studies of nitrate and nitrate reduction.

**Results and discussion:** The comparison of differently synthesized bimetallic catalysts allows to establish fundamentally relevant property-chemistry-performance relationships and helps to establish the optimal catalyst formulation. In combination with detailed reaction kinetics mechanistic insights can be obtained and modelling of reactors for nitrate and nitrite reduction on ship is feasible.

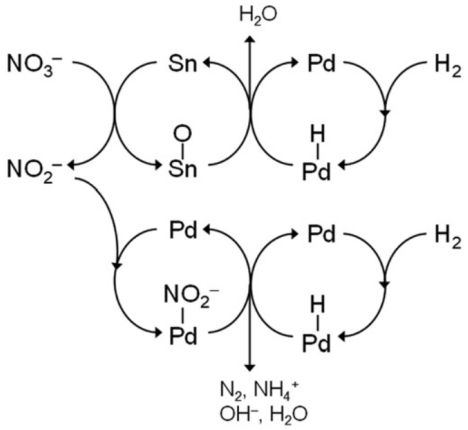

**Figure 1: Reaction network of $NO_x$ reduction showing the reduction of nitrate to nitrite by oxidation of tin to tin(II) oxide and subsequent tin regeneration by hydrogen spill-over. Nitrite is then reduced to nitrogen and ammonia as undesired side product.[3]**

# Recycling of end-of-life long-chain polyamides via an ammonolytic hydrogenation process

R. Coeck[1*], A. De Bruyne[1], D. De Vos[1]

[1]*cMACS, Katholieke Universiteit Leuven, Leuven, Belgium*
[*]*robin.coeck@kuleuven.be*

**Keywords:** Nylon, polyamides, ammonolysis, hydrogenation, heterogeneous catalysis, polymer recycling

**Introduction.**

Polyamides (PAs) are important engineering plastics that find their use in a wide variety of applications as a result of their high stability. While PA6 and PA66 are often used for more general purposes (e.g. carpet), long-chain polyamides (LCPAs) are more expensive with better mechanical properties and are therefore mainly used in specialized niche applications (e.g. water pumps). Polyamides' high stability and durability are obstacles when dealing with end-of-life PA waste. Typically, one can deal with plastic waste via either landfilling, waste-to-energy (WtE) or recycling. Landfill is no longer acceptable; and for high value plastics it would be highly inefficient to burn the material and generate some electricity in the process (WtE), while continuing to produce virgin plastic from a mostly crude oil based feedstock.[1] This is particularly the case for nitrogen containing plastics such as polyamides, which in addition to typical greenhouse gases (i.e. $CO_2$), also release $NO_x$ gasses. Although recycling is clearly the best option, efficient recycling methods are limited. Here, a new chemocatalytic ammonolysis process for LCPAs was developed, which can operate under relatively mild conditions and uses cyclopentyl methyl ether (CPME) as a green solvent.

**Experimental/methodology.**

Reactions were performed in a 25 mL pressure Parr batch reactor. In a typical reaction, the reactor is filled with a substrate containing 1 mmol secondary amide bonds, $Nb_2O_5$ catalyst (0.10 g of catalyst), RuWOx-catalyst (2 mol% Ru), undecane (20 µL) and CPME (10 mL). Then, the reactor is pressurized with 6 bar $NH_3$ and 50 bar $H_2$, and heated to 200°C. After reaction, the mixture is analyzed via H-NMR and GC(-MS).

**Results and discussion.**

The ammonolysis of *N*-hexylhexanamide, a model component for polyamides, was initially investigated. Niobium oxides ($Nb_2O_5$ and $Nb_2O_5.nH_2O$) were found to be effective heterogeneous catalysts. After a reaction time of 5 hours, a conversion of 36% was achieved with $Nb_2O_5$. Further kinetic experiments suggested that the ammonolysis reaches an equilibrium conversion (i.e. 45%) after 24 hours. Aside from the ammonolysis, niobium oxides also catalyzed the dehydration of primary amides. In a second stage, the ammonolysis was coupled to a hydrogenation process to convert the generated primary amides to primary amines. This resulted in a bicatalytic ammonolytic hydrogenation process with $Nb_2O_5$ and $RuWO_x/MgAl_2O_4$ as the corresponding catalysts. Actual industrial plastic samples (i.e. PA 10.10, PA 11 and PA 12) were completely depolymerized, leading to α,ω-diamines. The process was proven to be robust against common impurities (e.g. plasticizers, antioxidants, other plastic contaminations and fillers). However, any sulfur-containing compounds must be removed in order to maximize the lifespan of the Ru-catalyst.

# Production of low-chlorine oil through catalytic pyrolysis of solid recovered fuels (SRF) over ZSM-5, Beta and USY zeolites

J. Cueto[1], G. Pérez[1], M. Paniagua[2], G. Morales[2], J. A. Melero[2], D. P. Serrano[1,2]*

[1]*Thermochemical Processes Unit, IMDEA Energy Institute, Móstoles, Spain*

[2]*Chemical and Environmental Engineering Group, Rey Juan Carlos University, Móstoles, Spain*

[*]*david.serrano@imdea.org*

**Introduction.** Municipal solid waste production has increased considerably during the last decades. It is expected that this quantity will rise by up to 70 % in 2050 [1]. The current management policies are focused on prevention, reduction and mechanical recycling. However, not all the wastes can be recycled, so other uses must be found to prevent their accumulation in landfills. In this context, these wastes suppose a valuable source to produce solid recovered fuels (SRF), which consist of highly calorific fractions such as plastics, textiles, wood, and elastomers [2]. Among the available waste-to-energy or waste-to-chemicals technologies, pyrolysis has received an increasing interest due to its great flexibility and relatively simple operation. However, the use of SRF as feedstock for pyrolysis has been scarcely studied. Considering the heterogeneity of this raw material, the presence of high amounts of chlorine in its matrix may suppose an important limitation when it comes to feeding the final oil into a traditional refinery scheme. Consequently, the oil dehalogenation is one of the most determinant aspects to be understood. This work investigates the performance of various zeolites (ZSM-5, Beta and USY) in SRF catalytic pyrolysis in terms of dechlorination of the so-produced oil.

**Experimental/methodology.** SRF provided by 'Reciclados Palancia Belcaire' (Spain) has been pretreated by washing with milli-Q water and thermal heating at 300°C under $N_2$ flow. After this previous step, thermal and catalytic pyrolysis was carried out in an *ex-situ* set up passing an ascendant nitrogen stream. Temperatures of the thermal and catalytic zones were set at 550 and 400°C, respectively. 0.5 zeolite / SRF was used as mass ratio and the zeolites employed for catalytic runs were: n-ZSM-5 (Si/Al=42, Clariant), Beta (Si/Al=15, Clariant) and USY (Si/Al=40, Zeolyst).

**Results and discussion.** The main products of SRF catalytic pyrolysis are gaseous and liquid organic fractions, whereas in the thermal reaction waxes are mainly produced (Figure 1a), followed by a carbonaceous residue (char) and an aqueous phase. Interestingly, the gases are rich in light olefins, whereas the oil possesses a high content of aromatic hydrocarbons (with high differences between the zeolites tested: 87 and 47-48% for ZSM-5 and BETA-USY, respectively), which opens the way for their application not only in the production of fuels but also for raw chemicals. Other important finding is that chlorine is accumulated mainly in the char and aqueous phase fractions, thus leading to an oil with a relatively small Cl content (20 ppm in the oil for BETA).

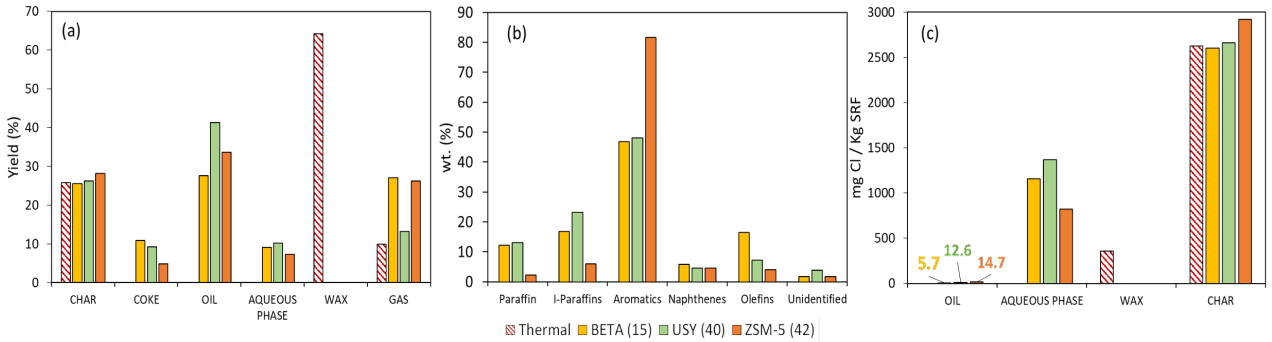

**Figure 1. Fraction yields (a), oil composition (b) and chlorine distribution (c) in the SRF pyrolysis.**

**Keywords:** Polyurethane, pyrolysis, catalysis, downstreaming

**Abstract**
Over the years, an increase of focus has been observed in the recycling of polyurethane (PUR) due to changes in regulation & environmental issues. The increase of landfill costs and decrease of space has forced more awareness in alternative recycling methods for polyurethane. [1] substantial research has concluded in three recycling and recovering methods that are economically and environmental accepted nowadays. 20% Mechanical processing (only postproduction waste), [1,2] 50% landfilling (combined postconsumer and postproduction waste), [3] and 30% is processed via thermal degradation (hydrogenation, pyrolysis, or gasification). [4] However, an efficient method to retrieve the starting material from end of life waste (EOL) is still desired.

For this reason, the Circular foam project has been started which is a collaboration between 23 parties within the EU with the polymer company Covestro as the leading organization. The project aims to design a downstream process for the conversion of EOL polyurethane found in refrigirators into raw material. which can be used to produce new polyurethane, resulting in a circular economy. Two approaches that have been considered are chemical and thermal decomposition. This work specifically focusses on thermal decomposition.

Pyrolysis has found it's way into industry via the recyling of biomass [5] and various plastics (PET, PE, PVC, PP, PS, PE, and Mix). [4] Pyrolysis is a process based on thermal decomposition. Long polymer chains are converted into smaller fragments at elevated temperature (350 – 900$^0$C) under anaerobic conditions (e.g. $N_2$ atmosphere). The resulting oil, gas and ash is of great value for industry. [4] Since pyrolysis has shown it potential by succesfully recycle various plastics and feedstocks, it has been chosen as the pathway to convert EOL PUR into virgin oil. Currently, the parameters of interest are temperature and choice of catalyst.

A general catalyst screening has been conducted to determine which type of catalyst is suitable for the depolymerization of PUR. A total of 10 different catalysts have been considered such as zeolites, clays, alumina's, and oxides e.g. H ZSM-5/zeolite HY, bentonite, various alumina oxide's and calcium oxide respectively. Positive results were observed with the use of alumina's and oxide's since significant amounts of desired products were observed.

As continuation of the project, an extended screening was conducted with analogs of the alumina or oxide based catalysts. However, no direct correlation between parameters of interest and formation of desired compounds was observed. For this reason Future work will revolve around analysis of various catalyst to verify which parameters have a significant influence on the formation of the desired products (e.g. particle size, BET, Brønsted/lewis acid sites etc.) In addition, model compounds will be synthesized and pyrolyzed in present of various catalysts to support the parameters of interest. These parameters will be investigated to a further extent.

**Keywords:** Hydrogen peroxide**,** oxidative degradation, bifunctional Pd/Fe-ZSM-5 catalysts.

**Introduction:** The contamination of water bodies with pollutants from petrochemical, pharmaceutical and agricultural waste streams is a rising dilemma and induces risk to human and aquatic life[1]. Conventional techniques for water treatment are highly reliant on chlorination, however, there are concerns regarding the accumulation of toxic chemical residues, as well as increased energy demand associated with the use of alternative stoichiometric oxidants[2]. The oxidative degradation of organic pollutants *via* the *in-situ* synthesis of $H_2O_2$ has the prospect to substitute chlorine-containing compounds for water treatment due to diminishing the health and environmental implications while contributing increased activity in contrast to previous procedures to water treatment.

**Experimental/Methodology:** A series of PdFe-ZSM-5 catalysts were prepared *via* an excess chloride impregnation procedure. Catalyst testing was conducted in a Parr Instruments stainless steel autoclave reactor to investigate the efficacy towards the degradation of phenol and enhance improvements towards catalyst stability over previously studied materials.

**Results and Discussion:** Time-on-line studies reveal that generally catalytic performance towards $H_2O_2$ formation is not detrimentally affected by the addition of Fe and despite the introduction of Fe, the degradation of phenol was favoured. The greatest rate of phenol conversion was attained by 0.5 wt% Pd/3 wt% Fe-ZSM-5 (70 %) over 2 h in comparison to 0.5 wt% Pd/0.5 wt% Fe-ZSM-5 (45 %). XPS analysis revealed the surface speciation of the monometallic Pd catalyst is comprised of a combination of both $Pd^0$ and $Pd^{2+}$. The inclusion of Fe generates a significant shift in Pd oxidation state with the quantity of $Pd^0$ escalating significantly. Thus, the increase in $H_2O_2$ synthesis activity and phenol degradation activity of the Fe-containing catalysts can be assigned to the variation of Pd oxidation state.

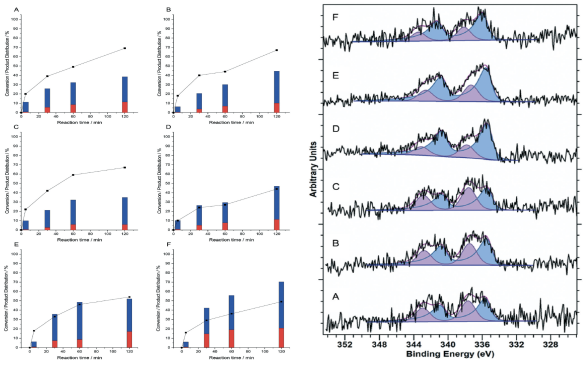

**Figure 1.** (**Left**) Comparison of the catalytic activity towards the oxidative degradation of phenol *via in situ* $H_2O_2$ synthesis as a function of reaction time over. **Introduction.** Intense population growth has significantly impacted drinking water quality, resulting in release and accumulation of contaminants of emerging concern (CECs) in water bodies. Pollution by CECs is likely to increase, requiring the development of practical efficient treatment technologies. Catalytic wet peroxide oxidation (CWPO) is a technology that has demonstrated some advantages, allowing complete degradation of several CECs. This work compares the efficiency of several catalysts (clays, carbon-based and hybrid materials) in the CWPO of paracetamol (PCM), a model pharmaceutical compound.

**Experimental/methodology.** The synthesis of pillared clay (PCLAY), carbon nanotubes (CNT@PP) and hybrid carbon-coated magnetic nanoparticles (CoFe@C) are reported elsewhere [1-3]. CWPO reactions were conducted considering the following conditions: $[PCM]_0$ = 100 mg $L^{-1}$, $[H_2O_2]_0$ = 474 mg $L^{-1}$, $pH_0$ = 3.5, T = 80 °C, $c_{catalyst}$ = 2.5 g $L^{-1}$, 24 h. PCM and $H_2O_2$ were followed by HPLC and UV-Vis, respectively, as described in previous works [1].

**Results and discussion.** The results are summarised in Fig. 1. The removal of PCM in the presence of CoFe@C is much faster than CNT@PP and PCLAY (Fig. 1,a), especially if excluding the effect of adsorption (Fig 1,c). The consumption of $H_2O_2$ follows the order CoFe@C > PCLAY > CNT@PP (Fig. 1,b). The leaching of iron is higher for PCLAY, followed by CoFe@C and CNT@PP (Fig. 1,c). Thus, CNT@PP allows for a similar degradation of PCM to PCLAY while resulting in lower leaching. The hybrid material (CoFe@C), on the other hand, shows great potential by resulting in a faster PCM degradation and lower iron leaching.

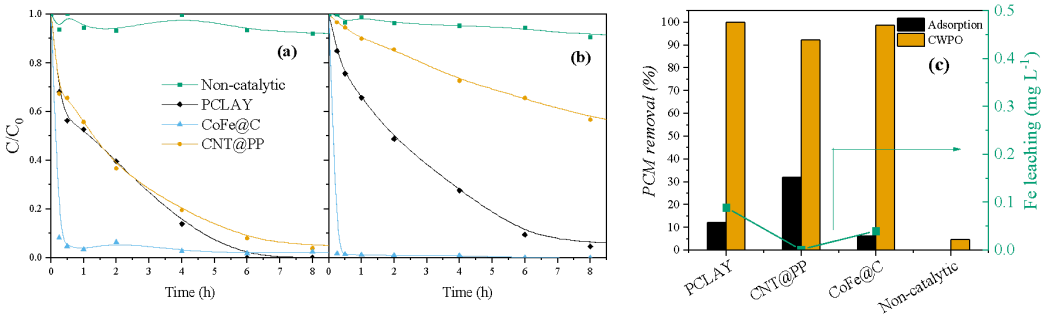

**Fig. 1**. Normalized concentration of (a) PCM and (b) $H_2O_2$, and (c) comparison between adsorption, CWPO, and iron leaching.

# Influence of bicarbonate, other anions and carbon dioxide in the activity of Pd-Cu catalysts for nitrate reduction in drinking water

D.T. González[1], J.A. Baeza, L. Calvo, M.A. Gilarranz
[1]*Universidad Autónoma de Madrid, Madrid, Spain.*
[*]*dydia.gonzalez@uam.es*

**Introduction.** Catalytic reduction is an interesting removal technique as it is able to convert nitrate into harmless gaseous $N_2$ using a reducing agent such as $H_2$, without generating any secondary waste. However, it is also necessary to make sure that harmful intermediates as $NO_2^-$ and $NH_4^+$ are avoided since they are also regulated for EU. Therefore, it is key to control the selectivity in the reaction. The effect of ions in natural waters have been investigated by several authors, showing catalyst deactivation, and favouring $NH_4^+$ formation. In addition, various studies have shown that anions, especially $HCO_3^-$, have a more negative effect on the catalytic activity. Therefore, in this work the effect of salts on $NO_3^-$ reduction using a Pd-Cu catalyst supported on carbon black has been investigated, with a focus on the reaction mechanism and fate of $HCO_3^-$.

**Experimental/methodology.** The effect of different ions usually present in drinking water ($Ca^{2+}$, $Mg^{2+}$, $Cl^-$, $SO_4^{2-}$ and $HCO_3^-$) has been studied. For this purpose, two types of water were tested: synthetic water (SW) and commercial drinking water (DW) spiked with $NO_3^-$ ($[NO_3^-]_0$ =100 mg/L). The experiments were carried out in a glass reactor jacketed at 25 °C and atmospheric pressure using a Pd-Cu (2:1) catalyst, 5 wt%, supported on carbon black (ENS350). During the nitrate reduction cycles $H_2$ (1 NmL/min) and $CO_2$ (50 NmL/min) were continuously bubbled. For the specific study of the effect of $HCO_3^-$, a serie of assays were performed in which 100 mg/L $HCO_3^-$ was added at zero time reaction.

**Results and discussion.** The results of ions effect in the water showed that in the presence of low concentrations, no noticeable variations were seen in the catalytic activity. However, when the tested water contained high concentrations, mainly of anions (55.6 mg/L $Cl^-$, 52.1 $SO_4^{2-}$), $NO_3^-$ conversion may be affected, obtaining a final conversion of 82 % and a $NH_4^+$ selectivity higher than 20 %. Previous studies related to the ions effect on the $NO_3^-$ catalytic reduction have attributed the decrease in $NO_3^-$ catalytic activity to competition for adsorption on the active sites [1]. In addition, a significant effect was observed in the catalytic activity when the $HCO_3^-$ ion was present in the tested water (39.8 mg/L $Cl^-$, 52.8 $SO_4^{2-}$, 298 mg/L $HCO_3^-$), obtaining a final conversion of 57.2 %. Thus, a specific study about $HCO_3^-$ effect was carried out, comparing reactions with Milli-Q water in absence and presence of this anion. Total conversion was obtained in both reactions due to the high activity of the catalyst. However, the time necessary for total conversion in the $HCO_3^-$ absence was 60 min, increasing up 120 min when $HCO_3^-$ was present. In addition, low $HCO_2^-$ concentrations were found in these reactions, which suggests that a $HCO_3^-$ reduction was taking place during $NO_3^-$ catalytic reduction. Studies related to $HCO_3^-$ reduction suggest a mechanism similar to $NO_3^-$ nitrate reduction [2], so there would be a competition for adsorption in the active sites and availability of $H_2$ for the reduction to $HCO_2^-$ and $NO_2^-$, respectively.

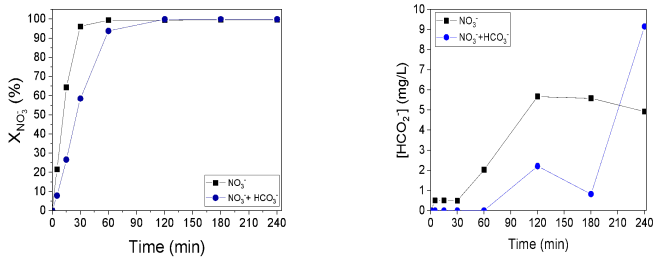

**Figure 1. (a) Effect of $HCO_3^-$ on $NO_3^-$ conversion, (b) Formation of $HCO_2^-$ vs time reaction on nitrate reduction with Pd-Cu/ENS350.**

**Keywords:** Catalytic ozonation; Catalytic reduction; Macrostructured catalysts; Integrated catalytic treatment.

**Introduction.** Heterogeneous catalysis, applied for water treatment, has been widely studied to remove several organic and inorganic contaminants occuring in water [1]. Although different reaction conditions and catalysts are necessary to remove both types of pollutants, this methodology appears as a simpler, efficient, and economical alternative to perform definitive remediation of different classes of contaminants [1,2]. Bromate ($BrO_3^-$) is a carcinogenic compound of great environmental concern, is a typical by-product resulting from ozonation of bromide-containing waters or from oxidation of brominated organic compounds; it is classified as a possible human carcinogen; and is regulated at a maximum of 10 µg/L in drinking water [3]. The present work aims to develop an integrated continuous catalytic system, for the simultaneous removal of organic and inorganic species in water, using adequate macrostructured carbon catalysts. The system consists on the serial application of catalytic ozonation for the degradation of water contaminated with brominated organic compounds, followed by a catalytic reduction process for $BrO_3^-$ conversion into $Br^-$.

**Experimental/methodology.** Macrostructured catalysts were synthesized using a washcoating methodology (CNT coated macrostructured catalysts and Pd-Cu bimetallic macrostructured catalysts supported on CNT:$TiO_2$) [4]. Catalytic experiments were performed in a custom-made experimental set-up. Brominated organic pollutants (Bromophenol Blue, Tetrabromobisphenol A, and 2,4,6-Tribromophenol) were studied as model contaminants susceptible to generate $BrO_3^-$, after ozonation treatment ($C_0$=1 mg $L^{-1}$ of each pollutant), that would be afterwards converted into $Br^-$ during the second process. Organic species concentration was followed using liquid chromatography coupled to tandem mass spectrometry (LC-MS/MS); $BrO_3^-$ quantification was performed using a HPLC-LC20-AI with post column reaction.

**Results and discussion.** The integrated treatment system was applied for the complete treatment of water contaminated with brominated organic pollutants. The absence of catalyst in the oxidation system allowed the full degradation of the organic species with a higher formation of $BrO_3^-$, and the absence of catalysts in the hydrogenation column did not promote $BrO_3^-$ conversion; also, the use of a catalysts during ozonation treatment plays a key-role on the decrease in the amount of $BrO_3^-$ formed after oxidation of the organic species. The results obtained allowed to conclude that, after the application of the catalytic ozonation treatment, the organic pollutants were fully removed from the water leading to the formation of high $BrO_3^-$ concentrations (concentration above the limit allowed by law). When directly forwarded to catalytic reduction treatment, it was possible to decrease $BrO_3^-$ concentration present in the water for values very close to its maximum legal limit in water (10 µg $L^{-1}$, conversion of around 86 %). The catalysts proved to remain stable and active (without metal phase leaching) during long reaction periods.

**Keywords:** oxidative desulfurization, dibenzothiophene, DBT, mesoporous silica, SBA-15, titanium

**Introduction.**

To replace fossil-based fuel, biodiesel production from waste cooking oil is environmentally friendly and gives renewable energy with lower pollution. However, biodiesel contains high amount of impurity, such as sulfur, and needs to be purified before using in a vehicle engine [1]. Oxidative desulfurization (ODS) is a promising method to remove sulfur compounds. Oxidation of organosulfur compounds leads to the formation of their sulfoxides/sulfones, which are highly polar and thus can be easily removed by polar solvents [2]. Titanium-containing mesoporous materials have attracted attention because of larger access to the active site and the presence of coordinately unsaturated tetrahedral titanium able to interact with the primary oxidant, leading to excellent catalytic activity [3]. In this work, a one-pot incorporation of titanium into SBA-15 framework was synthesized and compared to a conventional impregnated catalyst. The ODS of dibenzothiophene (DBT) as a model sulfur-containing compound was investigated, and their surface properties were related to the ODS activity. Eventually, the one-pot synthesized catalyst showed outstanding catalytic activity in the ODS system.

**Experimental/methodology.**

SBA-15 sample was prepared using an aqueous solution of pluronic P123 triblock copolymer and hydrochloric acid. Tetraethoxysilane (TEOS) was used as the silicon source. One-pot synthesized Ti-SBA-15 catalysts with various titanium loading were prepared by co-condensation of TEOS and titanium acetylacetonate or titanium butoxide. For the incipient wetness impregnated catalyst, titanium acetylacetonate in ethanoic solution was dropped slowly into SBA-15. Finally, the samples were calcined at 550 °C for 5 hours. The ODS of DBT was conducted at 80 °C for 2 hours in the presence of hydrogen peroxide ($H_2O_2$/DBT = 4 molar ratio).

**Results and discussion.**

Titanium containing SBA-15 catalysts provided well-defined hysteresis loop of type H1 associated with capillary condensation and desorption in open-ended cylindrical mesopores and there were large surface area (830 - 880 m²/g) and big pore size (4.5 - 5.2 nm). The Lewis acidity of the catalyst prepared by the titanium acetylacetonate precursor was higher than that of the catalyst prepared by the titanium butoxide precursor revealed by in situ IR of pyridine adsorption. $^{29}$Si NMR spectroscopy gave an evidence of titanium inserted into silica framework for the one-pot synthesized catalyst. These data show the better dispersion of titanium and the presence of active $Ti^{4+}$ tetrahedral sites through Si-O-Ti bonds in the one-pot preparation.

At the same titanium loading, the novel titanium incorporated SBA-15 catalyst by one-pot synthesis showed largely superior ODS activity (100 %) compared to the conventional impregnated catalyst (51 %). Moreover, the ODS activity of the one-pot synthesized catalyst rapidly reached 100 % within 15 minutes in case of Si/Ti molar ratio 10 and 20. In this work, a novel one-pot synthesized Ti-SBA-15 catalyst was developed with high activity in the oxidative desulfurization of DBT, which should also exhibit high efficiency in removing sulfur-containing compounds in biodiesel derived from waste cooking oil.

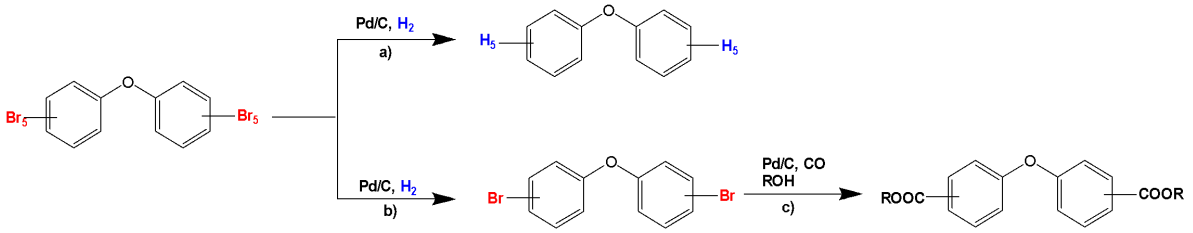
# Full Catalytic Dehalogenation of Brominated Flame retardants



Gj. Hulaj, S.Windels, B. Krasniqi, D. De Vos*

*Centre for Membrane separations, Adsorption, Catalysis and Spectroscopy – KU Leuven, Leuven, Belgium*
*dirk.devos@kuleuven.be

## Introduction

Brominated flame retardants belong to a large group of organohalogen chemicals, which are used in a variety of polymers such as high-impact polystyrene and epoxy resins, which are then used in commercial products such as computers, electronics and electrical equipment, textiles, and furniture foam [1]–[2]. It is important to note that some of them are now in use, some are banned, and others under assessment [3]. As these compounds are nearly impervious to degradation and highly environmentally persistent with deleterious effects on human health, there is a real incentive to develop technologies to rid the environment of such deleterious substances. The best current method is to debrominate them fully via pyrolysis, hydrothermal treatment, or catalytic pyrolysis. However, this leads to a very low-value fraction which is at best suitable to be used as fuel [4]. Ultimately the compounds are burned or incinerated. Here we explore different strategies to catalytically detoxify or upcycle these BFRs.

Regarding debromination, we developed a catalytic method to convert BFRs into valuable products. This catalytic method includes two pathways (see scheme 1.) for revalorization of BFRs: full debromination via hydrogenolysis reaction using Pd/C, and partial debromination via hydrogenolysis in combination with deep dehalogenation via carbonylative debromination. The resulting oligo-carboxylic acids or esters are easily recovered and revalorized, e.g. in resins.

**Scheme 1. a) Full hydrogenolysis of BFRs; b) Partial hydrogenolysis and c) model reaction: catalytic conversion of dibromodiphenyl ether to diester.**

## Results and discussion

After the completion of the reaction, high yields of bromine-free valuable products were obtained under mild conditions using Pd/C as a catalyst (Table 1). Regarding the second pathway, DecaBDE was chosen as a model reactant, in which after the partial hydrogenolysis reaction, a yield of about 35% of dibromodiphenyl ether was obtained. The latter was then used as a model for the carbonylative debromination reaction using Pd/C as a catalyst. About 80% yield of dimethoxycarbonyl diphenyl ether was obtained, which is a valuable product for the production of polyesters.

**Table 1. Full hydrogenolysis of BFRs for 6h using Pd/C (5 wt%) 5 mol% , 2,6 - Lutidine as a solvent and base**

| Entry | Substrate | T ($^0$C) | p($H_2$) bar | Product | Yield [%] |
|---|---|---|---|---|---|
| 1 | Decabromodiphenyl ether | 75 | 5 | Diphenyl ether | 89 |
| 2 | Decabromodiphenyl ethane | 75 | 5 | Dibenzyl | 94 |
| 3 | Tetrabromobisphenol A | 100 | 10 | Bisphenol A | 95 |
| 4 | 1,2-bis(2,4,6-tribromophenoxy)ethane | 75 | 5 | 1,2-diphenoxyethane | 98 |

# Plastic Waste Recycling via Zeolite-based Hydrocracking

L. Chen[1*], N. Michailidou[1], L. Radloff[1], S. Winiesdorffer[1], M. Geske[1], M. Al-Naji[1], M. Bender[2] and F. Rosowski [1,2]

[*]*lunhan.chen@tu-berlin.de*

**Introduction.** Only a small fraction of around 12% of plastic waste is recycled world-wide, with mechanical recycling as the main established method [1]. However, mechanical recycling is limited to pure polymers and the polymer quality is degrading with each cycle. New technologies for chemical recycling of plastics are on the rise, in which pyrolysis is the most investigated and developed method [1]. In pyrolysis, chemical bonds are thermally cracked, resulting in a wide range of hydrocarbons and high amount of coking [2]. Depending on the obtained pyrolysis oil quality, a hydrogenation step as after-treatment is required to purify the product fraction by removal of heteroatoms. Therefore, catalytic hydrogenative cracking could be an alternative to pyrolysis in order to obtain a valuable liquid product fraction of saturated hydrocarbons within one procedure step [2].

**Experimental/methodology.** The typical experiments are carried out in a batch reactor (300 mL) from Parr instruments at temperatures between 250 – 340 °C, 60 bar of $H_2$ pressure, 700 rpm and 2 – 15h of reaction time. The hydrogenative fragmentation of Polyolefins into a range of hydrocarbons in gas (C1 – C4), liquid (C5 – C21) and wax (C>21) products is studied. Gas phase products are analyzed with GC coupled with TCD. The liquid and wax composition are separately identified and quantified with GC-MS and GC-FID. Parent zeolites, with different Si/Al molar ratio, and metal loaded zeolites were investigated in the reactions mentioned above.

**Results and discussion.** Among different tested reaction temperatures, experiments at 300 °C with selected zeolites resulted in a high liquid product fraction. The yield of gas and liquid fractions are shown in Figure 1, obtained after the conversion of LLDPE over HZSM-5 and H-BEA of similar Si/Al ratios of 15 and 12.5, respectively, and at reaction times between 2 and 15h. Zeolite HZSM-5 was reported to pre-dominantly produce gas products which was also observed in this work [2-3]. Despite the similar Si/Al ratios, LLDPE conversion with H-BEA resulted in a significant higher amount of liquid yield (42% after 4h). With longer reaction times, the liquid yield is decreased as longer hydrocarbons are cracked into shorter, volatile alkanes [4]. The liquid product composition validated the fragmentation of LLDPE to alkanes, via cracking and H-transfer on acid sites, as well as further aromatization to aromatic products. It is noteworthy to mention that, with longer reaction times from 2h to 15h, the alkane yield is decreased from 49% (2h) to 14% (15h) alkanes, whereas aromatics increased from 37% (2h) to 67% (15h). In summary, the acid sites of investigated parent zeolites alone are active enough to convert LLDPE into alkane and aromatic products, which makes zeolite-based supports a promising choice for the hydrogenative cracking of polymers.

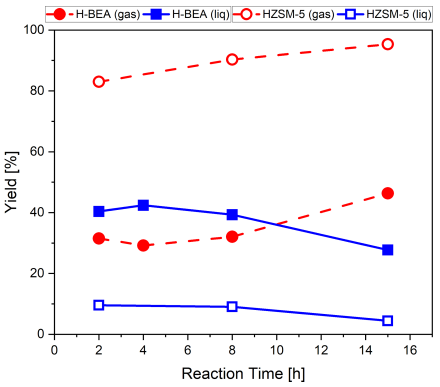

Figure SEQ Figure * ARABIC 1: Gas and liquid yields from LLDPE with parent zeolites at 300 °C, 60 bar $H_2$ and 700 rpm, from 2 – 15h.

**Keywords:** Pyrolysis, chemical recycling, zeolite catalysts, Thermo-chemical processes

**Introduction.** The exponential growth of plastic wastes represents serious threats to both terrestrial and marine ecosystems. The conventional waste treatment methods (mechanical recycling and incineration) are not able to cope with the waste generation rate (especially of impure/contaminated plastics) and ever stricter environmental regulations on $CO_2$ emissions and required recycling rates. Here, chemical recycling is considered as an important alternative to mechanical treatment and incineration of plastic wastes. It allows for the transformation of waste plastics into basic chemical substances which can be used as secondary feedstocks in chemical and petrochemical industries [1]. Chemical recycling via thermo-catalytic pyrolysis is an attractive approach to transform plastic wastes into useful chemicals, and in this regard, zeolites and zeolite-based materials are among the versatile catalytic materials for the thermo-catalytic treatment of plastics [2,3,4]. In our work [4] on chemical recycling of plastics, we presented a systematic study on the thermo-catalytic pyrolysis of polyolefins over MFI (HZSM-5) zeolite catalysts (in one and two-stage processes) to produce aromatics and light olefins. In continuation of this recent study, the present work deals with pyrolysis-catalysis of polyolefins with an aim to produce BTEX rich pyrolysis oil and syngas.

**Experimental.** For the pyrolysis-catalysis of polyolefins, a three-stage experimental setup was employed. In the first stage, pyrolysis vapors were produced by thermal (non-catalytic) treatment of polyolefins. In the second stage, thermo-catalytic conversion of the pyrolysis vapors over MFI (HZSM-5) zeolite catalyst was carried out to obtain pyrolysis oil and gas. After the second stage, the pyrolysis oil produced was separated from the pyrolysis gas. The pyrolysis gas was then mixed with Ar and $CO_2$ and fed to the third stage reactor for catalytic dry reforming over Ni loaded MFI (silicalite-1) zeolite catalyst for syngas production. In the second stage, commercially available HZSM-5 zeolite was used as catalyst, whereas for the third stage Ni/Silicalite-1 catalyst was prepared. All catalyst materials were characterized by XRD, $NH_3$-TPD, $H_2$-TPR, SEM, and $N_2$ physisorption. The influence of catalyst properties, as well as the operating conditions on the product distribution was investigated.

**Results and discussion.** The results obtained from the preliminary tests confirmed that in the second stage, the composition of pyrolysis oil (BTEX content) and gas ($C_1$-$C_4$ alkanes and $C_2$-$C_4$ olefins mainly) can be tuned by varying the reactor temperature as well as the acidity of the HZSM-5 catalyst. Furthermore, in the third stage, 20%Ni/silicalite-1 showed appreciable conversions of pyrolysis gas and $CO_2$ to syngas at 700 °C. A detailed and systematic study on the influence of catalyst properties, reactor temperature at different stages and GHSV (in the third stage) on the product distribution is underway and the results will be presented.

**Introduction:** The large-scale production and consumption of polyolefins such as polypropylene (PP) is leading to the generation of significant amounts of environmentally damaging plastic waste, with the majority being buried as landfill [1]. A promising route to chemically recycle plastic waste is the catalytic hydrogenolysis process to generate high yields of valuable liquid alkanes through selective internal C-C bond cleavage [2]. Given this, we have developed highly active shaped $Ru/CeO_2$ catalysts (nanocube and nanorod) for the hydrogenolysis of various pristine and post-consumer polypropylene to liquid alkanes. Furthermore, the chain length of the produced liquids could be controlled via alteration of the reaction conditions. This control allows for tuning of the liquid reaction product dependent on the intended application.

**Experimental:** Shaped $CeO_2$ (nanocube and nanorods) were synthesised by a hydrothermal method according to literature [3]. Non-shaped $CeO_2$ was purchased from Sigma Aldrich. The catalysts ($Ru/CeO_2$) were prepared using an incipient wetness method using $Ru(NO)(NO_3)_3$ and calcined at 500 °C. Catalysts were denoted: NR – nanorod, NC – nanocube, SA – Sigma-Aldrich. Catalysts were pre-reduced at 300 °C for 2 h prior to testing. Hydrogenolysis reactions were carried out using a Parr reactor with 2 g polymer and 0.1 g catalyst. The reaction was carried out at various temperatures (180-250 °C), metal loadings (0.5-5 wt.% Ru), $H_2$ pressures (10-30 bar), and reaction times (8-60 h). Analysis of gas fraction was conducted using GC-FID and the liquid fraction was analysed by GPC. Catalyst characterisation was performed on fresh catalysts to identify structure-activity relationships and include XRD, BET, CO chemisorption, ICP-OES, TEM, and $H_2$-TPR.

***Table 1**. Catalytic performance of 2Ru/$CeO_2$-(SA/NR/NC) in the hydrogenolysis of isotactic polypropylene-12 kDa.*

| | $Y_{solid}$(%) | $Y_{liquid}$(%) | $Y_{gas}$(%) | Liquid $M_w$ (Da) | PDI |
|---|---|---|---|---|---|
| $Ru/CeO_2$-SA | 47 | 43 | 10 | 5451 | 2.41 |
| $Ru/CeO_2$-NR | 28 | 70 | 10 | 1924 | 2.35 |
| $Ru/CeO_2$-NC | 5 | 68 | 27 | 984 | 1.5 |

**Results and discussion:** The 2 wt.% $Ru/CeO_2$ catalysts were observed to have well-dispersed Ru species by CO chemisorption, TEM and XRD, with the shaped catalysts showing enhanced Ru dispersion (NR = 100% and NC = 72%) when compared to the non-shaped (SA = 23%). $H_2$-TPR also showed different Ru speciation for the shaped catalysts and enhanced H-spillover onto the support. This enhancement of the metal-support interaction and smaller cluster size led to increased activity for the shaped catalysts when compared to the non-shaped. Optimisation of the reaction conditions allowed for control of the product yields and liquid product chain length, as shown in Figure 1 for different reaction times. Table 1 shows the catalytic results for the hydrogenolysis of PP (Mw 12 kDa) under optimised conditions (220 °C, 30 bar $H_2$, 500 RPM, 16 h), with the NC catalyst which exhibited the highest activity with the shortest liquid hydrocarbons (984 Da) with

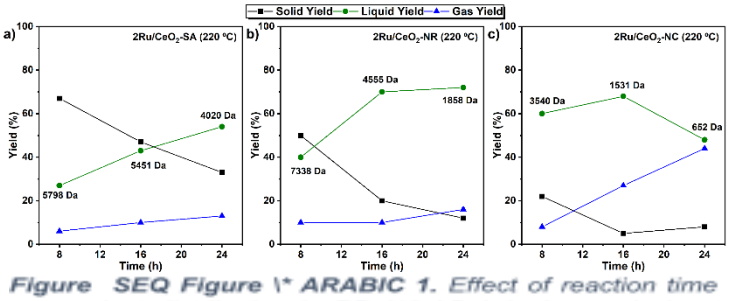

***Figure SEQ Figure * ARABIC 1**. Effect of reaction time on product distribution in PP (12 kDa) hydrogenolysis at 220 °C for 2 wt.% Ru supported a) $CeO_2$-SA b) $CeO_2$-NR, c) $CeO_2$-NC catalysts.*

the smallest polydispersity index (1.5). In addition, post-consumer PP products such as file sheets, fragrance cases, and centrifuge tubes were successfully depolymerised over the shaped catalysts.

**Introduction.** Catalytic wet peroxide oxidation (CWPO) is one efficient technology that uses proper catalysts for the decomposition of $H_2O_2$ into hydroxyl radicals, responsible for oxidizing organic pollutants. In this work, a new method for synthesizing magnetic pillared clays (MPILCs) was developed for further application in the elimination of dyes from aqueous solutions by CWPO. The MPILCs were prepared from natural clays found in large deposits of Kazakhstan (ShNC and UNC, from Shymkent and Ural deposits, respectively) by intercalation of iron and manganese cations in the space between the layers of clay silicates upon hydrolysis with NaOH. The activity of the MPILCs as catalysts for CWPO were tested and evaluated in the decomposition of the dye methylene blue (MB).

**Experimental/methodology.** The MPILCs were synthesized by adapting the procedure presented elsewhere [1]. The co-precipitation of Mn(II) and Fe(III) occurred upon the addition of NaOH solution (5 mol $L^{-1}$) until pH 10 was obtained. The solution was stirred for 30 minutes on a magnetic stirrer and heated to 100°C. Then, the solids were separated from the water, dried in an oven at 105°C for 2 h, and further calcined at 400 °C for 3 h in a muffle furnace, resulting in $MnFe_2O_4$/Shymkent and $MnFe_2O_4$/Ural, depending on the natural clay used as precursor. The CWPO experiments were conducted considering the following conditions: $C_{MB,0}$= 50 mg $L^{-1}$, catalyst dose = 0.5-2.5 g $L^{-1}$, $T$ = 348 K.

**Results and discussion.** The results are shown in Fig. 1. Increasing the dose of MPILCs, the active centers available for catalyst-$H_2O_2$-MB interactions increase, achieving higher MB removal (Fig. 1a, b). Comparing the results, it is observed that the removal of MB in the presence of $MnFe_2O_4$/Shymkent (Fig. 1a) occurs much faster than with $MnFe_2O_4$/Ural (Fig. 1b). Natural clays exhibit low catalytic activity compared to the developed $MnFe_2O_4$/PILC catalysts. The catalysts also show good resistance to the leaching of metal particles into solution, being thus concluded that $MnFe_2O_4$/PILCs demonstrate great potential for further application in treatment of real complex wastewater.

a) b)

# Systematic screening of conventional and hierarchical zeolites for the catalytic conversion of end-of-life tyre pyrolysis vapours to aromatics

S.D. Stefanidis[1], S.A. Karakoulia[1], E. Pachatouridou[1], E. Heracleous[1,2], A.A. Lappas[1,*]

**Keywords:** Tyres, recycling, catalytic pyrolysis, zeolites, aromatics

**Introduction.** Over 1 billion new tyres are sold globally every year, and a roughly equal number of them enter the pool of end-of-life tires (ELTs). The tyre recycling methods used nowadays do not produce materials that can be reused by the tyre industry, while ~50% of the EU's ELTs are not recycled and are instead exported to other countries. This study is part of the EU project BlackCycle, which aims to develop a technology for the recycling of ELTs into raw materials that can be used for the production of new tyres. Via pyrolysis, ELTs can be converted into pyrolysis oil, solid and gas products. Highly aromatic pyrolysis oils can be used as feedstock for the production of virgin carbon black, which is a major component in the manufacturing of tyres. In this work, conventional and hierarchical zeolites with variable silica-to-alumina ratios (SAR) and catalyst-to-feed (C/F) ratios were screened for the catalytic conversion of ELT pyrolysis vapours towards aromatic compounds.

**Experimental/methodology.** The ELT feedstock was provided by Aliapur S.A., and was described as "granules of multi-brand truck tyres 1-3 mm". The conventional zeolites used were Y zeolites with SAR 5 and 30, a ZSM 5 zeolite with SAR 80 and a Beta zeolite with SAR 25, all purchased from Zeolyst. Hierarchical Y and ZSM-5 zeolites were used as well. The hierarchical Y was synthesised by desilication of the commercial Y SAR 30 (Y SAR 30 DS), while the hierarchical ZSM-5 was synthesised by desilication of the commercial ZSM-5 SAR 80 (ZSM-5 SAR 80 DS). The screening was carried out in a bench-scale fixed bed reactor using 2.8 g of ELT and
C/F ratios of 0.25, 0.5 and 1. Both the pyrolysis and the catalytic conversion temperatures were 500 °C.

**Results and discussion.** Upgrading the ELT pyrolysis vapours with any of the zeolites used resulted in a decreased yield of pyrolysis oil in favour of permanent gases and coke formed on the surface of the zeolites. However, this was accompanied by a significant increase in the aromaticity of the pyrolysis oils, as indicated by their increased C/H molar ratio (**Figure 1**). In the case of the Y zeolites, the Y SAR 5 resulted in the most modest increase of the C/H ratio, which indicated that its high density of acid sites was not favourable for the efficient conversion of the ELT vapours. On the other hand, the Y SAR 30 achieved significantly higher C/H ratios when compared to the Y SAR 5. The Beta SAR 25 achieved similar C/H ratios as the Y SAR 30, but with reduced pyrolysis oil yield. The ZSM-5 SAR 80 achieved a more moderate increase in the C/H ratio, accompanied by a moderate decrease in the pyrolysis oil yield. This was attributed to a lower activity of the ZSM-5 SAR 80, which in turn was attributed to the small pores of the ZSM-5 structure. Finally, the hierarchical zeolites Y SAR 30 DS and ZSM-5 SAR 80 DS exhibited higher activity and achieved the highest C/H ratios in the pyrolysis oils, while at the same time, they achieved a more moderate reduction of the pyrolysis oils yield compared to their conventional counterparts.

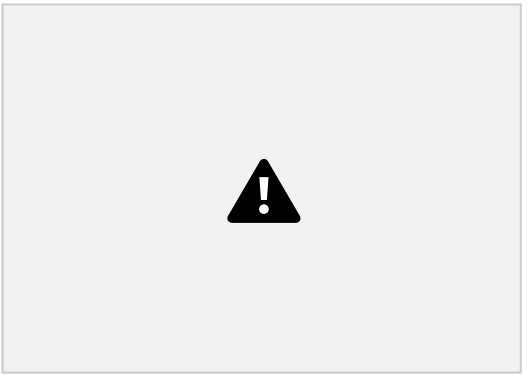

**Figure 1. C/H molar ratio of the pyrolysis oils produced with the different catalysts vs. the pyrolysis oil yield.**

**Keywords:** PAN, catalyst, azo-dye, advanced oxidation process

**Introduction:** Nowadays, accessible clean water and energy resources are among the highest priorities for sustainable economic growth and societal well-being. Water scarcity is an increasing problem globally making it imperative that wastewater is treated and reused in industrial processes, for irrigation and feeding livestock, thus saving potable water for drinking [1]. Emerging contaminants such as azo dyes and their transformation products have adverse impacts on human health and the environment. The textile industry is one of the fastest-growing industries daily. Dyeing wastewater accounts for around a quarter of the total industrial wastewater and has become a serious worldwide environmental issue because of low biodegradability and the high toxicity of their transformation products. Reactive orange 16 (RO16) is a reactive azo dye with a nitrogen-nitrogen (N=N) bond. The main challenge in the decolourization and degradation of azo dyes is the breakdown of azo bonds, leading to the removal of dye from water. Conventional wastewater methods such as adsorption, biological treatment, filtration, chemical treatment, and flocculation are not efficient in degrading the aromatic and heterocyclic structures of the dye molecules. Therefore, extensive efforts have been directed globally toward the development of suitable, efficient, and eco-friendly processes for the removal of persistent pollutants. Advanced oxidation processes (AOPs) have the potential to achieve complete mineralisation of pollutants from water. Currently, most AOPs are employed using hydrogen peroxide ($H_2O_2$), Fenton reactions, catalysts, ultraviolet (UV) light, and a combination of Fenton reactions with UV light (photo-Fenton), and catalysts with UV light (photocatalysts). Up till now, effective catalysts are produced in the form of a powder suspended in a model solution of pollutants but there has been difficulty in sustaining their immobilisation on suitable substrates. Many existing reactors use produced nanoparticles in the form of suspension where the separation and reuse of the catalyst are difficult to achieve with significant catalyst loss, efficiency, and cost-effectiveness of the process [2], [3].

**Experimental/methodology:** The presented study aims to investigate the removal of RO16 dye as a model of recalcitrant pollutants using the photo-Fenton process. The solid phase catalyst [4], a surface functionalised polyacrylonitrile (PAN) fibre comprising iron (III) was tested for a varied number of parameters (wavelength of light, hydrogen peroxide concentration, reusability of the catalyst, and the extent of leaching of the active site of the catalyst). The removal of RO-16 from the water was monitored by measuring the absorbance at 254 nm (removal of aromaticity) and 493 nm (decolourisation) by UV-Vis spectrophotometer.

**Results and discussion:** The obtained results of performed tests show the efficient removal rate of aromaticity of RO16 dye using the photo-Fenton process changing varied number of parameters. The results of reusability (after five consecutive cycles) show no deactivation of the catalyst occurred, which indicates its potential long-life span for its efficient working in the removal of contamination from water which is making it highly suitable for scale-up implementation.

# Direct Conversion of Glycerol into Glycidol in a Gas-Phase Packed-Bed Reactor over Caesium-Treated ZSM-5 Catalysts

Andrii Kostyniuk[1*], David Bajec[1], Blaž Likozar[1]

[1]*National Institute of Chemistry, Ljubljana, Slovenia*
[*]andrii.kostyniuk@ki.si

**Keywords:** HZSM-5, caesium nitrate, glycerol, dehydrative epoxidation, glycidol.

**Introduction.** Glycerol is the main byproduct in the biodiesel industry representing roughly 10% of the mass of the biodiesel produced, which led to a decrease in glycerol commercial price due to its high abundance on the world market. Glycerol valorisation can be carried out in a gas phase over heterogeneous catalysts, where acrolein, acrylic acid, dihydroxyacetone, hydroxyacetone, allyl alcohol, epichlorohydrin, lactic acid, 1,2-propanediol, 1,3-propanediol, ethanol and very recently glycidol are the most promising value-added products of this process [1,2]. Glycidol is an important product for industrial commercialization due to its many applications and its high profitability on the world market. For example: as a monomer and semi-product in the synthesis of surfactants, polyurethanes, polyamides, polycarbonates, polyesters, high-boiling polar solvents, lubricating oils, components for body care products, laundering detergents, disinfectants, etc. Our group has implemented recently [3] the "green" and one-step glycidol production from glycerol without $H_2$ in a gas-phase packed-bed continuous-flow reactor under atmospheric pressure.

**Experimental/methodology.** The synthesis of the caesium zeolite catalysts with $SiO_2/Al_2O_3$ = 30 and 1500 molar ratios was obtained by the wet impregnation method. The influence of Cs species incorporation into ZSM-5 zeolite on the acidity-basicity and its catalytic performance was elucidated. The structural, morphology, acidic, and basic properties of alkali-treated zeolite catalysts were systematically investigated by various analytical techniques such as ICP–MS, XRD, $N_2$ physisorption, STEM–EDX, SEM, pyridine-DRIFT, $CO_2$–TPD, $NH_3$–TPD, and TGA. The reaction was carried out in the laboratory Microactivity-Reference reactor (PID Eng&Tech). Typically, 0.5 g of the catalyst was placed in a packed-bed tubular reactor and stabilized with glass wool on both sides. The 10 wt% aqueous solution of glycerol was injected into the hot box with a 307 HPLC Piston Pump (Gilson Inc.). The carrier gas was $N_2$ (20 ml/min) and its flow was controlled by a mass flow controller. The hot box and reactor were kept at 140 °C and 350 °C, respectively.

**Results and discussion.** In this work, the catalysts evaluation results indicated that the 20wt%Cs/ZSM-5(1500) catalyst was the most effective in the direct glycerol conversion into glycidol via dehydrative epoxidation reaction with the participation of basic sites (Figure 1).

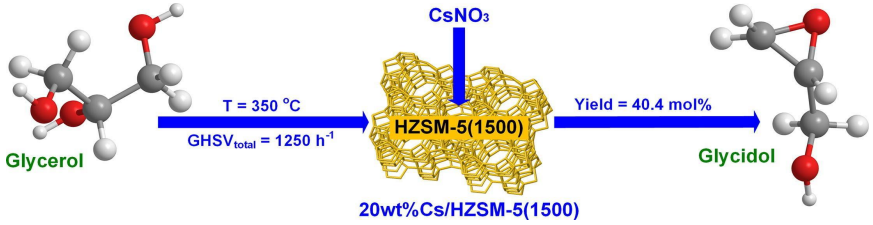

**Figure 1. Catalytic dehydrative epoxidation of glycerol into glycidol.**

This catalyst showed relatively high stability and selectivity, which was attributed to the presence of a suitable amount of basic sites and the strong $CsNO_3$/HZSM-5 support synergetic interaction. It was observed that Si species partly dissolved from the HZSM-5 framework. At the same time, the conversion of glycerol reduced from 86.3 mol% to 27.4 mol% within 3 h time-on-stream. On the other hand, the selectivity increased from 41.4 mol% to 64.3 mol% after 27 h. The highest achieved glycidol yield was 40.4 mol% with 10 wt.% glycerol in the feed at 350 °C reaction temperature and $GHSV_{total}$ = 1250 $h^{-1}$.

**Keywords:** Ceria, Titania, LHLs, water remediation

**Introduction.** The performances of semiconductor photocatalysts, like titania or ceria, can be tuned by appropriately doping with heteroatoms, like noble metals, which significantly decrease the band gap to visible light range. Another strategy to improve semiconductor properties is the ligand-to metal charge transfer with aromatic compounds. [1] The use of naturally occurring aromatic, like lignocellulose recovered from specific biomasses, has recently been investigated for titania [2]. This work deals with the preparation of carbon-activated $CeO_2$ and $TiO_2$ as photocalysts for the removal of water contaminants. As source of aromatic dopants were used ligneo humic like compound (LHLs) obtained by sewage sludge treatments which lead to a double benefits, namely recovery of resources and containment of the final waste to be disposed of, in coherence with "circular economy" principles.

**Experimental/methodology.** Three LHLs were used for the synthesis of $CeO_2$-LHLs and $TiO_2$-LHLs composites: 1) commercial (comm), extracted by primary sludge (PS), and extracted by sewage scum (SS). The oxides were precipitated in presence of the LHLs with a weight ratio of 10 $MeO_2$ to 1 LHLs and 1 $MeO_2$ to 1 LHLs. The obtained materials were treated at 250°C in $N_2$ flow. The samples obtained, along with the corresponding oxides without LHLs, were characterized by BET, XRD, TGA under air flow, XPS, SEM and UV-vis. The degradation of methylene blue by standard procedure ISO 10678 (2010) will be used to evaluate the catalytic activity.

**Results and discussion.** The different LHLs used were able to modify the characteristic of the cerium and titanium oxides both in terms of morphologies and in terms of electronic properties. In Figure 1 the TGA and its derivative of the N2 treated samples are displayed. The profile of decomposition of the different LHLs interacting with $TiO_2$ is function of the nature of the ligneo humic compound used as carrier for titania growth.

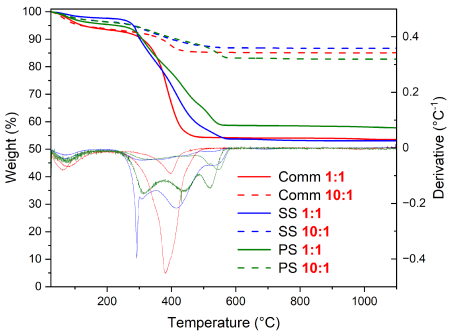

Figure 1. TGA and derivative of $TiO_2$ supported on humic acid: comm, SS and PS with ratio Ti/LHLs =1:1 or 10:1.

**Keywords:** plastic wastes, pyrolysis oil, zeolites, circular economy

**Introduction**

Plastics have an important and growing role in our economy and daily lives, providing many benefits like food and drungs safety. However, their high production rate, short usage time, and poor waste management led to their ever-growing accumulation in nature. The latter along with plastic's non-biodegradable nature has caused serious negative effects on the environment and human health [1]. Considering the above issues, chemical recycling of plastic wastes, like pyrolysis, is one of the main sustainable alternatives to regenerate and reuse plastics, simultaneously contributing to a circular economy for plastics and to disposal waste volume reduction [2].

This study refers to ex-situ catalytic upgrading of mixed plastic wastes pyrolysis oil to a higher quality oil (with gasoline-like properties), suitable to be served as a feed to steam crackers already used in petrochemical industries, for further conversion to plastic monomers. Efforts are directed towards developing a selective and stable catalyst and process options, so as to avoid overcracking to gas products.

**Experimental/methodology**

The experiments of pyrolysis oil upgrading were performed in gas phase and in a fixed-bed reactor, using model compound (eicosane) as feed. The effect of the solvent on eicosane conversion was studied using octane and dodecane as solvents (15 wt% eicosane in octane or dodecane, 400 °C, W/F = 164 $g_{cat} \cdot h\ mol_{C20H42}^{-1}$ ) over a commercial $SiO_2/Al_2O_3$ catalyst (SAR=5.9, BET= 573 $m^2/g$).

**Results and discussion.**

In the presence of octane and dodecane as solvent, eicosane was converted by 52% and 35.5% respectively, mainly forming liquid products. Under the selected reaction conditions 60-70% of the products formed are in the range of C5-C15 with the rest being C1-C4 gases (mostly propylene and iso-butylene). Worthy to note that pure octane and dodecane showed negligible conversion, under the same conditions. Further characterization by TPO, TPD, BET of the used catalysts will be performed to determine coke deposits and adsorbants and to understand the reasons for the observed difference in eicosane's conversion and the loss of activity.

Except of the $SiO_2/A_{l2}O_3$ catalyst, preliminary tests using model compounds mixture as feed will also be conducted over microporous zeolites with tailored acidic characteristics. Moreover, in order to improve the catalytic performance (increase catalyst activity, isomerization and hydrogenation rate), metals like Ni, Cu, Mo are to be doped on the above catalysts. The effluent will be analysed and characterised with several methods (e.g. GC/FID, GC-MS, NMR, GPC). The best preforming catalysts in terms of activity and selectivity are going to be evaluated for the upgranding of the real plastic waste pyrolysis oil, both in batch and continous flow conditions, and they will be thoroughly characterized for coke deposits, halogen and metal poisoning. The preparation of the catalysts and their evaluation in the selective upgrading of plastic pyrolysis oil is in progress.

**Keywords:** In-situ $H_2O_2$ production, Pd-based catalysts, phenol degradation

**Introduction.** Hazardous and harmful organic compounds in industrial wastewater endanger public health and the natural environment.[1] To date, various chemical/biological treatment techniques have been widely developed for removing those contaminants (e.g. phenols). Among them, the hydrogen peroxide ($H_2O_2$)-based Fenton reaction has been considered a potential water treatment approach due to its superior efficiency and technical feasibility, by generating highly active radical and non-radical species (e.g. $HO^{\cdot}$, $O_2^{-\cdot}$, $^1O_2$) via the Fenton pathway for organic pollutants removal. However, using highly concentrated $H_2O_2$ pre-formed through the industrial anthraquinone oxidation (AO) process faces storage and transportation issues and environmental hazards.[2] Therefore, the strategy of in-situ $H_2O_2$ production directly from $H_2$ and $O_2$ avoids the above issues and promotes decentralized local water treatment using the in-situ Fenton pathway.

**Experimental/methodology.** A series of mono- and bi-metallic 1wt.% Pd-Fe/$TiO_2$ catalysts were prepared using an excess-chloride co-impregnation procedure.[3] Catalytic activity was conducted using a Parr Instruments stainless steel autoclave to evaluate the performance towards in-situ $H_2O_2$ synthesis and Phenol degradation.

**Results and discussion.** Enhanced catalytic activities toward phenol conversion were observed over bi-metallic 1wt.%Pd-Fe/$TiO_2$ catalysts, with the highest rate of phenol conversion (46%) achieved over a 2 h reaction using the optimal 0.25wt.% Pd–0.75wt.% Fe/$TiO_2$ formulation, almost four times more active than the Pd-only analogue. XPS analysis revealed that the introduction of Fe caused a clear shift in Pd speciation, towards $Pd^{2+}$, and simultaneously increased the amount of $Fe^{2+}$ species in 1wt.%Pd-Fe/$TiO_2$ catalysts, which are responsible for generating reactive oxygen species (e.g. $^{\cdot}OH$) by activating $H_2O_2$ via Fenton pathway.

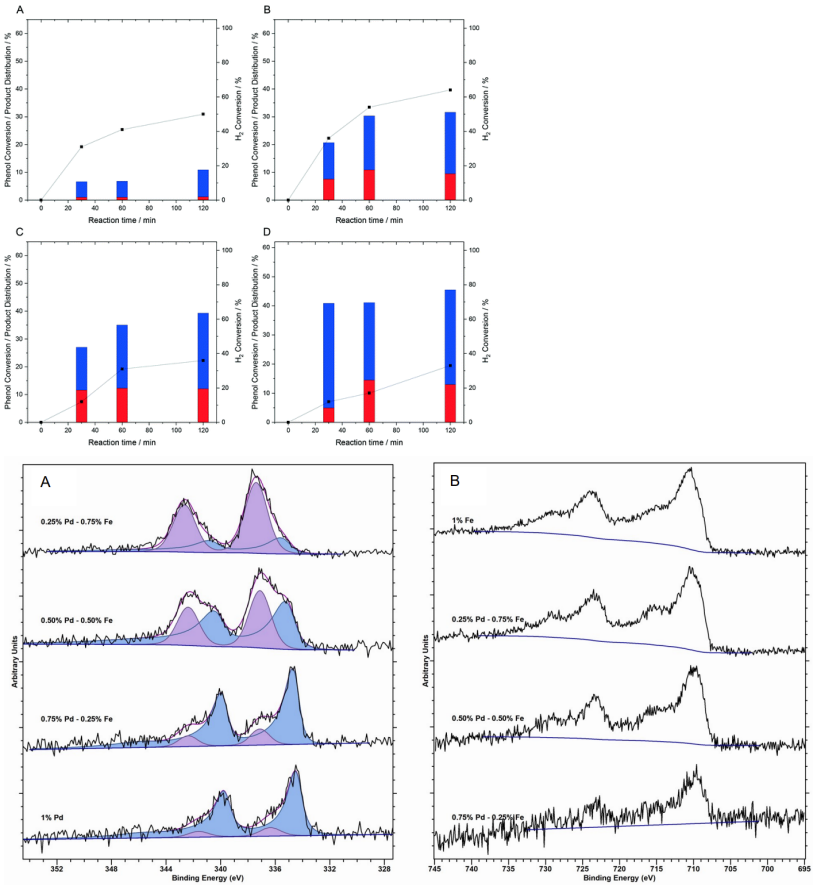

**Figure 1.** (Left) The catalytic activity of 1wt.% Pd-Fe/$TiO_2$ catalysts towards the oxidative degradation of phenol, via in situ $H_2O_2$ production. (A) 1wt.% Pd/$TiO_2$, (B) 0.75wt.% Pd–0.25wt.% Fe/$TiO_2$, (C) 0.5wt.% Pd–0.5wt.% Fe/$TiO_2$, and (D) 0.25wt.% Pd-0.75wt.% Fe/$TiO_2$. **Keywords:** Non-thermal-plasma, PFAS, Perfluorooctanoic acid, Hydroxyl radicals

## Introduction

Fluoroalkyl compounds are used in a range of industries, household products and fire-fighting equipment. Due to their resistance to decomposition they are often known as forever chemicals [1]. Conventional water treatment plants fail to degrade them leading to eventual accumulation in the environment. The use of non-thermal plasma (NTP) is emerging as an effective Advanced Oxidation Process for their degradation in aqueous media.

## Experimental

The NTP discharge apparatus consists of a copper cathode and stainless steel anode (Fig. 1). A vial containing 1 ppm aqueous PFOA with a dispersed alumina catalyst ($Al_2O_3$) was placed on a grounded anode. The cathode was placed perpendicular at a distance of 5 mm from the water surface. PFOA degradation was determined by negative ion ESI quadrupole time-of-flight MS (Agilent 6546 LC/Q-TOF).

## Results and discussion

Figure 2 shows the degradation of PFOA (a model per-fluoro alkyl compoud) obtained after 20 min of plasma treatment in the absence (25%) and presence of catalyst (complete degradation). The degradtion products obtained in the process are also presented in figure 2. High energy electrons generated during plasma discharge interact with water and produce a mixture of reactive species ($e^-$, $HO^\bullet$, $H^\bullet$, $O_2^{\bullet-}$, $H_2O_2$ $O_3$, $H_3O^+$ $H^+$ $O^+$ $O^-$) and UV radiation [2,3].

The effect of the presence of a solid phase catalyst is clear and the higher degradation efficiency of PFOA in the presence of catalyst could be ascribed to several effects. Photocatalysis is unlikely given the bandgap of $Al_2O_3$ but electron impact upon the surface generating electron-hole pairs which may generate $^\bullet OH$ and $O_2^{\bullet-}$ radicals increases the level of PFOA degradation [2,4].

In addition, the catalyst may create plasma microdischarges inside its pores increasing the production of reactive species [2]. No change of the physico-chemical properties of the catalyst has been observed after plasma treatement (specifically using UV Vis and XPS analysis).

**Keywords:** PET nonwoven , $TiO_2$, Photocatalysis, dip coating

**Introduction.**

In recent years, as water pollution caused by industrial development has become serious, the importance of water filters has increased. Among them, titanium dioxide ($TiO_2$), a representative photocatalytic material, has shown excellent performance in removing pollutants due to its strong oxidation power through light irradiation [1]. It is applied to remove pollutants by coating on a support, especially in water treatment devices, but has the disadvantage of limited surface area. Powder type photocatalysts are also used, but they have the disadvantage of requiring a separation and collection process as well as economic disadvantage.

Polyethylene terephthalate (PET) nonwovens with network structure are used as filters due to their low cost and high mechanical strength [2]. In this study, needle-punched PET nonwovens were coated with $TiO_2$ to maximize their surface area, thereby maximizing their photocatalytic properties.

**Experimental/methodology.**

The coating of $TiO_2$ was carried out by dip coating method. The dip coating method uses taitanium (III) chloride ($TiCl_3$) as a precursor and has been reported to form $TiO_2$ at low temperatures [3]. Therefore, PET nonwovens were immersed in a $TiCl_3$ aqueous solution and reacted at a low temperature for 24 h to form $TiO_2$. The unreacted material was then washed and dried to obtain coated nonwovens.

**Results and discussion.**

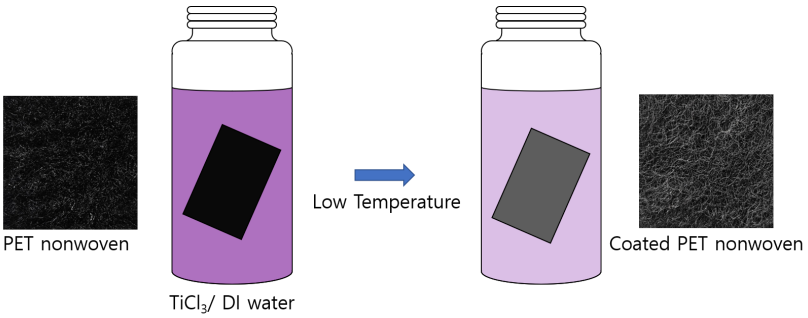

**Figure. 1.** Scheme of $TiO_2$ dip coating process on PET nonwoven

After coating, the nonwoven fabric was coated with white-colored $TiO_2$. The coated nonwoven fabric was then weighed to calculate the weight gain before and after. FT-IR analysis showed that the peak of $TiO_2$ appeared throughout, confirming that $TiO_2$ was coated. To confirm the photocatalytic properties of the coated PET, an organic matter degradation experiment was conducted. UV-VIS analysis was performed to confirm the degradation of organic matter.

In this study, $TiO_2$ coating of PET nonwoven fabric was performed by dip coating method. $TiO_2$ coating was confirmed. As a result, it can be expected to be applied to a simple and effective water treatment PET filter through photocatalytic reaction.

**Keywords:** Micro/nano plastics, Upcycling, recycling, thermochemical conversion, pyrolysis, gasification.

**Introduction.** Plastics are produced primarily from fossil fuels; the transition to a carbon-neutral economy will necessitate significant life cycle changes for plastics. Micro/nano plastics are generated when synthetic textile fibers are washed, endangering the environment. Pyrolysis is an emerging approach for waste valorisation, aimed at producing carbon materials and hydrogen [1]. Herein we demonstrate the use of a catalytic-packed bed reactor to co-produce solid carbon nanomaterials alongside hydrogen from both synthetic and natural textile derived micro/nano fibres.

**Experimental/methodology.** Bimetallic Ni-Fe catalyst with a molar ratio of 1:3 (10% metal loading) supported on γ-$Al_2O_3$ was prepared by a wet impregnation synthesis method. Catalytic-pyrolysis of cotton and PET was carried out in a one-stage, fixed bed reactor. Interlock fabrics without finishing were provided by Cotton Incorporated. Prior to the reaction, the fibres were reduced to microfibres. The quartz reactor was loaded with a pre-mix of 30 mg of textile microfibre and 15 mg of the catalyst. Pyrolysis was carried out in Ar (99.99% purity, 110 ml/min) at 500 °C, at a heating rate of 10 °C/min and held at 500 °C for 30 min.

**Results and discussion**. $H_2$ was produced when Ni-Fe catalysts were used to pyrolyze PET and Cotton textile microfibers, with the maximum production value attained at 500°C for both samples (Figure 1). The production of $H_2$ occurs at a higher temperature than the production of hydrocarbon products, which may be the result of catalyst reduction and subsequent hydrocarbon gas-phase cracking. The FT-IR spectrum demonstrates that thermal treatment altered the chemical functionalities and, consequently, the chemical composition of both samples. In addition, the TGA data show a distinct reduction of C-O-R chemical functionalities, which could be due to the decomposition of ethers, lactones, phenols, etc [1].

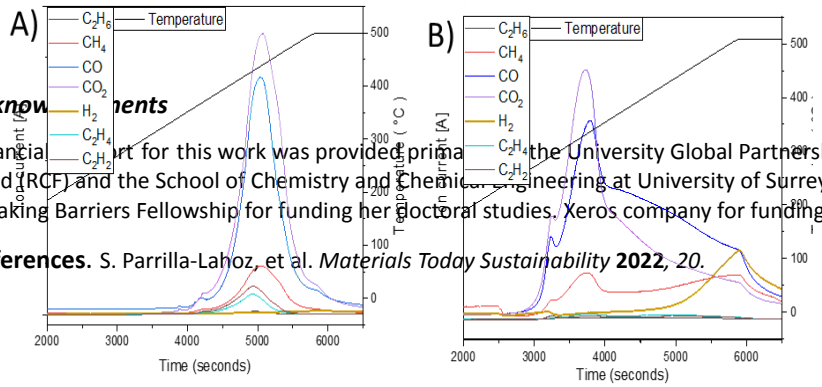

**Figure 1. Gas releasing behaviors during catalytic pyrolysis process of A) Polyester microfibers and B) Cotton microfibers.**

# Catalytic hydrogenation of water pollutants by platinum metal catalysts

A. Plá-Hernández[1*], A.E. Palomares Gimeno[1], F. Rey[1]

[1]*Instituto de Tecnología Química, Universidad Politécnica de Valencia - Consejo Superior Investigaciones Científicas, Avenida de los Naranjos s/n, 46022, Valencia, España)*
[*]Corresponding author: *adplher@itq.upv.es*

**Introduction.** Water is a fundamental resource and is necessary to guarantee its quality, mainly when it is used for human consumption [1]. Most disinfection treatments are based on the use of chlorine compounds such as chlorine dioxide. However, this process can produce by-products such as chlorite, chlorate and bromate [2] that have negative effects on health. For these reasons, the World Health Organization set a limit for these pollutants in drinking water. An interesting alternative for the removal of these water pollutants from water is the catalytic reduction with hydrogen. In this reaction $ClO_3^-$ and $BrO_3^-$ are reduced to innocuous products such as $Cl^-$ and $Br^-$.

**Experimental/methodology.** Catalysts were prepared by incorporating platinum to different metal oxides using different processes. After the addition of the Pt-precursor, the material was calcined at 350ºC and activated with hydrogen at 200ºC. The experiments were performed in a batch stirred tank reactor at room temperature and atmospheric pressure, using hydrogen as reducing agent. The typical experiments were made with 1 g of catalyst and 0,6 L of polluted water with 50 ppm of chlorate/bromate. The analysis of the reactants and products was made by ionic chromatography. The catalysts were characterized with different techniques such as inductively coupled plasma (ICP), X-ray diffraction (XRD), hydrogen chemisorption, temperature programmed reduction (TPR), $N_2$ adsorption and scanning electron microscopy (SEM).

**Results and discussion.** The catalytic study was carried out using platinum supported on different materials and prepared by different procedures. The results obtained with the catalysts supported on $Al_2O_3$ showed an important influence of the metal precursor calcination temperature on the catalytic activity, obtaining the best results with the catalysts calcined at 350ºC, decreasing the activity when the catalyst was calcined at higher temperatures. These results have been related with a higher platinum dispersion at lower calcination temperature, as it was observed by characterizing the catalysts with $H_2$ chemisorption and electron microscopy. The influence of the support on the catalytic activity was studied with platinum catalysts supported on $Al_2O_3$, $TiO_2$ and zeolites. The use of zeolites as catalytic support showed that the topology, the Si/Al ratio and the amount of sodium are the main factors influencing the catalytic activity. The best results are obtained with the Pt catalysts supported on zeolites that contain a higher number of acid centres, with accessible structures and with low sodium content. These characteristics improve the dispersion of platinum and enhance the interaction of the reactants with the active sites. In this way, the best results were obtained with the catalyst supported on FAU with a Si/Al ratio of 6. On the other hand, the use of $TiO_2$ as a support was also studied in presence and in absence of light. In presence of light, an improved catalytic activity was observed, decreasing it in darkness. These results indicate the presence of a photocatalytic reduction of chlorates that increases the catalyst activity, obtaining in these conditions and with this support the best activity. Finally, the influence of the reaction media temperature on the catalyst activity was studied obtaining better results when decreasing the water temperature, due to the higher solubility of hydrogen in water. These results show that it is possible to remove water pollutants such as chlorate by catalytic reduction using Pt catalysts, but is necessary to tune the characteristics of the support that enhance the platinum dispersion and improve the catalytic processes.

# Microwave-hydrothermal assisted synthesis of $ZnFe_2O_4$/RGO nanocomposites for the removal of organic pollutants from wastewater

Kun-Yauh Shih[1*], En-Rui Wang[1]

[1]*Department of Applied Chemistry, National Pingtung University, Pintung, Taiwan*
[*]*sky@mail.nptu.edu.tw*

**Keywords:** nanosorbent, $ZnFe_2O_4$/RGO, nanocomposites

**Introduction.** Nearly 200 years of industrial development have led to environmental pollution. Dyes from pharmaceutical and other industries are major organic pollutants. Organic dyes are not easily decomposed in the natural environment due to their stable and complex chemical structure. Dye molecules may block sunlight from entering the water and reduce the level of dissolved oxygen in the water system. Therefore, the removal of organic dye molecules from industrial and municipal wastewater has become a very important issue. The high specific surface area and the special chemical structure of $ZnFe_2O_4$/RGO nanomaterials allow them to optimize water quality by adsorbing large amounts of organic pollutants in water through electrostatic attraction and π-π interaction with the aromatic region of dye molecules. The main purpose of this study was to prepare $ZnFe_2O_4$/RGO magnetic nanoparticles by microwave hydrothermal method using a combination of low-toxicity zinc ferrite and reduced graphene oxide. The dye adsorption mechanism of this nanosorbent was investigated by using $ZnFe_2O_4$/RGO to adsorb hazardous MB dyes.

**Experimental/methodology.** GO was prepared using $H_2SO_4$ and $KMnO_4$ as oxidizing agents and synthesized from natural graphite powder by a modified Hummers method. To synthesize the ZFG nanosorbent, 50 mg GO was dispersed in 30 mL of deionized water at room temperature. After adding 0.42 mmol $Fe(NO_3)_3$ and 0.21 mmol $Zn(NO_3)_2$, the solution was sonicated for 30 min and the pH of the solution was adjusted to 12 with 2 M NaOH. After sonication for 15 min, the solution was transferred to a Teflon-lined container and the samples were heated using the microwave. The heating temperature was controlled at 140, 160, 180, and 200 °C to synthesize the various materials of $ZnFe_2O_4$/RGO. Finally, the $ZnFe_2O_4$/RGO is filtered and dried in an oven at 75 °C for 12 hours.

**Results and discussion.** Raman spectra show that spinel-type ZF and ZFG exhibit similar features in the low-frequency region (100-1000 cm -1) corresponding to the $A_{1g}$ symmetric and $F_{2g}$ asymmetric modes of spinel-type $ZnFe_2O_4$. GO, RGO and $ZnFe_2O_4$/RGO have two obvious peaks near 1341 and 1589 $cm^{-1}$ that belong to the D-band and G-band of the Raman spectrum of graphene, respectively. The intensity ratio of D band to G band ($I_D$ /$I_G$) of RGO and all $ZnFe_2O_4$/RGO is higher than the GO. This means that RGO and $ZnFe_2O_4$/RGO have more surface defects. For the RGO and $ZnFe_2O_4$/RGO FT-IR spectra, the absorption band at 1550 cm -1 is the C=C skeleton stretching vibration of the graphene structure. The absorption bands at 850 to 956cm-1 are overlapping regions of epoxide, hydroxyl, C=O contribution, and carboxyl group. TEM showed that $ZnFe_2O_4$ nanoparticles had the smallest particle size and narrow distribution width at 180℃, which is consistent with the results that shorter nucleation and crystallization times can produce small particle size and high dispersion.

The adsorption capacity and dye removal efficiency of $ZnFe_2O_4$, RGO, and various $ZnFe_2O_4$/RGO nanomaterials on MB solutions was investigated. The results showed that the adsorption capacity and removal efficiency of dyes increased rapidly with time in the first 3 min. and decreased significantly after 3 min. In addition, the theoretical maximum adsorption capacity of ZFG-18 calculated using the Langmuir model was 212.77 mg $g^{-1}$ higher than that of $ZnFe_2O_4$, RGO, and other $ZnFe_2O_4$/RGO. Two main mechanisms of the MB adsorption process were observed by FT-IR, Raman spectroscopy, and adsorption measurements at different pH values. The first mechanism is the electrostatic interaction between the MB dye = N + H group and the residual oxygen functional groups of RGO. The second mechanism is the π-π interaction between the RGO carbon skeleton and the dye molecules. VSM measurement and recovery tests show that $ZnFe_2O_4$/RGO can be separated with magnets and has a long recovery life. Therefore, $ZnFe_2O_4$/RGO has potential application in wastewater treatment.

# Catalytic pyrolysis of single-use plastic waste over hierarchical zeolite to obtain fuel grade hydrocarbons

Subhashini[1], Tarak Mondal[1,*]

[1,*] Department of Chemical Engineering, Indian Institute of Technology, Ropar, India.

[*]*E-mail: tarakmondal@iitrpr.ac.in*

**Keywords:** Single-use plastic, herarchical ZSM-5, catalytic pyrolysis, fixed-bed reactor

**Introduction.** Municipal solid waste management has been one of the most pivotal factors that affect the environmental health terribly. Plastic waste contributes around 13% of total municipal solid waste. Plastic waste management has gained global awareness and thus recycling such massive quantities is targeted. Catalytic pyrolysis has been the most suitable approach to convert the waste plastic into a source of energy and chemicals. The use of catalyst also helps to lower the energy requirement of the process as well as the residence time. Zeolite catalysts are used for their key features i.e., thermal stability, acid strength, pore size and pore distribution. Zeolites with mesopores and micropores are also favourable because primary cracking of polymer molecules of plastics occurs in mesoporous surfaces and then further cracking over microporous surfaces leads to small chain hydrocarbons.

**Experimental/methodology.** The hierarchical zeolite catalyst was synthesized by hydrothermal method to carry out the catalytic pyrolysis reaction of the waste plastic polymers and obtain smaller fractions of the hydrocarbons in the range of fuel grade hydrocarbons. The catalytic pyrolysis reaction of the waste plastic polymers was carried out in a fixed bed reactor made of stainless steel under inert environment in an ex-situ manner with catalyst to waste ratio as 1:10.

**Results and discussion.** With the use of synthesized hierarchical zeolite the pyrolysis temperature for various waste plastic reduced to the range of 400-450℃ as compared with the thermal degradation, and produced desired fuel range liquid oil. The synthesized hierarchical zeolite catalyst has also shown comparable selectivity towards the production of C9 - C20 range hydrocarbons. The obtained liquid oil components were determined by using GC-MS and the major components were alkanes, alkenes, aromatics, ketones and a few aldehydes. Presence of these functional groups was confirmed by the FTIR and proton NMR analysis of the liquid oil.

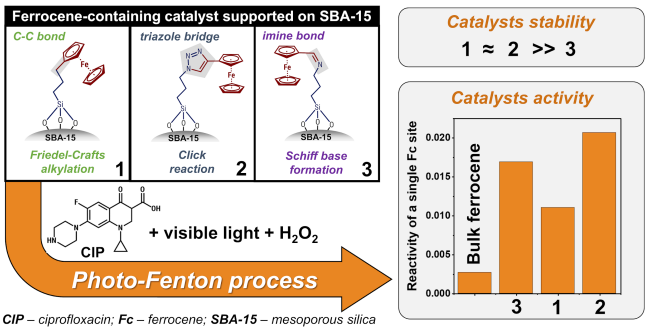
# The influence of ferrocene anchoring method on the reactivity and stability of SBA-15-based catalysts in degradation of ciprofloxacin via photo-Fenton process

A. Walkowiak*, L. Wolski, M. Ziolek



*Adam Mickiewicz University, Poznań, Faculty of Chemistry,*
*Department of Heterogeneous Catalysis, ul. Uniwersytetu Poznańskiego 8, 61-614 Poznań, Poland*
**adrian.walkowiak@amu.edu.pl*

**Keywords:** Advanced oxidation processes; photo-assisted degradation of antibiotics; $H_2O_2$; ferrocene.

**Introduction.** Ferrocene (Fc) is a stable organometallic iron compound which can activate $H_2O_2$ toward the formation of reactive oxygen species (ROS; e.g. hydroxyl radicals) through the so-called Fenton reaction [1]. An important feature of Fc is its strong light absorption in the UV-Vis range. It makes this compound an attractive candidate for visible-light-driven photo-Fenton processes which have been frequently reported as much more efficient than typical Fenton reactions [2]. Photo-Fenton reaction is an example of Advanced Oxidation Processes which are a group of methods highly efficient in the removal of organic pollutants, such as antibiotics, whose steadily growing production and consumption entails severe environmental and medical issues [1]. In this study, different ferrocene-containing materials were prepared via post-synthetic modification of mesoporous SBA-15 silica. As-prepared composites were addressed to the catalytic degradation of ciprofloxacin (CIP), a model antibiotic pollutant, in the presence of $H_2O_2$ and/or visible light.

**Experimental/methodology.** First, SBA-15 silica was functionalized using selected organosilanes and then Fc (or its derivative) was anchored using three various procedures, namely: i) Schiff base formation, ii) Friedel-Crafts alkylation, and iii) click reaction (azide-alkyne cycloaddition) (see Fig. 1). The prepared materials were thoroughly characterized with the use of XRD, $N_2$ physisorption, FTIR, DR-UV-Vis and XPS. The reactivity and stability of the as-prepared hybrid organic-inorganic materials in CIP degradation via photocatalytic, Fenton and photo-assisted Fenton processes were examined, and the degradation efficiency was evaluated spectrophotometrically.

**Results and discussion.** Results obtained in this study showed that Fc anchoring method had a significant impact on the efficiency of Fc anchoring as well as the reactivity and stability of SBA-15-based catalysts. As concerns the reactivity of a single Fc active site in the photo-Fenton process, the most reactive were Fc species from the catalyst prepared by click reaction (formation of triazole ring). Moreover, it was found that the catalysts prepared by the click reaction and Friedel-Crafts alkylation were much more stable in three subsequent reaction cycles than the catalysts prepared via Schiff base formation. Based on the above, it was established that the most promising method for the preparation of SBA-15-based catalysts for the degradation of CIP via the photo-Fenton process is the click reaction. Fc species anchored via this method on the siliceous support are not only the most reactive but also exhibit the highest long-term stability under the working conditions applied in this work. More details will be delivered during the presentation.

**Keywords:** sustainable chemistry, green catalysis, waste valorization, humins, polyoxometalates, biomass, synthesis and characterization

**Introduction**

Sustainability is one of the most important aspects of modern chemical research, as our dependence on finite fossil raw materials is not feasible in the long term. Therefore, alternative and easily available raw materials must be found to replace fossil raw materials as fuels or bulk chemicals. A sustainable and cheap option for this is biomass. However, the conversion of biomass into platform chemicals, such as the conversion of cellulose to levulinic acid, often produces unwanted by-products, like humins. Humins are black, polymeric solids that are insoluble in common solvents.[1] They are often formed from sugar based biomass under acidic conditions and high temperatures. These solids pose a problem, as their formation is unavoidable, they are a waste of raw materials, and by clogging reactors and catalysts they cause damage to chemical plants and safety issues. [2]

In our research, we have investigated the valorization of humins by catalytic conversion into low molecular weight carboxylic acids like formic acid (Figure 1). This will make the conversion of biomass into platform chemicals more efficient and prevents formation of undesired by-products.

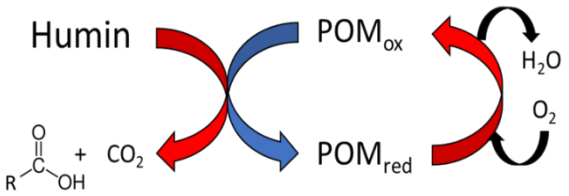

**Figure 1: Simplified catalytic cycle for the conversion of humins using polyoxometalate (POM) catalysts.**

**Experimental**

All reactions were carried out in a 10-fold oxidation system with ten 20 mL hastelloy reactors capable of pressures up to 80 bar and temperatures up to 200 °C. A variety of different humins were prepared from different sugars to simultaneously study the effect of different reaction conditions on humin formation and subsequent conversion. Polyoxometalates, which were synthesized in our research group, were used as catalysts for the oxidative conversion of the humins. Liquid phase analysis was carried out using NMR spectroscopy and GC-MS.Moreover, gas phase analysis was done via offline GC.

**Results and discussion**

In our experiments we have sucessfully converted up to 50 % of the humic mass. The main products were formic acid, acetic acid and carbon dioxide. The highest conversions were shown by humins that were synthesized in acetic acid, which is an ideal solvent for most of the industrial processes that produce humins as a by-product.

**Keywords:** Faujasite, Zeolite, Diffusion, Cracking, Plastics

**Introduction.** Zeolite Y is a commonly utilized molecular sieve in various catalytic processes, such as fluid catalytic cracking (FCC) [1], hydrocracking, biomass upgrading [2], and, more recently, the depolymerization of plastics into aromatics [3]. Understanding ion exchange, diffusion, and dealumination processes is critical for gaining insights into activity and stability of zeolite Y during different catalytic reactions. While fluorescent probes have been developed to examine intracrystalline diffusion in other zeolites, such as ZSM-5 and β [4], this has not yet been done for zeolite Y. For such studies, large zeolite crystals are required, but the preparation of large crystals of zeolite Y using traditional methods can be costly [5] and, in some cases, involve the use of non-benign structure directing agents (SDAs) [6].

**Experimental/methodology.** In this study, we first synthesized large zeolite Y crystals with sizes of ~ 50 µm using simple and readily available precursors and replaced the reported SDAs with a more environmentally friendly and more economical one (i.e., choline chloride) as it is used in e.g., animal feed. We performed ion exchange using ammonium nitrate (AN) and ammonium oxalate (AO). After calcination, the AN treated sample was dealuminated by steaming and acid leaching. We then studied not only the morphology and structure of the crystals, but also intracrystalline diffusion inside the bipyramidal zeolite crystals using various fluorescent probes. Finally, we followed the cracking of plastic (i.e., polypropylene, $M_W$ = 6,000 g/mol) over the crystals using in-situ confocal fluorescence microscopy (CFM).

**Results and discussion.** Using different characterization techniques, we can conclude that dealumination by steaming/acid leaching is structure related (as evidenced by triangular features in both SEM and CFM images of the coked crystals-Fig. 1a-c), while dealumination which occurred simultaneously during the ammonium exchange by AO is defect-related and forms macro-meso pores inside the crystals (Fig. 1d-f).

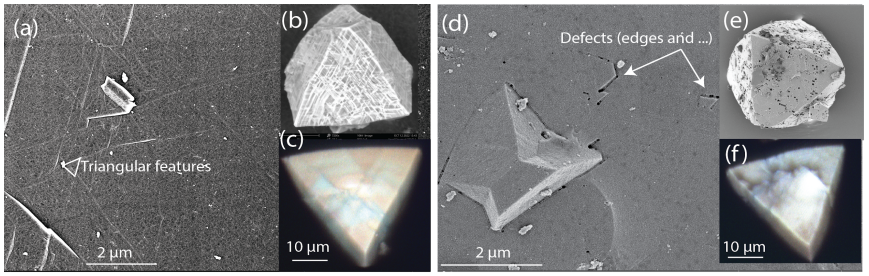

Fig. 1 (a, b) SEM and (c) CFM images of steamed HY zeolite crystals-presence of structure related features, (d, e) SEM and (f) CFM images of AO treated crystals-presence of isotropic pores near defect. CFM images of fluorescence coke species are obtained using 405 nm laser excitation on coked crystals after plastic cracking at 250 °C for 20 min.

# The detoxification and revalorisation of plastic-waste extracted phthalate plasticizers into safe alternatives

Simon Windels[1], Wouter Stuyck[1] and Dirk E. De Vos[1]

[1]*Centre for Membrane Separations, Adsorption, Catalysis and Spectroscopy, KU Leuven, Leuven, Belgium*

**Keywords:** Waste valorization, Legacy additives, Plasticizers, Detoxification

**Introduction.** In light of emerging PVC recycling techniques, large amounts of endocrine disruptive phthalates are expected to become available in the near future as hazardous waste streams. These legacy additives have been dominating the global plasticizer market, however they are gradually being replaced by safer alternatives. [1] In light of this transition, we recently developed a process in which real post-consumer waste-extracted phthalate plasticizers were hydrogenated into safe cyclohexanedicarboxylate plasticizers, such as DINCH. [2] However, based on the intrinsic value of aromatics, the loss of this functionality can be considered adverse, leading us to prioritize its preservation in this work. More specifically, benzoic acid was selectively obtained from the one-pot hydrolysis-decarboxylation of
end-of-life phthalate plasticizers, carefully avoiding the overdecarboxylation to benzene. In support of a

circular plastic economy, this drop-in chemical could be simply purified and employed in the production of industrially relevant benzoate plasticizers, such as diethylene glycol dibenzoate.

**Experimental/methodology.** All reactions were performed in a 50 mL high-pressure Parr® reactor vessel at elevated temperature (100 °C – 250 °C) under an inert atmosphere ($N_2$). The experiments were stopped by fast cooling of the reactor in an ice-in-water bath. The reaction samples were analyzed by
High-performance liquid chromatography (HPLC) and Proton nuclear magnetic resonance ($^1$H-NMR).

**Results and discussion.** The decarboxylation of phthalic acid in water was investigated in an initial series of experiments, which revealed that noble metals catalyze both the decarboxylation to benzoic acid as the subsequent conversion to benzene under similar reaction conditions. Despite vastly different adsorption characteristics for aromatics, the maximum obtained yield of benzoic acid seemed to be independent of the noble metal. In contrast,
Cu-catalyzed decarboxylations showed a completely deviating reaction profile as the conversion rate of phthalic acid was not only remarkably higher but the consecutive decarboxylation did not proceed, yielding

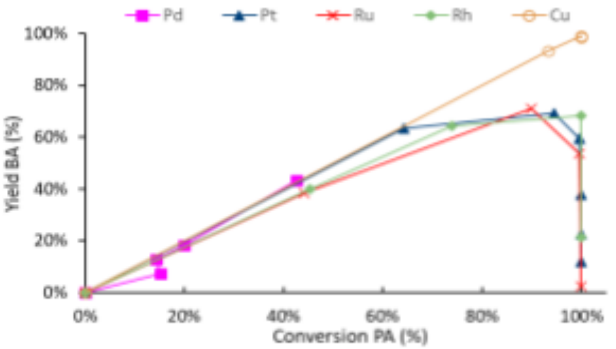

Fig: Metal-catalyzed decarboxylation of phthalic acid

> 99% benzoic acid. In light of the green chemistry principles, telescoping of this decarboxylation reaction with a preceding hydrolysis of (plastic waste-extracted) phthalate plasticizers was pursued. To that end, the effect of the hydrolysis catalyst (acid or base), residual PVC (and impurities) and the alcohol side-chains on the decarboxylation was evaluated. To illustrate our proposed revaluation strategy, an industrially relevant benzoate plasticizer was synthesized in high yields from such waste-extracted phthalate esters, in which no excessive purification of the intermediates was required.

**Keywords:** scaling relationships, volcano plots, inverse design, $CO_2$ reduction, pincer complexes, frustrated Lewis pairs

**Introduction.**

Developing and implementing tools for rapid estimation of catalyst performance can significantly expand the search space and accelerate the discovery process. To this end, we present a computational framework aimed at accelerating the exploration/optimization of catalyst landscapes by combining concepts from physical-organic chemistry, statistical techniques, and genetic optimization algorithms.

**Methodology.**

Our approach typically relies on establishing linear and nonlinear scaling relationships for mapping the chemistry/geometry of the active site of catalysts to their performance through intuitive electronic/structural descriptor variables. The resulting volcano plots/activity maps[1] then guide us to recognize "sweet spots" in the respective descriptor spaces that fulfill the criteria for maximum activity/selectivity. Leveraging this information, we perform straightforward “direct” screening of large libraries of catalysts to identify the ones with desired properties. Additionally, the maps are also utilized in a genetic algorithm-based catalyst optimization pipeline enabling the “inverse” design of candidates.

**Results and discussion.**

We demonstrate the efficacy of the toolkit in identifying catalysts with improved activity/selectivity for industrially important chemical processes involving $CO_2$ reduction. We focus on two case studies.

In the first one, we aim to predict the selectivity of first-row transition metal pincer catalysts for stepwise hydrosilylation of $CO_2$ to formic acid, formaldehyde, or methanol level.[2] Here, the hydride affinity of the catalysts is used as a descriptor to capture the selectivity trends in a composite volcano picture allowing the identification of metal/ligand combinations for accessing a particular product level. These predicted trends were validated experimentally.

The second case study focuses on the challenging discovery of frustrated Lewis pairs (FLPs) for the direct catalytic hydrogenation of $CO_2$.[3,4] Here, we map the chemical and geometrical compositions of FLPs to their activity using the Lewis strength of the components and their relative spatial arrangements. The predicted FLP combinations from the maps are experimentally validated to achieve the first reports of catalytic turnovers in this reaction.[3] Utilizing the chemistry and the geometry-based tools together, we not only perform a direct screening of curated databases of FLPs but also implement a genetic optimization pipeline for identifying promising candidates with desired catalytic properties. Finally, analysis of these leading candidates enables the formulation of pragmatic and experimentally relevant design principles for further exploration of FLP-based catalysis.

**Keywords:** Machine Learning, reaction rate, rare events, reactive trajectories

**Introduction.** Determining reaction paths and rates are one of the key points required to accurately characterize catalytic reactions. As there are generally many elementary steps and intermediates during such transformations, it is difficult to determine reliable reaction constants from theoretical simulations based on harmonic transition state theory. Methods have been devised to overcome this limitation. In our work, we explore a rare events simulation method called Adaptive Multilevel Splitting (AMS)[1], combined with ab initio molecular dynamics to sample reactive trajectories. Thanks to the Hill relation[2], we propose a way to theoretically compute unbiased reaction times and paths.

**Experimental/methodology.** The Hill relation requires to estimate the probability of reaching the product state before coming back to the reactant. To estimate the probability of such a rare event, it is split in the succession of multiple more likely sub-event (see Figure 1.a inset). The AMS algorithm was implemented in combination with a periodic plane-wave DFT (VASP) software. The progress of the transition is quantified using a one-dimensional Reaction Coordinate (RC) to place the splitting levels (see Figure 1.a). The RC along with the definitions of reactant and product states are built using supervised machine learning tools and unbiased molecular dynamics.

**Results and discussion.** The proposed method is applied on the case study of the conformations and dissociations of water on the (100) γ-alumina surface. Reaction rate constants are compared to those obtained via harmonic transition state theory (hTST). The reactive trajectories are classified using clustering methods allowing to differentiate reaction mechanisms. The sampled reactive trajectories are analyzed to identify TS structures in the sense of equal probability of reaching the product and reactant state, see Figure 1 b). Although the TS structures of water dissociation are rather similar, we find that the rate constant calculated with AMS can be two orders of magnitude smaller than the value obtained with hTST (Figure 1 c). This discrepancy is attributed to entropic effects which are better taken into account with AMS.

We believe that this method provides an innovative way for better quantifying reaction rates, and extensions to more complex reaction mechanisms are currently investigated.

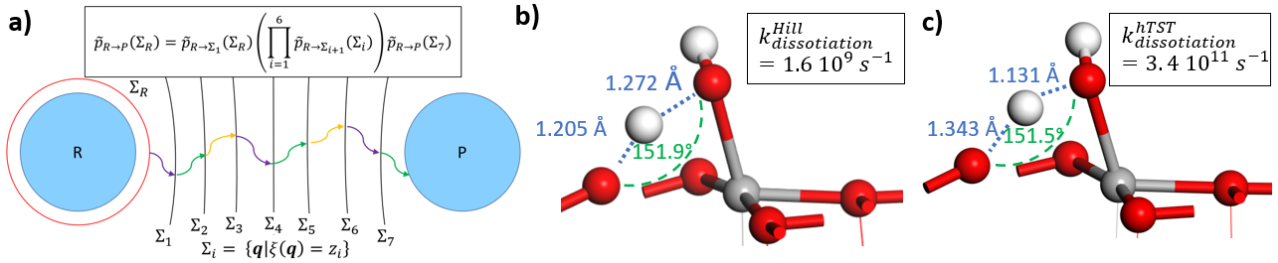

**Figure 1: a)** Illustration of multiple levels of a reaction coordinate placed between the reactant state and product splitting the rare event into multiple more likely ones. The inset displays the expression of the probability estimator. **b)** Average transition structure sampled with AMS. The inset corresponds to the estimated rate constant calculated with the Hill relation. **c)** Saddle point on the potential energy surface according to hTST. The inset corresponds to the estimated rate constant calculated with hTST.

# Principles of Spin Catalysis

J. Gracia[1*], M. Fianchini[1], C. Biz[1]

[1]*Magnetocat SL, Alicante, Spain*
[*]*jose.gracia@magnetocat.com*

**Keywords:** spin catalysis, magnetic catalysts, strongly correlated materials, quantum spin exchange

**Introduction.** Strongly correlated electrons enhance the activity of certain catalysts. Understanding "why" and "how" is strictly dependent on understanding complex quantum phenomena, like metal− insulator transitions and ferromagnetism. An improved fundamental view of the quantum interactions (correlations) lets us uncover additional details of the most relevant spin electronic factors in catalysis and their origin, nature, and influence. The importance of this fundamental research on orbital magnetism and spin-potentials is not only confined to a pure academic scientific domain but, being deeply intertwined, as it is, with the efficiency of electrocatalytic processes and technologies for the production of green hydrogen, it bears a tremendous impact on the idea of a cleaner and more sustainable world.

**Experimental/methodology.** Theoretical work about the new advances about the role of spin-potentials in electrocatalysis.

**Results and discussion.** Quantum correlations have drastic effects on the energy of magnetic materials and thus in catalysis.[1] Just as spintronics deals with advanced spin-based technology and devices where both the charge and spin of the electrons are modulated to offer a wide diversity of functionalities, similarly, the idea that the surface reactivity may be modulated by the influence of cooperative spin potentials, in open shells via the orbital engineering of earth-abundant magnetic systems is a tangible reality. Strongly correlated electrons, in fact, can affect the efficiency, cost, implementation, and environmental footprint of any heterogeneous catalyst. Quantum spin exchange interactions (QSEI) are a subtle phenomenon lying outside of the domain of classical physics, however they are responsible for the unusual intrinsic properties of magnetic catalysts. The influence of cooperative QSEI in materials with unpaired electrons can be seen in their characteristic structure, electronic conductivity, chemical bonding,[2] catalytic activity, and selectivity.[3]

We mainly present the physics that describe and rationalize the quantomechanic origin of QSEI in open shells, showing how spin-potentials enhance the reaction mechanisms of magnetic catalysts. This improved theoretical description is the only path to understand all kind of catalysts, from weakly to strongly correlated. A complete treatment of orbital physics, synergistically integrated into classical catalytic concepts like the Sabatier's principle, promises to improve predictions in the design of future catalysts and technologies.

# *Operando* spatial reactor analysis and kinetic study of oxidative coupling of methane

J.Palomo, N. Koenraadt, J. de Kort, A. Urakawa*

*Catalysis Engineering, Department of Chemical Engineering, Delft University of Technology, Delft, 2629 HZ, The Netherlands*

* A.Urakawa@tudelft.nl

**Keywords:** OCM, *operando* thermal analysis, spatial reactor analysis, kinetic modeling.

**Introduction.** Oxidative Coupling of Methane (OCM) is a direct and exothermic reaction for the conversion of methane into ethane and ethylene. However, due to the high temperatures required for methane activation, deep oxidation reactions take also place, which lower the yield towards the desired $C_{2+}$ products. In the last decades, a huge effort was put into the development of efficient catalysts. On the other hand, the number of studies dealing with understanding OCM reaction mechanism and kinetics is limited. OCM proceeds through a complex homogeneous-heterogeneous reaction network. In addition, the presence of both endothermic and exothermic reaction steps in OCM results in the apparition of temperature gradients in the catalyst bed [1]. This intrinsic complexity makes the elucidation of comprehensive kinetic models a challenge. In the present work, we examine the OCM reaction mechanism and kinetics, using *operando* spatial resolved reactor analysis techniques.

**Experimental/methodology.** MgO and $La_2O_3$ were used as catalysts. Spatially resolved temperature and concentration profiles under *operando* conditions, were obtained using a customized reactor system that allows gas sampling and temperature measurements at different axial reactor positions (1 µm precision). A thermal infrared camera was used to determine presence of localized thermal phenomena in catalyst bed. A comprehensive kinetic model was developed for the OCM process.

**Results and discussion.** IR thermography images of the catalyst bed showed temperature deviations as high as 100°C (see Figure 1a), evidencing the importance of these physical phenomena in the OCM process. Isothermal operation was achieved, in case of MgO catalyst, by physically mixing the catalyst with SiC. For kinetic study, 39 gas phase reactions and 8 heterogeneous surface reactions were considered. Kinetic and thermodynamic parameters for the heterogeneous elementary steps were estimated.

The kinetic model reproduced the experimental data with a high accuracy (Figure 1b). A rate analysis was carried out, being it feasible to estimate the importance of both the heterogeneous and homogeneous reactions in the overall OCM process.

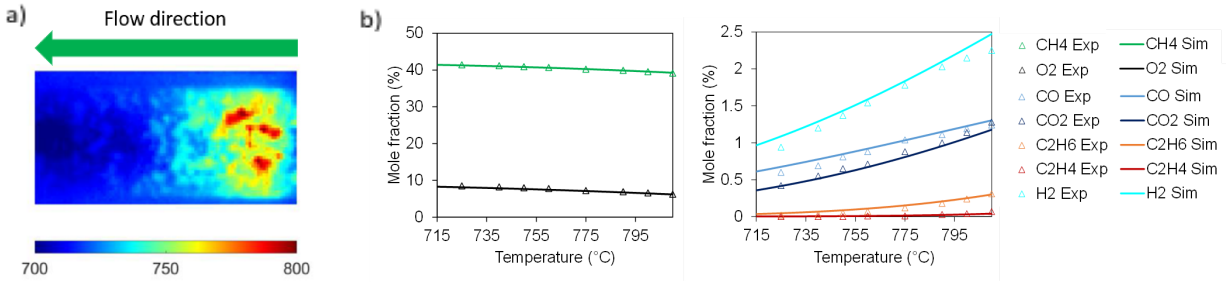

Figure 1. a) IR thermography of MgO catalyst bed, 700 °C, $W_{cat}$ = 80 mg, $W_{SiC}$ = 57 mg, $CH_4/O_{2,0}$= 4 and $P_{CH4}$ = 40%, Fv = 150 mL $min^{-1}$. b) Reactant and products mole fractions as a function of temperature, $W_{cat}$= 15 mg, $M_{SiC}$= 250 mg, Fv = 150 mL $min^{-1}$, $CH_4$:$O_2$ = 4, $P_{CH4}$ = 40%.

**Keywords:** crystalline $Mo_3VO_x$, propane ammoxidation, local structure

**Introduction.** Crystalline Mo-V-Te(Sb)-Nb oxide catalyst (MoVTe(Sb)NbO) has attracted much attention due to its outstanding catalytic performance for the ammoxidation of propane to form acrylonitrile (AN). This catalyst is constructed by the structural arrangement based on $\{Mo_5(Nb)O_{21}\}^{7-}$ pentagonal units and $\{MO_6\}$ (M = Mo,V) octahedral, forming hexagonal and heptagonal channel micropores in the crystal structure. Among these channels, Te or Sb is located mainly at the hexagonal channel and partly at the heptagonal channel. It is widely believed that its excellent catalytic properties are originated from the sophisticated structural arrangement in which the constituent elements are located in each specific structural site, allowing the cooperation of each catalytic function to realize the multi-step reactions. In fact, orthorhombic $Mo_3VO_x$ catalyst (MoVO) having an identical crystal structure with MoVTe(Sb)NbO showed poor selectivity toward AN. In this study, we found that MoVO showed outstanding catalytic properties for the ammoxidation of propane without introducing Te, Sb, and Nb simply by heat-treating MoVO above 550 °C under inert gas flow.

**Experimental/methodology.** MoVO was synthesized by the repoted procedure.[1] MoVO-x was prepared by the heat treatment of MoVO at x °C under flowing 50 mL $min^{-1}$ of $N_2$ (x: heat treatment temperature). Reaction conditions of propane ammoxidation: reaction temperature, 440 °C; catalyst amount, 0.05-0.6 g; reaction gas, $C_3H_8/O_2/NH_3/He$ = 1.2/2.9/1.5/14.4 mL $min^{-1}$.

**Results and discussion.** Effects of heat treatment temperatures on the propane ammoxidation were investigated using MoVO-x. Figure 1 shows the AN selectivity of various catalysts at the propane conversion of 47%−50%. When the heat treatment temperature was 450-500 °C, the selectivity to AN was 24.6%−31.3%, and was substantially lower than that of MoVTeNbO used as a comparison (AN selectivity, 62.6%). However, the AN selectivity increased drastically by simply increasing the heat-treatment temperature, and MoVO-600 showed a similar AN selectivity with MoVTeNbO at the similar propane conversion (AN selectivity, 56.7%). XRD measurements revealed that the crystal structure of MoVO changed only a little by the heat treatment below 500 °C. However, $V_{0.95}Mo_{0.97}O_5$ (VMo) phase started to segregate from MoVO above 550 °C. Since the contents of V in the VMo phase (V/Mo = 0.98) is larger than that of MoVO (V/Mo = 0.37), it was found that V is preferentially removed from the MoVO structure by the heat treatment above 550 °C. V was removed from the specific structural site in MoVO since the lattice parameters and IR absorptions for the structural framework of MoVO changed by its removal. HAADF-STEM measurements implied the disordering of the metals adjacent to the V site in the hexagonal channel of MoVO in MoVO-600. Based on the results obtained above, we concluded that the V site located at the hexagonal channel was removed by the heat treatment above 550 °C to form the VMo phase. Acid properties were changed by removing this V as evidenced by $NH_3$ adsorption TPD and IR, which might prevent $NH_3$ from undesired combustion to enhance the AN selectivity.

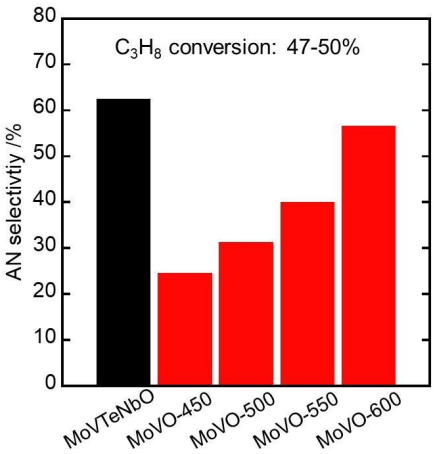

**Figure 1. AN selectivity at the propane conversion of 47−50%.**

**Keywords:** NMR relaxometry, Carbon-based catalyst, 2D T1-T2 low-field NMR relaxometry, 13C high-field NMR, T1/T2 relaxation times, adsorption.

**Introduction.**
NMR relaxometry can be used to guide the understanding of a catalytic reaction [1]. In particular, high-field $^{13}C$ NMR analyses (400 MHz) allow measuring the relaxation time T1 of organic molecules in the presence of solvent. The ratio between $T1_{bulk}$ (molecule in solution) and $T1_{ads}$ (T1 measured in the presence of the catalyst) allows to quantify the strength of the interaction between the substrate and the catalyst, as the lower the $T1_{ads}/T1_{bulk}$ the higher the interaction. Considering the molecule-catalyst interaction one of the fundamental parameter of a catalytic cycle, the $T1_{ads}/T1_{bulk}$ ratio can be possibly correlated to the catalytic activity, importantly including the solvent as an active participant. However, such High-field NMR experiments allow collecting information only of local molecular dynamics. The variation of T1 is a proof of a preferred orientation, but an absence of a preferred orientation does not always mean that there is no interaction. Such limitation can be overcome by two-dimensional T1-T2 correlation spectra at low field NMR (20 MHz), where similar adsorption measurement, which are sensitive to the environment of the molecular probe, can prove the reality of the surface dynamics. So, $^{1}H$ Low-field NMR and $^{13}C$ High-Field NMR could be considered as complementary analyses to collect information of local molecular dynamics and on surface dynamics, returning a much more complete picture of the interaction that a molecule can have with the surface of a catalyst, which is crucial in defining the catalytic activity and selectivity.

**Experimental/methodology.**
In this work, the interaction of an aliphatic (n-octanal) and aromatic (benzaldehyde) aldehyde with a carbon based catalyst (Pd/C) has been studied by high-field and low-field NMR relaxometry, providing information about the different molecular motions on the catalyst surface. In particular, the solvent-effect (p-xylene) was explored. Moreover, all the experimental data have been compared to molecular modelling and to theoretical motions modelling [2].

**Results and discussion.**
Relaxation time ratio $T1_{ads}/T1_{bulk}$ in high-field NMR have been measured for benzaldehyde and n-octanal in p-xylene and in the presence or absence of Pd/C catalyst. The same molecules have been reacted in p-xylene with $H_2$ in the presence of catalyst showing a very different activity which was correlated with the different $T1_{ads}/T1_{bulk}$ ratio measured. Moreover, it could be also possible to demonstrate the fundamental role of the solvent. Then by parallel low-field NMR experiments and modelling we were able to qualify and quantify the affinity of the substrates with the catalytic surface. The interrelation of low-field and high-field NMR analyses finally allowed collecting information of local molecular dynamics and on surface dynamics, returning a remarkable and complete picture of the interaction of a molecule with a catalyst surface in the presence of solvent.

**Keywords:** bimetallic catalysts, hydrogenation, gold, palladium

**Introduction:** Dilute Pd-in-Au alloys are valuable materials for selectively hydrogenating alkynes and isomerizing alkenes [1,2,3]. By diluting Pd in a Au host, the selectivity towards semi-hydrogenated alkene isomers can be significantly enhanced and the unfavorable over-hydrogenation to alkanes suppressed. Yet, a detailed mechanistic study on the origin of the enhanced alkene selectivity over dilute alloy catalysts is still missing. Here, we combine experiment and theory to unravel the reaction mechanism, identifying rate-limiting and selectivity-controlling steps in 1-hexene hydrogenation over dilute Pd-in-Au catalysts [1].

**Experimental/methodology:** isotopically labelled 1-hexene hydrogenation experiments using $D_2$ were conducted under steady state conditions and at high 1-hexene conversion (92%) to gain insight in the reaction mechanism over the $Pd_4Au_{96}$ and Pd catalysts. Quantitative analysis of all products and the number of deuterium atoms incorporated was achieved by simultaneously using an online mass spectrometer to monitor the HD formation, and a gas chromatography mass spectrometer to quantify the hexene and hexane products. Density functional theory calculations (DFT) were used to compute the free energy profiles for 1-hexene hydrogenation to n-hexane, and for isomerization to 2-hexene on a Pd atom in Au surface ($Pd_1Au$). Next, the reactivity and product selectivity of the calculated reaction mechanism for $Pd_1Au$ was evaluated under operating temperature and pressure using microkinetic models.

**Results and discussion:** the isotope exchange hydrogenation experiments show that 1-hexene and hydrogen over a bimetallic $Pd_4Au_{96}$ in silica catalyst preferentially form 1-hexene isomers, (trans&cis) 2- and 3-hexene, and only small amounts of hexane. The reaction is consistent with a Horiuti–Polanyi mechanism, similar to a mono-metallic Pd nanoparticle catalyst. Computation of the free energy profiles for 1-hexene hydrogenation and isomerization over a single Pd atom in a Au surface indicated that isomerization of 1-hexene to 2-hexene is energetically favorable due to the relatively large barrier for $H_2$ dissociation preventing hydrogenation to n-hexane. Microkinetic modeling established that $H_2$ dissociation on the single atom Pd sites, and H-spillover from these sites onto the Au host are rate-limiting and key in steering the selectivity of dilute Pd-in-Au alloys towards the hexene isomers. The mechanistic insights from this study contribute to the rational design of optimized dilute alloy catalysts for selective alkene isomerization.

# Comparison of mechanisms of deNOx and de$N_2O$ processes on partial hydrated bimetallic Cu-Zn dimers in clinoptilolite zeolite - DFT study

I. Kurzydym[1], I. Czekaj[1*]

[1] *Department of Organic Chemistry and Technology, Faculty of Chemical Engineering and Technology, Cracow University of Technology, Poland, Warszawska 24, 31-155 Cracow*
[*] *izabela.czekaj@pk.edu.pl*

**Keywords:** zeolites, deNOx, de$N_2O$, bimetallic, copper, zinc, DFT, SCR, clinoptilolite

**Introduction.** Nitrogen oxides (NOx) from human activities are a source of dangerous air pollutants such as acid rain and photochemical smog [1]. These pollutants are harmful to both human health and the environment. One of the more damaging nitrogen oxides is $N_2O$ [2,3]. It is produced, for example, during nitric acid production or as a by-product of the $NH_3$-SCR process. As one of the greenhouse gases, it causes destruction of the ozone layer and its global warming potential (GWP) is approximately 310 times higher than the more famous gas $CO_2$. Currently, in plants where nitrogenous compounds are synthesised, the reduction of NO and $N_2O$ takes place separately. In order to reduce costs, save space and time, a major problem is to find a catalyst that allows the simultaneous removal of these oxides [4].

**Experimental/methodology.** The ab initio density functional theory (DFT) method was used to calculate the electron structure of the presented clusters with StoBe software. The exchange and correlation functional was approximated with a Perdew-Burke-Ernzerhof (PBE) functional. It was used for the electron exchange and correlation. Milliken populations and Mayer's bond order factors were used to precisely analyse the electron structure of the clusters.

**Results and discussion.** The clinoptilolite zeolite with a Cu-Zn partially hydrated bimetallic dimer deposited was used as the catalyst in the study. Two variants were presented - an OH group on copper and an OH group on zinc.

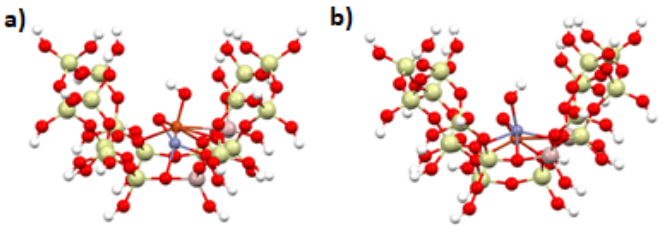

Figure 1. Cluster model of the clinoptilolite zeolite structure with deposited bimetallic dimer: a) Cu–O–Zn with OH group on Cu and b) Cu–O–Zn with OH group on Zn.

An analysis of the reaction mechanisms of the deNOx and de$N_2O$ process was carried out. The energy differences between the stages of the process were presented. In addition, bond lengths and bond orders have been analysed to understand the nature of the systems in more detail. It was shown that, in the case of the de$N_2O$ process, the order of the NO/$N_2O$ molecules has a significant impact on the activation energies of the process. The different systems show similar efficiencies for both deNOx and de$N_2O$ reactions. The adsorption energy of the OH group on the metal is important in this case - the OH group has a higher affinity for the zinc atom.

# *Ab Initio* Predictions for Heats of Adsorption and Reaction Barriers for Alkanes in Acidic Zeolites

F. Berger, M. Rybicki, J. Sauer*

*Humboldt-Universität zu Berlin, Germany*
**js@chemie.hu-berlin.de*

**Introduction.** Experimental kinetic studies deal with complex reaction networks, whereas computational studies can provide energy barriers, reaction energies, and pre-exponentials for individual reaction and adsorption steps. If made with sufficient, i.e. chemical, accuracy (± 4 kJ/mol), computational predictions are very useful to check critical steps in microkinetic models. Whereas the vast majority of kinetic experiments yield apparent enthalpy barriers, $H^{\ddagger}_{app}$, atomistic understanding and rationalization of the function of catalysts requires knowledge of intrinsic enthalpy barriers, $H^{\ddagger}_{intr}$. Therefore, adsorption enthalpies, $H_{ads}$, are needed to derive intrinsic enthalpy barriers from apparent barriers,

$$H^{\ddagger}_{intr} = H^{\ddagger}_{app} - H_{ads}, \quad (1)$$

but they are difficult to measure at reaction temperatures. In contrast, accurate computational methods can provide consistent adsorption enthalpies and intrinsic barriers at low and elevated temperatures. We propose an accurate quantum mechanical (QM) method that enables us to answer the long-standing question whether intrinsic activation enthalpies for alkane cracking depend on the alkane length or not.

**Methodology.** Our hybrid high level QM:low level QM method [1] has been demonstrated to yield chemical accuracy (4 kJ/mol for energies and one order of magnitude for rate constants) for the methylation of ethene, propene and butene in H-ZSM-5. Here, we combine density functional theory with some account of dispersion (DFT-D) as a low-level method for the full periodic structure and second-order Møller–Plesset perturbation theory (MP2) as a high-level method for cluster models to locally describe the molecule–surface interactions.

**Results and Discussion.** We apply this hybrid MP2:DFT-D approach in combination with molecular dynamics (MD) sampling (at the DFT-D level) to 19 cases of alkane adsorption in acidic zeolites with adsorbates ranging from methane to *n*-hexane and five zeolite models (H-MFI, H-CHA, and H-FAU) with low and high Si/Al ratios (2.6 to 23). The heats of adsorption show a mean absolute deviation from experiment of less than 2 kJ/mol.

The predicted heats of adsorption at reaction temperatures (650 K) support experimental results derived from spectroscopic measurements [2]. The Table shows that the observed decrease of experimental apparent barriers from propane to pentane for alkane cracking in MFI (28 kJ/mol) is largely due to increasing adsorption strengths (21 kJ/mol) and to a much smaller extent to decreasing intrinsic barriers (7 kJ/mol).

**Alkanes in H-MFI (650 K): Experimental apparent activation enthalpies, $H^{\ddagger}_{app}$, calculated and experimental adsorption enthalpies, $H_{ads}$, as well intrinsic activation enthalpies, $H^{\ddagger}_{intr}$, purely based on experiments, Exp., or derived from experimental apparent barriers and calculated adsorption enthalpies, Calc., all in kJ/mol.**

| alkane | $H^{\ddagger}_{app}$ | $H_{ads}$ | | $H^{\ddagger}_{intr}$ | |
|---|---|---|---|---|---|
| | Exp.[2] | Exp.[2] | Calc. | Exp.[2] | Calc. |

# Mechanism of CO-PROX Reaction over Mixed and Bare Cobalt Spinel Catalysts Revealed – DFT and isotopic investigations

F. Zasada[1], C. Hudy[1], K. Steenbakers[1], Z. Sojka[1],

[1]*Jagiellonian University, Kraków, Poland*
[*]*zasada@chemia.uj.edu.pl*

**Introduction.** Development of new efficient CO-PROX catalysts is mainly conditioned by an in-depth understanding of the reaction mechanism that governs the catalysts performance. One of the most attractive group of CO-PROX catalysts are spinels ($AB_2O_4$), which catalytic performance may be modified in the intended fashion upon careful selection of the A and B redox cations[1]. The guiding concept of these studies was to perturb the CO-PROX reaction progress by doping the parent cobalt spinel oxide ($Co_3O_4$) with foreign cations, and analyze the response of the isotopic $CO_2$ and $H_2O$ profiles to the reaction temperature and catalyst selectivity getting insight into mechanistic details. The experiments have been confronted with DFT molecular modeling and first principle thermodynamics simulations.

**Experimental:** A series of mixed spinel oxide catalysts, $M_xCo_{3-x}O_4$ (M = Cr, Mn, Fe, Ni, Cu, and Zn), was synthesized via the combustion method, using nitrate precursors and then thoroughly characterized (XRF, XPS, XRD, IR, SEM). The catalytic tests were carried out in a gradient-less quartz reactor with a QMS spectrometer (Hidden) used for the detection of the diagnostic lines. For DFT modelling the spin unrestricted periodic-GGA+U DFT method with PW91 xc functional, implemented in the VASP package was used. The interaction of spinel planes with gaseous molecules of CO-PROX process at different conditions (T, $p_x$, x = CO, $H_2$, $O_2$, $H_2O$, $CO_2$) was accounted by first principles thermodynamics (FPT).

**Results and discussion.** It was shown that the predicted results can be reconciled with the experimental isotopic compositions of $CO_2$ and $H_2O$, and their evolution with the progression of the CO-PROX reaction only whith assumptionthat the suprafacial (Langmuir-Hinshelwood/Eley-Rideal, LH/ER) and intrafacial (Mars-van Krevelen, MvK) mechanisms operate concurrently. The essential features of the proposed fluctuating mechanism involve three main catalytic cycles, the relative participation of which depends on the catalyst nature and the reaction conditions[2]. Cycle I covers the indirect CO oxidation via suprafacial $\alpha$–$CO_3^{2-}$ and intrafacial $\beta$-$CO_3^{2-}$ intermediates (LH/ER and MvK-LH/ER), whereas cycle II refers to direct CO oxidation into $CO_2$ by lattice oxygen (MvK). The last cycle (III) involves direct, unpreferable oxidation of hydrogen by adsorbed oxygen (LH/ER or EP).

In the revealed mechanism two types of carbonate adspecies are distinguished, depending on the adsorption locus (octahedral or tetrahedral cations). The carbonates attached to the dual $Co^{tet}$⌣$Co^{oct}$ centers, are characterized by much higher energy of dissociation into $CO_{2(g)}$ than carbonates stabilized on the $Co^{oct}$⌣$Co^{oct}$ pairs ($\Delta E$ = 1.29 eV and $\Delta E$ = 0.69 eV, respectively) and behave as spectators that being accumulated during the CO-PROX reaction are primarily observed in the IR spectra, but are rather of minor importance for the CO-PROX reaction. The $Co^{oct}$⌣$Co^{oct}$ stabilized adspecies, in turn, are easily decomposed into $CO_{2(g)}$ thus act as interemdiates of CO-PROX. This observation resolves the contradictory claims about the mechanistic role of carbonates found in the literature[3]. The involvement of carbonate intermediates is directly confirmed by the established correlation between the selectivity and the relative content of $C^{18}O_2$ and $C^{16}O_2$ in the CO-PROX reaction products. The nascent Mars van Krevelen oxidation of direct CO oxidation into $CO_2$ is coupled with the subsequent LH/ER step, which is prompted by dissociative refilling of the oxygen vacancies by $O_2$, leading to the formation of $O_{ads}$.

**Keywords:** carbon dioxide, hydrogenation, *ab initio*, alloy catalyst, palladium, copper, zinc

**Introduction:**

Methanol synthesis by direct hydrogenation of $CO_2$ has been recognised as a potential route towards sustainable fuels for transport and a circular fuel economy.[1] The facilitation of direct $CO_2$ hydrogenation to methanol via a surface HCOO formate intermediate is crucial for desirable selectivity, as shown in the theoretical study of Cu catalysts by Medford *et al.*[2] Our previous work has shown that flat surfaces of a Pd catalyst have a high activation energy of initial $CO_2$ activation and hydrogenation to HCOO.[3] However, Pd-based catalysts supported on ZnO are potent catalysts for this reaction, with their reactivity attributed to the PdZn binary metallic phases.[4]

**Methodology:**

The reactivity of Tetragonal Body-Centred (TBC) PdZn (110) and (101) and Body-Centred Cubic (BCC) CuPd (110) alloy surface facets towards $CO_2$ activation and hydrogenation has been investigated computationally with comparison against low-index monometallic Face-Centred Cubic (FCC) Cu, Pd and Hexagonal Close-Packed (HCP) Zn surfaces. We used periodic DFT to ensure accurate representation of the metallic and alloy structures and catalytic processes, using the semi-local Bayesian error estimation density functional (mBEEF). [5, 6] All surface structures were verified against experimental observables. Transition states (TS) in the reaction pathway were investigated using NEB approaches to study the energy profile.

**Results and discussions**

$CO_2$ adsorption energy and activation energy of hydrogenation to the HCOO intermediate were calculated on Cu, Pd and Zn, CuPd and PdZn surfaces. The preferred starting $CO_2$ geometry was chemisorbed - a negatively charged and bent geometry, rather than physisorbed – a neutral and linear $CO_2$ geometry. [3] Chemisorption of $CO_2$ was exothermic on Pd (100) and Pd (110), and endothermic on Pd (111), Cu (100), (110), PdZn (101), (110) and CuPd (110) surfaces. The two largest TS energies were on surfaces that could only accommodate physisorbed $CO_2$, i.e., HCP Zn (0001) and FCC Cu (111). The results infer that metastable chemisorbed $CO_2$ intermediate facilitates further hydrogenation. The rate determining step varies across the metals where the surface with smallest TS energy is considered – for Cu it is $CO_2$ chemisorption, for Pd it is hydrogenation of chemisorbed $CO_2$, and for Zn it is hydrogen adsorption. In both investigated Pd-M (M = Cu, Zn) alloys, Pd is the more electronegative metal, and the surface atoms have a significant amount of negative charge from M. On Pd-M alloys $CO_2$ preferably binds *via* carbon to Pd and *via* oxygen to the Cu or Zn. CuPd shows a hydrogen adsorption energy between that of Cu and Pd metals, more stable $CO_2$ chemisorption, and a TS energy near that of Cu and Pd. Upon alloying Pd with Zn, the TS on PdZn (110) is reduced in energy below the net zero reaction energy, thereby highlighting the catalytic capability of this alloy. The study brings insight into rational design of modern $Cu_xPd_yZn_z$ alloy catalysts in $CO_2$ hydrogenation.

# Continuous oxidation of methane into methaol by $N_2O$ over Cu-Zeolite: A combined experimental and theoretical study

Ning Liu, Biaohua Chen*, Ning Wang
*Faculty of Enviroment and Life, Beijing, China (100124)*
* chenbh@bjut.edu.cn

**Keywords:** Methane diretct oxidation to methanol, Zeolite, $N_2O$, reaction mechanism

**Introduction.** Methane ($CH_4$) transformation into methanol ($CH_3OH$) and its derivative (dimethyl ether, DME) has attracted great attentions due to growing production of natural gas by recently developed shale gas technology [1]. Direct oxidation of methane into methanol (DMTM) constituted a candidate, wherein the Cu modified zeolites [2] have shown promise in selectively converting $CH_4$ into $CH_3OH$ under ambient conditions. Large amounts of works are mainly focused on $CH_4$-stepped-oxidation including steps of catalyst pre-oxidation (by $O_2$), $CH_4$ oxidation and $CH_3OH$ extraction (by $H_2O$), which can hardly meat the demand of real chemical productions due to extremely low production capability (0-30) μmol $g^{-1}$ catalyst $h^{-1}$. In this regard, developing continuous DMTM technique along with efficient catalyst is highly desirable.

**Experimental/methodology.** A series of Cu-, Fe-zeolites was prepared by wet-ion-exchange method. XRD, $N_2$-adsorption/desorption, $H_2$-TPR, UV-vis, XPS were employed to characterize the physiochemical properties of prepared samples. Continuous oxidation of $CH_4$ by $N_2O$ was evaluated on a fixed bed reactor, under reaction conditions of GHSV of 12,000 $h^{-1}$, $N_2O$ : $CH_4$ : $H_2O$ ratio of 15 : 30 : 10 (balanced by He) and atmospheric pressure. The DFT, AIT and AIMD calculations were conducted based on the VASP and CP2K.

**Results and discussion.**

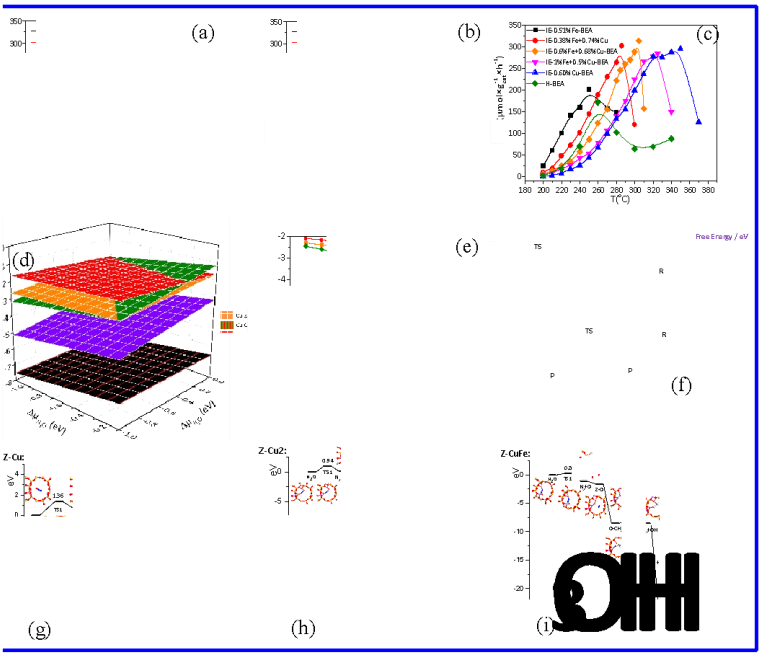

**Fig. 1** (a-c) $CH_3OH$ generation rate over series of Cu-, Cu-Fe-BEA zeolites; (d-e) active center stability evaluations by AIT; (f) free energy surface during AIMD simulation of $H_2O$-medieated proton transfer over [Cu-$CH_3$-Fe-OH]Z; (g-i) DFT mechanism simulation results over (Z-Cu), (Z-2Cu) and [Cu]+-[Fe]+ (Z-Cu-Fe).

Present work investigated continuous oxidation of $CH_4$, utilizing $N_2O$ as oxidant, over a series of Cu-, Fe-zeolites (BEA, MFI, FER). The generation rate of the $CH_3OH$ can reach as high as 300~2300 μmol $g^{-1}$catalyst $h^{-1}$ $CH_3OH$. Excellent reaction stability was also verified by 70 h's long-term activity test. Finally, the mechanistic insight into the effects of $H_2O$ as well as active center motifs were further studied by density functional theory (DFT) simulations, ab initio thermodynamics (AIT) and ab initio molecular dynamics (AIMD), based on which the reaction mechanism were well illustrated.

[*]*luca.mastroianni@abo.fi*

**Introduction**. Selective oxidation of primary alcohols to corresponding aldehydes plays a pivotal role in the modern chemical industry. The oxidation processes can be catalyzed by gold nanoparticles, but the critical issue is the nanoparticle size, which should be within few nanometers, because large gold particles are passive in catalysis. Concerning the structure sensitivity of gold in the selective oxidation of alcohols to aldehydes, conflictual results have been reported [1]. Lateral interactions on the catalyst surface might have a significant impact on the reaction energetics. Particularly, water has been suggested to play a prominent role in assisting oxidation processes [2]. In this work, the oxidation of primary alcohols promoted by gold nanoparticles was investigated both experimentally and computationally. The reaction kinetics and product distribution were determined in a microreactor for oxidative dehydrogenation of primary alcohols ranging from methanol to butanol. The effect of water was investigated by adding it to the reaction mixture in different amounts. The oxidation pathways were elucidated from a computational viewpoint on Au (111) surface to understand the role of water in elementary steps, thus proposing a plausible reaction mechanism for alcohol oxidation on gold nanoparticles.

**Experimental/methodology.** The microreactor device consisting of 10 plates with 9 parallel channels was coupled to an on-line gas chromatograph, equipped with a capillary column and a flame ionization detector. The gas flows were regulated with mass flow controllers and the alcohols were fed to the system with high precision pumps. The channels were coated with $Au/Al_2O_3$ catalyst prior to the experiments. Computational studies were performed using the Density Functional Theory (DFT) code GPAW [3].

**Results and discussion.** The observed reaction network comprised three parallel reactions, where the main reaction products were the aldehydes and ethers. The alcohol conversion was enhanced by the presence of water (Fig. 1a), which also resulted in an improved aldehyde selectivity (Fig. 1b).

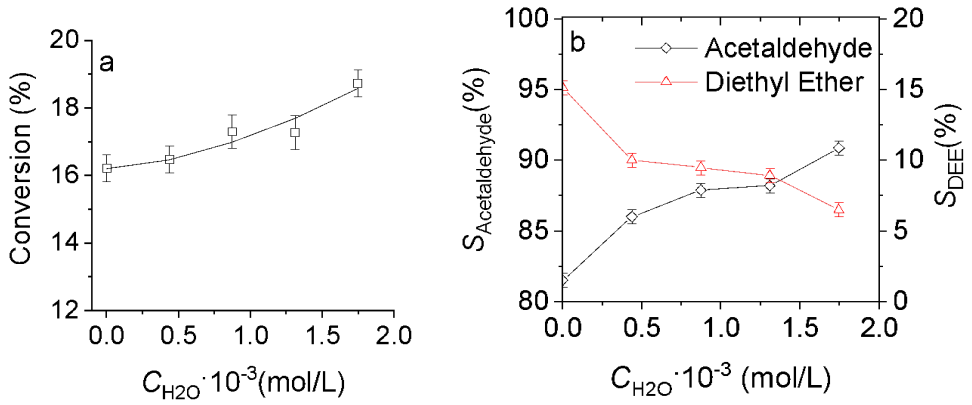

**Figure 1. Ethanol oxidation over a gold on alumina catalyst in a microreactor at 250 °C: a) conversion and b) product distribution as a function of water concentration.**

The DFT calculations proved that the oxygen dissociation is facilitated by the presence of water, thus supporting the experimental observations. Therefore, the combination of DFT calculations and experiments employed in this work was instrumental in revealing the role of water in alcohol oxidation on gold nanoparticles from the mechanistic viewpoint.

**Keywords:** Multiscale modelling, computational fluid dynamics (CFD), density functional theory (DFT)

**Introduction.** Understanding how the chemical kinetics is coupled to the transport processes in a catalytic reactor is an essential prerequisite for optimizing the performance of a catalytic reaction. The methanol-to-dimethyl ether reaction is catalyzed by the zeolite H-ZSM-5; and in this presentation, we apply multiscale modelling to investigate how the kinetics and transport processes depend on each other.

**Experimental/methodology.** A multiscale methodology[1] is used to couple the kinetics at the catalytic sites to the diffusion in the catalyst pellets and further to the gas flow in the reactor. The kinetics at the catalyst sites is computed using DFT calculations. A detailed pore structure of the catalyst pellet is obtained through X-ray tomography measurements. This pore structure is then used to simulate diffusion in the catalyst pellets. Finally, the gas flow in the reactor outside the catalyst pellets is obtained by use of CFD simulations.

**Results and discussion.** Figure 1 shows the average concentration of gas phase and average coverage of adsorbed species in a volume segment of length $\Delta Z$ = 0.0001 m placed at various positions along the reactor. The methanol-to-dimethyl ether reaction is fast indicated by the observation that the concentration of products has reached a constant level already 2 mm from the start of the catalyst bed.

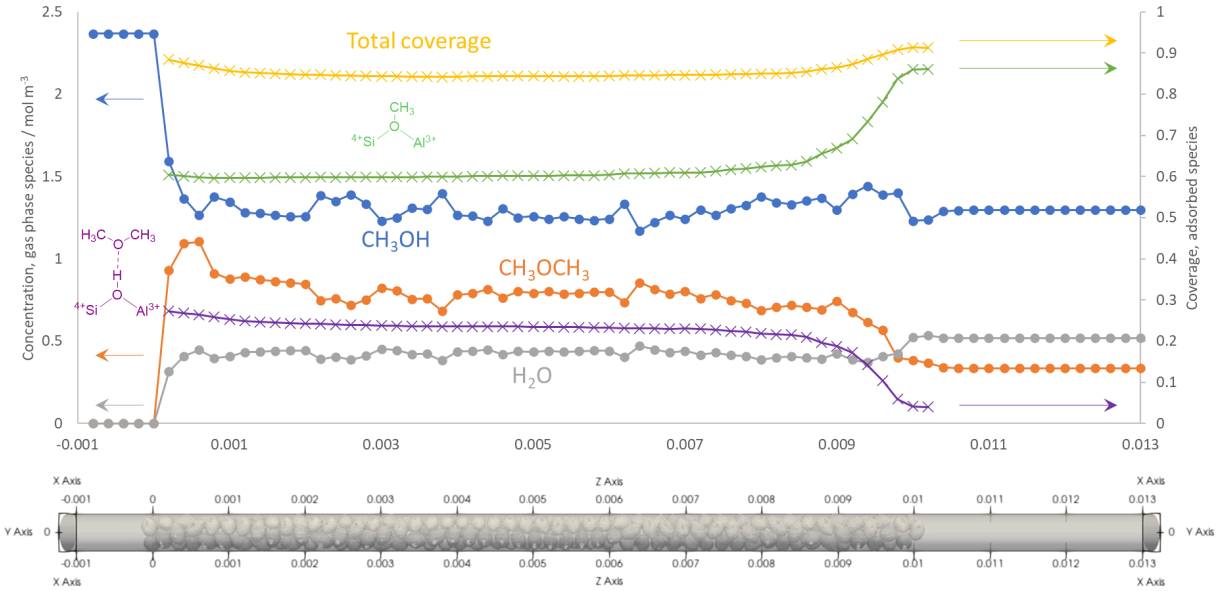

**Figure 1. Concentration of gas phase species (filled circles, left axis) and coverage of adsorbed species (crosses, right axis) along the reactor. $z$ = 0 m indicates the start of the catalyst bed.**

**Keywords:** hydrogen production, formic acid dehydrogenation, Pd/AC, kinetic modelling.

**Introduction.** The continuous generation of hydrogen by formic acid dehydrogenation (FAD) reaction at low temperature and in the absence of external additives is investigated in a fixed-bed reactor with the aim of providing a kinetic model that enables the further reactor desing. So far, significant progress has been done on the synthesis of heterogeneous catalysts, with the interest of producing CO-free hydrogen, and little on the chemical reaction engineering for the development of commercial technologies.

**Experimental.** A novel fixed-bed reactor configuration is proposed. A conductive β-SiC open-cell foam with high porosity (30PPI, supplied by SiCAT) is filled with a powdered commercial 10 wt.%Pd/AC catalyst (Noblyst® P1070, by Evonik). The FAD reactions were carried out up-flow at the following operating conditions: $C_{FA,0}$= 0.5-2 M, T= 25-55 ºC, $W_{CAT}$= 0.5 g, $Q_L$=0,125-1 mL $min^{-1}$, τ = 8.3-66.7 $g_{CAT}$ h $L^{-1}$ and using helium as a carrier gas ($Q_G$=17 mL $min^{-1}$). Gas samples were analyzed in a gas chromatograph (GC) while FA concentration in the liquid effluent was measured at 210 nm in a spectrophotometer.

**Results and discussion.** The FA concentration decreases by increasing the space time and reaction temperature (Fig 1a). It was found that the reaction follows a first order kinetic for FA. In general, the hydrogen flow rates measured by GC were lower than those calculated from the disapperared FA which indicates that some FA molecules or derivative from FA species remain on the catalyst surface without reacting, since hydrogen and $CO_2$ were the only gases detected in the gas stream. The kinetic parameters for both reactions, the FAD ($r_1$) and formation of FA -Pd catalyst species ($r_2$ of Scheme 1), were estimated.

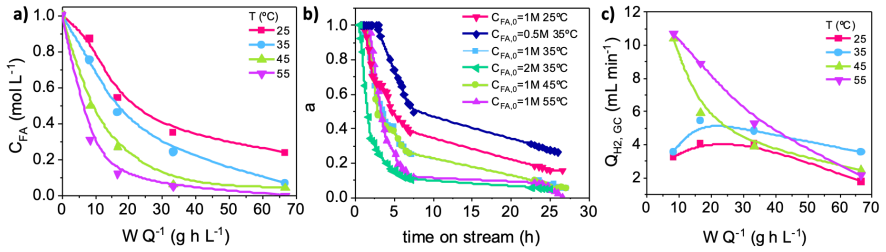

Figure 1. (a) Temporal FA concentration profiles and (b) catalytic activity *vs.* time on stream at $C_{FA,0}$= 0.5-2 M and T=25-55 ºC (c) hydrogen flow rates produced at $C_{FA,0}$= 1 M and T=25-55 C

The activity showed an exponential decay with the initial FA concentration and reaction temperature (Fig. 1b). According to these results, the elucidated kinetic model for the continuous production of hydrogen from FA is illustrated in Scheme 1.

$$\mathrm{FA} \xrightarrow{r_1} \mathrm{H_2} + \mathrm{CO_2}$$

$$\mathrm{FA} + \mathrm{catalyst} \xrightarrow{r_2} \mathrm{FA-catalyst}$$

$$(-r_{FA})_w = \left[k_1 \cdot \exp\left(-\frac{E_{a,1}}{RT}\right) \cdot C_{FA} + k_2 \cdot \exp\left(-\frac{E_{a,2}}{RT}\right) \cdot C_{CAT} \cdot C_{FA}\right] \cdot \exp\left(-k_d \cdot t\right)$$

$$(-r_{FA})_w \left(\frac{mol_{FA}}{g_{CAT} \cdot h}\right) = \left[9.87 \cdot 10^5 \cdot \exp\left(-\frac{53.6\ k\ mol^{-1}}{R \cdot T}\right) + 4.19 \cdot 10^4 \cdot \exp\left(-\frac{35.8\ kJ\ mol^{-1}}{R \cdot T}\right)\right] \cdot C_{FA} \cdot \exp\left(4.44 \cdot 10^2 \cdot \exp\left(-\frac{18.8}{RT}\right) \cdot C_{FA,0} \cdot t\right)$$

Scheme 1. Proposed kinetic model for the production of hydrogen from FA dehydrogenation

Noteworthy, the hydrogen flow rate profiles obtained (Fig. 1c) do not show the expected behavior. The hydrogen production decreases with the space time and is not influenced by temperatures above 35 ºC.

These results point out that the hydrogen mass transfer is controlling the catalytic performance. Therefore, the hydrogen production rate cannot be calculated from the FA reaction rate.

# Improvement of Data and Metadata Quality in Catalysis Research: A Use Case Collection Methodology

N.Huskova[1], T.Petrenko[1], T. Boenisch[1]

[1]*High-Performance Computing Center Stuttgart University, Stuttgart, Germany*

The goal of the NFDI4Cat project is to establish a national research data infrastructure for catalysis research in Germany that ensures the data and metadata collected and shared by researchers are of high quality and adhere to established standards [1]. To achieve this goal, a comprehensive use case collection methodology has been developed. The methodology begins with the collection of use cases from researchers in the catalysis community through a dedicated platform. This platform includes detailed guidelines for the information required in submissions, ensuring that the use cases collected are relevant, accurate and complete. The collected use cases are then evaluated based on established criteria for data and metadata quality. Any identified issues are addressed through collaboration with the submitting researchers, to ensure that the use cases meet the required standards.

The collected use cases are then standardized what includes mapping the data and metadata to relevant ontologies and vocabularies, as well as ensuring consistency across different use cases. After standardization process is finished, information provided in use cases will be represented in RDF (Resource Description Framework) format and connected to the developed ontology. RDF is a standard format for representing data and linking it to ontologies, which allows for easy integration and cross-referencing of data [2]. The use of RDF and ontologies ensures that the data is machine-readable, linked, and can be easily integrated with other datasets, making it more discoverable and useful for the catalysis research community. Within the project, special attention is paid on the collection of use cases from different fields, including biocatalysis, homogeneous catalysis, and heterogeneous catalysis. This will provide a comprehensive representation of the field and allow researchers from different areas of catalysis to benefit from the collected use cases.

Proposed methodology serves as a valuable resource for the catalysis research community, promoting adherence to established standards and ensuring that the data and metadata shared by researchers are of high quality. It will help to facilitate data sharing and collaboration, as well as support the advancement of catalysis research [3].

# Breaking Barriers to Kinetic Modeling of $CO_2$ Hydrogenation to Hydrocarbons using Machine Learning

Aleksandr Fedorov*, Anna Perechodjuk, David Linke

*Leibniz-Institut für Katalyse e.V, Rostock, Germany*
**aleksandr.fedorov@catalysis.de*

**Introduction.** The kinetic modeling of heterogeneous catalytic reactions plays a key role in applied science and particularly in chemical engineering. The model development is usually based on using an expert's knowledge about reaction mechanism, rate-determining and equilibrium stages as well as solving the inverse task of kinetic. Modern machine learning (ML) methods can help and accelerate the development of such models. The key advantage of ML is that only the data is required for building regression models and, thus, we do not need to suggest (guess) reaction mechanism, rate-determining stages etc. However, the requirement of a lot of data for training and building reliable ML models limits so far their application for the small data. In the present work, we used ML for the kinetic modeling of a rather small dataset. To improve the generalization of ML models, we constrained the architecture of ML models by integrating the chemical and chemical engineering knowledge of the process. Our approach was developed and validated by carrying out a numerical experiment and finally applied for the kinetic modeling of experimental data using a challenging real-world problem, the $CO_2$ hydrogenation to higher hydrocarbons, as an example.

Figure 1. Molar flow parity plots of the obtained ML models: A, B – baseline and improved models from the nume rical experiments, respectively; C – im proved model describing the real data. D – conversion-selectivity plot.

**Methodology and Experimental.** For numerical experiments a plug-flow reactor model was developed using the kinetic model describing the $CO_2$ hydrogenation to hydrocarbons and suggested by Lucas Brübach et al. [1]. The small training dataset mimicking a typical kinetic experiment was generated and used for training ML models. Another lager test dataset was created for validating the ML models. To apply the suggested approach for real-world data, a Fe-K-Cu/$Al_2O_3$ catalyst was prepared by a wet-impregnation method and tested in $CO_2$ hydrogenation under various reaction conditions using a high-throughput setup.

**Results and discussion.** Figure 1 shows the generalization of the obtained ML models. The standard (baseline) ML model describes the training dataset correctly. However, its predicting ability is very low when we try to use this model for describing the whole test dataset (Figure 1A). It confirms the general consensus that ML requires a lot of data for building reliable models. But our improved model which was enhanced by integrating the chemistry knowledge describes training and test datasets correctly (Figure 1B). It is worth noting that reliable ML models could be even obtained in the case of noisy data. Finally, the suggested approach was succesfully applied for modeling $CO_2$ hydrogenation to hydrocarbons based on the experimental data (Figure 1C and 1D). The obtained model was shown to be able to describe reagent consumptions and product formations as well as parrafins, olefins, and alcohols distributions correctly. Thus, the suggested approach based on the intergating the chemistry knowledge into the architecture of ML models allows one to build reliable ML models using only a small data set as typical for experimental investigations. Therefore, our work significantly expands the scope of the application of ML for describing, analyzing and developing models of dynamic systems.

**Keywords:** Visible light driven process, Biocatalyst, $CO_2$ utilization, unsaturated dicarboxylic acid

**Introduction.**

Many plastic products used around the world for their high availability are synthesized from petroleum resources, and the large amount of $CO_2$ emissions during their production process and dependence on fossil fuels are serious problems. Based on this background, this research focused on fumarate, unsaturated dicarboxylic acid, that is a raw material for plastics such as polybutylene succinate having a good biodegradability, and unsaturated polyester resin with an excellent versatility and attempted to construct a visible-light driven fumarate synthesis system from $CO_2$ and biomass-derived substance, pyruvate. In a previous study, the synthesis of fumarate from carbon dioxide and pyruvate was achieved by a multi-enzyme system using malate dehydrogenase (MDH) and fumarase (FUM) [1], which have high substrate selectivity under mild conditions, while expensive NADH, the coenzyme of MDH sacrificially oxidized. Then, fumarate production system from $CO_2$ and pyruvate by connecting the multi-enzyme system to a photocatalytic NADH regeneration system consisting of triethanolamine (TEOA) as an electron donor, zinc meso-tetra (4-sulfonatophenyl) porphyrin (ZnTPPS) as a photosensitizer and [Cp*Rh (bpy) ($H_2O$) ]$^{2+}$ (Cp* = pentamethylcyclopentadienyl, bpy = 2,2'-bipyridyl) as a catalyst[2] was invested in this study (**Fig. 1**).

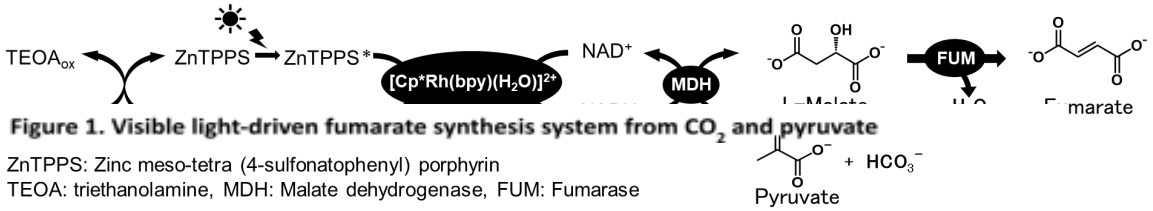

**Figure 1. Visible light-driven fumarate synthesis system from $CO_2$ and pyruvate**

ZnTPPS: Zinc meso-tetra (4-sulfonatophenyl) porphyrin
TEOA: triethanolamine, MDH: Malate dehydrogenase, FUM: Fumarase

**Experimental/methodology.**

The sample solution in HEPES-NaOH buffer pH 7.8 (5.0 mL) was consisted of sodium pyruvate (5.0 mM), $MgCl_2$ (5.0 mM), TEOA (0.2 M), ZnTPPS (10 μM), [Cp*Rh (bpy) ($H_2O$) ]$^{2+}$ (10 μM), $NAD^+$ (0.5 mM), MDH (0.7 U) and FUM (0.5 U). After removing dissolved oxygen from the sample solution, the gas phase was replaced with $CO_2$. The reaction was started by irradiating 250 W halogen lamp as a visible light under at 30 degrees Celsius. The concentration of L-malate and fumarate production was determined by an ion chromatograph system.

**Results and discussion.**

Over the irradiation time, L-malate and fumarate increased steadily and the concentration of fumarate production was estimated to be 49 μM after 5 h irradiation (**Fig. 2**). The result shows that L-malate was provided from pyruvate and $CO_2$ gas using MDH and NADH regenerated by visible light irradiation, and the L-malate was dehydrated with FUM to provide fumarate.

**Keywords: alumina, stability, modelling, ab initio molecular dynamics, metadynamics**

**Introduction.** γ-$Al_2O_3$ has remarkable properties as a support, but it is very sensitive to water. These structural changes can be retarded by the presence of polyols.[1] The mechanism of action of these additives is believed to lie in their chemisorption on the surface that would make γ-$Al_2O_3$ water-resistant[1]. However, little is known on which exposed facet(s) and what site(s) need to be particularly targeted for protection. The optimization of the structure of inhibitors is therefore a challenging task since the exact mechanism of the decomposition of γ-$Al_2O_3$ in liquid water remains unknown. We combine here experiments and theory to provide the atomistic mechanism for the early-stage decomposition of γ-$Al_2O_3$ in liquid water,[2] but also for the adsorption/desorption mechanism of (poly)-alcohols at the γ-$Al_2O_3$ / water interface.[3]

**Experimental/methodology.**

*Experiments:* A first alumina sample was obtained by calcination of commercial boehmite at 600 °C for 4 h. Three other shaped alumina were obtained: Fibers by precipitation of aluminum nitrate in an aqueous medium; Plates and Rods by a hydrothermal treatment of the first sample in water or in acidified water. Polyol adsorption isotherms were performed on the 4 samples using aqueous solutions of various polyols (0.5g.$L^{-1}$ to 8g.$L^{-1}$) and the polyol concentration before and after adsorption was determined by HPLC.

*Modeling.* γ-$Al_2O_3$(110)/water interface was modeled performing *ab initio* molecular dynamics at the PBE-D3 level of theory using CP2K.[4] The reactivity at the interface is assessed by *ab initio* metadynamics.[2,3]

**Results and discussion.** Alumina samples containing particles with different shapes were exposed to a hydrothermal treatment in presence of various concentrations of polyol (sorbitol and xylitol). We determined the minimum surface coverage of polyol at which the decomposition of alumina gets inhibited, a quantity referred to as inhibiting coverage. Since this inhibiting coverage strongly correlates with the fractional area of the (110) facet of the alumina sample and only with this area, we concluded that the decomposition is initiated at the (110) facet. Then, performing *ab initio* metadynamics simulations, we probed the reactivity of this $Al_2O_3$(110)/water interface and identified specific aluminum tetrahedral centers that are particularly reactive with water. We showed that interfacial water molecules are involved in the mechanism, both as reactants for the hydration of aluminum and as intermediates for the proton reshuffling required by the decomposition mechanism. We managed to determine the barriers (all lower than 80kJ.$mol^{-1}$) for the 6 successive addition/elimination steps in a single simulation. Furthermore, the effect of xylitol was rationalized: its adsorption locally rendered the surface more hydrophobic and pushes water molecules away from the Al sites identified as water-sensitive.[2] Then, we investigated in details the adsorption/desorption mechanism of (poly)-alcohols at the γ-Al2O3 / water interface and found that liquid water induces a barrier of at least 20kJ.$mol^{-1}$ due to the substitution of chemisorbed water and the solvent reorganization.[3]

**Keywords:** Single-atom catalysts, CO oxidation, Density Functional Theory, Microkinetic modeling

**Introduction.** Single Atom Catalysts (SACs) are a class of materials which maximize the utilization of noble metals by miniaturizing the active site down to a single metal atom.[2] SACs exhibit strong electronic coupling between the metal center and the host material. Thus, the electronic states of the metal form an ensemble, consisting of the ground and few metastable states [1], with metals in different oxidation states. The impact of dynamic oxidation states in reactivity for SACs towards, e.g. CO oxidation, are not fully understood. As these properties are difficult to study using experimental methods, computational studies can offer valuable insight.

**Experimental/methodology.** We present a Density Functional Theory (DFT) based Microkinetic model (MKM) that includes both ground and metastable states to address the reactivity of $Pt_1/CeO_2$ for CO oxidation. Electronic structure calculations were calculated with the Vienna Ab initio Simulation Package using the Perdew-Buke-Ernzerhof (PBE) functional and Hubbard correction with $U_{eff}$=4.5 eV applied to the 4f-orbitals of Ce. The MKM consists of a system of differential equations which were solved numerically using our own Python-based script. The simulations were carried out for a range of temperatures and different gas-phase compositions mimicking lean and very lean conditions.

**Results and discussion.**

Our DFT and MKM results together show that the reaction mechanism comprises two separate cyclic mechanisms. The cycles are sensitive to temperature, $CO:O_2$ ratio, and access to dynamic charge transfer. The apparent activation energy derived from our model is in agreement with experimental data in the literature. The agreement is only obtained if the dynamic oxidation state of the Pt center is accounted for in the microkinetic model. Based on our findings we suggest that samples with higher n-doping via oxygen depletion should be better in CO oxidation, as they help maintain the active state $Pt^0$ of the catalyst. This provides a general route to improve low-temperature oxidations at metal/oxide interfaces via charge transfer control.

**Introduction**.Light olefins are one of the most important intermediates in organic synthesis. The increasing demand for these chemicals, especially for propylene, drives propylene production for selective technologies, such as propane dehydrogenation or ethene and butenes metathesis.
Olefin metathesis is an important reaction of olefin disproportion, in which olefins are transformed into their homologues with longer or shorter carbon chains. Industrially used catalysts are silica-/alumina-supported molybdenum or tungsten oxides. Generally accepted mechanism (carbene mechanism) for supported $MoO_x$ or $WO_x$ catalyst assumes activation of C=C bonds in olefins into alkylidene intermediates (M=CHR, where M the metal atom, np. Mo or W, R —hydrogen atom or an alkyl group)-catalytically active species, which transforms upon further exposure to olefins yields into metathesis product and new alkylidene species. However, the number of alkylidene species on the surface of ill-defined catalysts usually does not exceed 2% [1]. Acid-base properties of catalysts support, post-synthesis catalyst modification, simple prior-reaction catalysts activation[2], and addition of organo-metallic compounds into the feed stream [3] or photoreduction with CO[4] have been found useful methods to tune the catalytic activity of the oxide-based catalyst.
This communication compares two approaches to activity enhancement of molybdena catalyst: by modification of acid properties of mesoporous silica support by Al-doping and by high-temperature pretreatment of silica-supported molybdenum catalyst in the flow of Ar, CO, $H_2$ and chosen alkanes.
**Experimental/methodology.**A series of Al-doped SiSBA-1 was obtained by post-synthesis silica treatment with ammonium hexafluoroaluminate as an external source of alumina. Obtained series was named AlSBA-1(x), where x-5, 15 and 30 stand for Si/Al molar ratio. Molybdenum oxide-based catalysts were obtained by the incipient-wetness impregnation method. The effect of pretreatment in the flow of Ar, CO, $H_2$, ethane and propane at 650$^o$C was investigated on the $5MoO_x$ supported on pure SBA-1. The catalytic performance in propene metathesis at 50$^o$C was measured by gas chromatography.
**Results and discussion.** It was found, that in comparison to conventional high-temperature pretreatment in inert gas or hydrogen, short pretreatment in hydrocarbon or carbon monoxide atmosphere significantly improves the catalytical activity of $5MoO_x$/SiSBA-1. Improvement in metathesis activity was also found in the case of Al doping of the silica support. However, with the increase in acidity, the decrease in selectivity to metathesis products was observed.

**Introduction**

Selective catalytic upgrading of biomass-derived feedstocks to fuels and chemicals is considered difficult owing to the complexity of the constituent's chemical structure and reaction environment. A firmly established strategy for the conversion of biomass-derived lactone molecules to useful chemicals involves the removal of oxygen-based functionalities via acid-catalyzed dehydrations. Differential stabilizations of the protonated transition state with respect to solvated protons are attributed to significantly causing higher reaction rates in polar aprotic solvents as compared to water. Taking insights from the relative stabilization of acidic protons in different solvents, mixtures of organic solvents with water are proposed, wherein on increasing the fraction of the organic phase, the aqueous phase is observed to preferentially cluster around the reactant with increased hydrogen bonding interactions. Moreover, acid-catalyzed reactions conducted in zeolites, also show an additional positive confinement effect, for which the steric stabilization of the transition state by the zeolite pores, leads to a drastic lowering of the activation energy. Ab-initio Molecular Dynamics (AIMD) simulations carried out in explicit solvent environments and have explained the reactivity of biomass-derived platform lactones in water and tetrahydrofuran (THF).

**Methodology**

AIMD-metadynamics implemented to predict the activation energy barrier and the reaction free energy for the acid-catalyzed dehydration reaction of MVL. Perdew–Burke–Ernzerhof (PBE) functional is used to calculate the electron exchange and correlation energies. Kohn–Sham orbitals are expanded using a short-ranged version of Gaussian-type double-ζ basis set optimized for the molecular system. The electronic density described using a norm-conserving Goedecker–Teter–Hutter pseudopotentials with a plane wave cut-off of 360Ry.

**Results and Discussions**

From the AIMD-metadynamics simulations, it is observed that in the solvated environment of water, a proton is forming stable hydronium ion clusters, whereas, in the case of THF, protonated reactant remains stable. The activation free energy barrier for the dehydration of MVL is observed to be higher by around 45 kJ/mol in water as compared to THF due to possible changes in the rate-determining step; C-H bond activation in water as compared to C-O bond activation in THF.

Intending to unravel the reactivity of MVL dehydration benefits from the confined pores of zeolite, MVL dehydration inside the BEA zeolite is performed in the gaseous phase (in the absence of solvents). The activity barrier for the MVL dehydration in the gaseous phase inside the zeolite drops off to 78 kJ/mol compared to the open solvation environment of water. For MVL dehydration inside zeolite in presence of water, the simulation is performed by occupying the zeolite pore with eight water molecules and MVL, preliminary results show higher reactivity barrier of dehydration in water compared to the gaseous phase inside zeolite.

**Introduction.** The global concern on the depletion of fossil resources and their environmental impact is pushing the scientific community to shift from petroleum-based to sustainable chemicals. Diphenolic acid (DPA) is gaining much interest as a bio-based alternative to the toxic and endocrine-disruptor bisphenol A in the synthesis of epoxy resins, polycarbonates, and isocyanate-free polyurethanes. DPA is usually prepared by solvent-free condensation of phenol and levulinic acid in the presence of a homogeneous Brønsted acid catalyst [1]. Both levulinic acid and phenol are easily available and can be extracted from lignocellulosic biomass [2]. Mineral acids such as hydrochloric and sulfuric acid are traditionally employed as homogeneous catalysts; however, they are highly corrosive and require wastewater treatment. Therefore, heterogeneous catalysts provide a very attractive green alternative thanks to their high safety and facile separation from the reaction mixture. Electrophilic aromatic substitution of phenol occurs in ortho-para positions generating two stereoisomers, but *p*,*p*'-DPA has a higher commercial value as it strongly resembles the chemical structure of bisphenol A. Together with the DPA formation, esterification of levulinic acid might take place as a simultaneous side reaction. It is well-known that trans-esterification is usually slower than esterification in the presence of standard acid catalysts. Therefore, the kinetic probability to produce ester by-products is dramatically reduced when employing ethyl levulinate rather than levulinic acid as the starting molecule. Despite the afore-mentioned advantage, the reaction between ethyl levulinate and phenol has never been investigated until now.

**Experimental/methodology.** In this work, the synthesis of DPA was performed starting from both levulinic acid and ethyl levulinate as substrates. Sulfuric acid, zeolites as well as sulfonic acid resins were screened as catalysts. Very precise kinetic studies were conducted with the best catalysts in an isothermal and isobaric batch reactor by varying the reaction temperature, the reactant molar ratio, and the catalyst loading. The reaction products were identified by $^{1}$H-NMR. The experimental data were used to derive rate expressions based on plausible catalytic reaction mechanisms. The kinetic model was combined with the batch reactor model consisting of ordinary differential equations (ODEs) to estimate the kinetic parameters by non-linear regression.

**Results and discussion.** The experiments revealed that the side reactions are suppressed when using ethyl levulinate as the reactant, showing a selectivity to *p*,*p*'-DPA close to unity for the first time. The catalyst screening revealed that the pore size of the heterogeneous catalyst plays a central role in the catalyst activity. The collected experimental results allowed a reliable quantification of the kinetic parameters. In future, the research will be focused on continuous operation in the presence of the best heterogeneous catalyst. The final goal is process intensification of the DPA production.

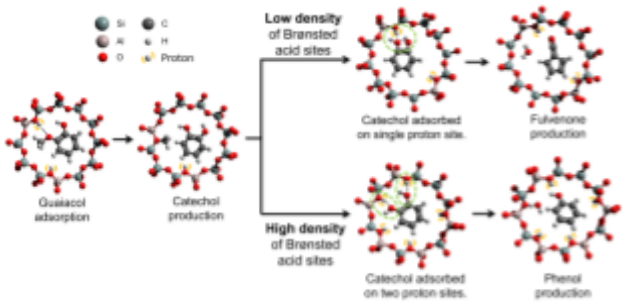
# Detecting Ketenes as Crucial Reactive Intermediates in Catalysis



Patrick Hemberger*[1]
*Paul Scherrer Institute, 5232 Villigen, Switzerland*
**patrick.hemberger@psi.ch*

**Keywords:** ketene, reaction mechanisms, reactive intermediates, operando, photoelectron photoion coincidence, spectroscopy

**Introduction.** Thanks to their reactivity, ketenes, such as ethenone (H2=C=O), are very popular synthons in organic chemistry, as they can undergo a large variety of reactions. Ketenes can yield amides, carboxylic acids, esters and acid anhydrides, but are also utilized as reactants in cycloaddition reactions. Due to their high reactivity, they are impossible to detect using conventional chemical analysis tools such as GC/MS or NMR, however they were identified as crucial reaction intermediates in catalysis.[1]

**Experimental/methodology.** In the last decade a new online and operando detection technique was developed by coupling photoelectron photoion coincidence spectroscopy (PEPICO) and vacuum ultraviolet synchrotron radiation from the Swiss Light Source (SLS) to investigate reactive and elusive intermediates in catalysis.[2,3] PEPICO combines both mass spectrometry and photoelectron spectroscopy as a reaction microscope to explore mechanisms in heterogeneous catalysis. A nearly atmospheric pressure reactor is combined with a molecular beam sampling interface. Thanks to the rapid expansion into high vacuum reactive species exiting the reactor are preserved and, together with stable products, are directly detected and quantified.

**Results and discussion.** In this contribution we will focus on the role of ketene derivatives during lignin catalytic fast pyrolysis (CFP) and the methanol-to-olefin (MTO) process using zeolites: We will discuss how state-of-the-art PEPICO detection tools gained new insights into catalytic fast pyrolysis (CFP) of methoxyphenols as a function of the Brønsted acid site density. Guaiacol (2-methoxyphenol, Figure 1, left) is demethylated to catechol, to undergo either acid-catalyzed dehydroxylation to phenol or dehydration to the fulvenone ketene (c-$C_5H_4$=C=O). Fulvenone branches out and yields many products.[4] By increasing the Brønsted acid site density, catechol dehydration is inhibited by isolating the vicinal hydroxyl groups by surface coordination over the zeolite (see Figure 1). We found a five-fold phenol selectivity increase over high acidity faujasites.

Furthermore, we will discuss the role of ketene and its methylated analogues during the methanol-to-olefine process. Here, we synthesized ketene in-situ from methyl acetate and explored its reactivity over HSZM-5 zeolites. We find strong evidence that the ethenone ($H_2C$=C=O) is methylated on the catalyst surface to intermediately yield methyl ketene, which will rapidly decompose to ethylene as one of the first olefins during the MTO process. A second methylation gives rise to dimethyl ketene, which is the precursor of propene, after subsequent decarbonylation.[5]

# Esterification of levulinic acid catalysed with metal(IV) phosphates: An efficient route to obtain fuel aditives

G. Rocha[1*], F. Lopes[2]

[1]*Chemistry Department, University of Aveiro, Aveiro, Portugal*
[2]*Chemistry Department, University of Aveiro, Aveiro, Portugal*
[*]*grrocha@ua.pt*

**Keywords:** levulinic acid, metal(IV) phosphates, fuel aditives

**Introduction.** Fossil fuels still dominate the energy market. But, the depletion of fossil resources increased the search for renewable alternatives. Among several biomass-based chemicals, levulinic acid (LA) and levulinic esters (LEs) are important platform compounds with wide application, such as fuel additives. The esterification of LA and biomass derivatives can be easily performed if catalysed by different solid acids. The acidic nature of metal(IV) phosphates enclose all the characteristics to act as efficient solid catalysts[1,2].

**Experimental/methodology.** Our work started with the synthesis and characterization of the α- and γ-zirconium phosphates (α- and γ-ZrP). Then, the catalytic performance of these catalysts was evaluated in the esterification reactions of LA with ethanol (EtOH) using the conventional reflux method (CV). Different LA:EtOH molar ratios and catalyst:LA mass ratios were studied at 78°C during 6 hours. The best results were achieved with a LA:EtOH molar ratio of 1:20 and a γ-ZrP:LA mass ratio of 30% (Figure 1). Two products, 5-ethoxy-5-methyldihydrofuran-2-one (ethoxy-PL), an intermediate, and ethyl levulinate (EL) were formed. A blank reaction using the CV method was also performed with the former best conditions.
With the former best parameters, the esterification reactions of LA were performed by the microwave assisted method (MW) at 80°C and 100°C during 2 hours (Figure 1). Good results were obtained with the α- and γ-ZrP either at 80°C or 100°C. Blank reactions were also performed in the same conditions.

Given the good results obtained, the reactions performed by the MW with the α-ZrP at 100°C and γ-ZrP at 80°C were choosed to be monitored each half an hour (Figure 2).

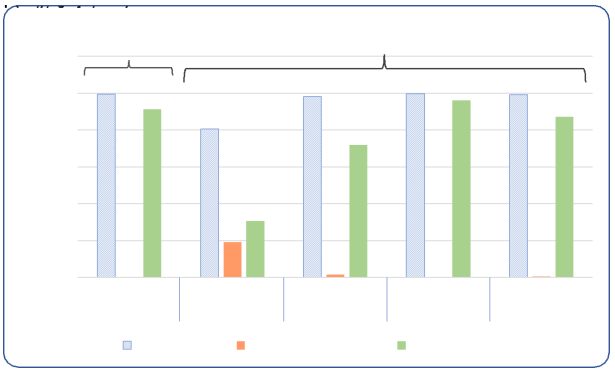

**Figure 1**

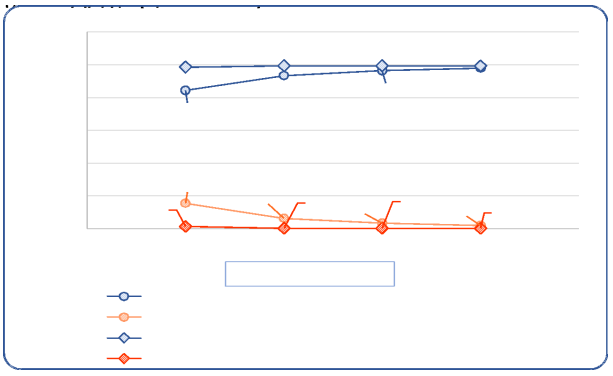

**Figure 2**

**Results and discussion.** The best LA conversions and EL selectivities were obtained with the MW after 2 hours of reaction either for the α-ZrP or γ-ZrP (Figure 1). These results are really good considering that the reaction time was substantially decreased from 6 to 2 hours, with both catalysts, which implies a considerable decrease in energy and water consumption. The results shown in Figure 2 are even more enlightening since it was verified that the monitored reactions start to give very good results even after 1 hour of reaction making our catalysts very promising in a near future.

The formation of the intermediate, ethoxy-PL, could compromise the formation of the EL in good yield. However, this step has been successfully overcome due to the perfect combination of several parameters (catalysts, molar ratio LA: EtOH, mass ratio catalyst:LA, temperature, time of reaction and method used).

**Introduction.** Approaching the level of molecular recognition of enzymes with solid catalysts is a challenging goal, achieved in this work for the competing transalkylation and disproportionation of diethylbenzene catalysed by acid zeolites. The key diaryl intermediates for the two competing reactions only differ in the number of ethyl substituents in the aromatic rings, and therefore finding a selective zeolite able to recognize this subtle difference requires an accurate balance of the stabilization of reaction intermediates and transition states inside the zeolite microporous voids.[1,2] We present a computational methodology that combines a fast screeening based on force fields of all zeolite structures able to stabilize the key intermediates of potentially competing reactions with a more demanding periodic DFT study of the reaction mechanisms on the most promising catalyst candidates.[3,4] Then, the large pore zeolites with different microporous structure of channels and cavities proposed by the computational study have been synthesized, characterized and their catalytic activity tested.

**Experimental/methodology.** Force field (FF) calculations were performed with the GULP software and the Dreiding FF. The Density Functional Theory (DFT) gas phase mechanistic study was performed using the M062X functional and the 6-31g(d,p) basis set, as implemented in the Gaussian09 software. Periodic DFT calculations were performed with the VASP code, using the PBE-D3 funcional and PAW pseudo-potentials.

**Results and discussion.** From gas phase DFT mechanistic studies we identified the key diaryl intermediates involved in transalkylation and disproportionation reactions. Using the OSDB database[5] and FF calculations we selected the fifty zeolite structures that better stabilize the two identified diaryl intermediates. The mechanisms were then recalculated with periodic DFT inside the micropores of the twelve most promising zeolite structures, which were synthesized and tested. The experimentally observed selectivity in each zeolite correlates with the relative stability of the diaryl intermediates involved in both reactions, while the catalytic activity or reaction rate correlates with the calculated activation energy for the rate determining step of the most favourable pathway. Altogether, the internal architecture of the IWV zeolite is the best suited to enhance the transalkylation of diethylbenzene with benzene.

# The Role of Metal in the Anaerobic and Selective Regeneration of $NAD^+$

Jianwei Li[1], Joseph W. Burnett[1], Claudia Martinez Macias[1], Russell F. Howe[2], and Xiaodong Wang*[1]

[1]*Chemical Engineering, School of Engineering, Lancaster University, Lancaster LA1 4YW, United Kingdom*

**Introduction.** Biocatalytic redox reactions provide a useful tool for selective chemical synthesis and have been widely applied to industrial processes due their high rate of reactions, chiral selectivity, and mild conditions. Oxidoreductases have shown be able to oxidise target substrates such as alcohols, aldehydes or carboxylic acids for pharmaceutical applications using cofactor $NAD^+$ **[1]**. But $NAD^+$ is significantly expensive and is consumed in these reactions (forming NADH). Therefore, developing processes that can efficiently oxidise NADH into $NAD^+$, namely regeneration, is important. However, the regeneration reaction has hardly been reported using supported metal catalysts. For the first time, a group of monometallic catalysts comprising Pt, Pd, Au, Ni, Cu and Co supported on non-conductive $SiO_2$ have been examined, with the role of metal revealed. Very surprisingly, with its capacity of donating electrons, NADH has effectively made a thermal/heterogeneous catalytic process "electrocatalytic", governed by the hydrogen evolution reactions.
**Experimental/methodology.** The catalysts (1 wt.%) were prepared by wet impregnation and reduced for 1 h in $H_2$ at 400°C (except Ni at 500°C). The catalysts were characterized by chemical analysis, TPR, XRD, TEM, BET and pore size analysis and XPS. Details on the characterisation procedures, reaction setup and analytical methods are available in our previous report **[2]**.
**Results and discussion.** All catalysts showed similar distributions of metal particle size and mean particle diameters of around 4 nm, and nitrogen adsorption/desorption showed negligible pore blockage of the SBA-15 following addition of metal. The data shown in **Fig. 1a** are NADH conversions after 1 hour of reaction at pH 7. As illustrated, only SBA-15 supported Pt, Pd and Cu give NADH conversions significantly higher than that seen in the absence of catalyst. **Fig. 1b** shows time dependence of the UV-VIS spectrum during NADH conversion over Pt/SBA-15 at pH 7. The decreasing absorbance at 340 nm due to the nicotinamide ring is not accompanied by any change at 290 nm, indicating that the undesired NADH decay reaction **[3]** does not occur in the presence of the heterogeneous catalyst. **Fig. 1c** plots NADH concentration versus time at three different pHs. Clearly, an acidic environment gave the highest conversion (i.e., 80% at pH 5, 30% at pH 7 and 15% at pH 9). The obvious promoting effect of acidic conditions indicates the participation of $H^+$ in the regeneration reaction. The selectivity of the NADH conversion to $NAD^+$ was determined by enzymatic assay as close to 100%. The order of turnover frequencies (Pt >> Pd > Cu > Au, Ni and Co) coincides with those otherwise observed in electrochemical hydrogen evolution reactions. This has revealed that NADH can convert the metal sites into a "cathode" without an external potential and the NADH to $NAD^+$ reaction involves transferring electron and hydrogen atom separately. The catalytic mechanism (**Fig. 1d**) will also be elucidated (i.e., path b is the plausible one) in the presentation.

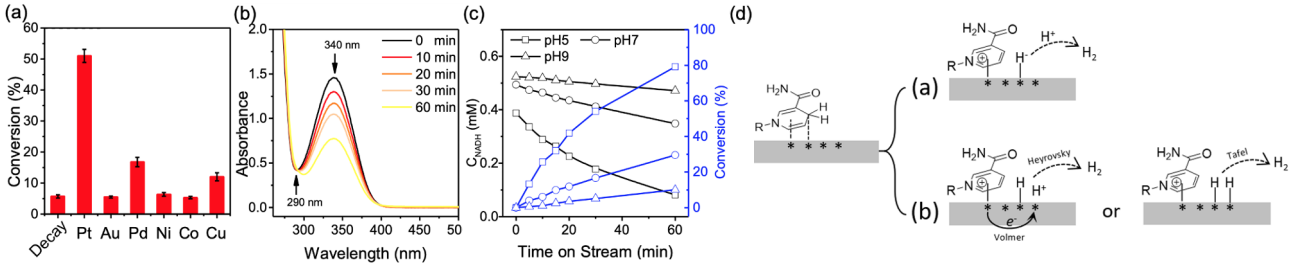

**Fig. 1. NADH conversions over different supported metals (a), UV-VIS spectrum scans over Pt/SBA-15 (b), temporal NADH concentration and conversion at different pH over Pt/SBA-15 (c), plausible reaction pathway (d). Reaction conditions: 37°C, 0.5 mM NADH, pH 7 (for a, b), 100 ml $min^{-1}$ $N_2$, 1 h, 60 mg (a, b) or 30 mg (c) of catalyst.**

**Keywords:** Photocatalytic; Deuteration; Radical; Deuteriodifluoromethylthiolation.

**Introduction.** Deuteration has been used in a wide range of applications such as organic synthesis, drug metabolism, nuclear magnetic resonance analysis and drug development. The incorporation of a fluorinated group into a molecule often alters its physicochemical properties and biological activity. In recent years, difluoromethanethiolated molecules have attracted a great deal of interest. We have developed a new $SCF_2D$-reagent deuterated benzenesulfonothioic acid, difluoromethyl ester ($PhSO_2SCF_2D$). And the introduction of the "$SCF_2D$" group into the aldehyde substrate by photocatalytic means.

**Experimental/methodology.** Adding aldehyde (0.5 mmol), $PhSO_2SCF_2D$ (1.2 equiv, 135 mg), $Ir(dF(CF_3)(ppy))_2(dtbbpy)PF_6$ (1.5 mol%, 8.4 mg), $K_2CO_3$ (0.25 equiv, 17.3 mg), anhydrous MeCN (4 mL) is added to the reaction tube (the feeding process is operated in a glove box). The reaction tube was placed in 10 W blue LEDs (455nm) at room temperature for 12-20 hours. The reaction solution was concentrated by a rotary evaporator, and products was separated by a chromatographic column.

**Results and discussion.** We investigated the scope of the transformation with respect to the aldehydes. In general, benzaldehyde with electron groups are converted smoothly into the desired product in high yields (76-87% yield). Benzaldehydes containing hydroxyl substituents are less reactive and therefore require longer reaction times (29-41% yield). At the same time, aliphatic aldehydes can be successfully applied in this scheme (66-81% yield). Moderate yields were obtained in the case of heterocyclic aldehydes (49-57% yield). SCF2D was also introduced into several complex aldehydes and the desired products were synthesised in moderate yields(47-53% yield).

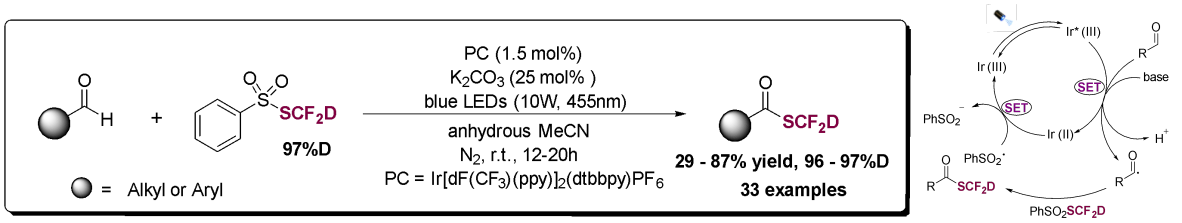

**Figure 1.** Deuterated difluoromethanethiolation of aldehydes

# Lifetime enhancement of methanol-to-olefins process via formaldehyde elimination over Ca species

Jinsong Luo[1], Tianci xiao[1], Chengyuan Liu[1*], Yang Pan[1*]

[1] *National Synchrotron Radiation Laboratory, University of Science and Technology of China, Hefei, China*
[*] *lcy2012@ustc.edu.cn; panyang@ustc.edu.cn*

**Introduction.** Ca-modification has been identified to be effective in promoting propylene selectivity as well as catalyst lifetime during methanol to olefins (MTO) process. Recently we found that increasing Ca loading has caused a surge of $H_2$ and CO in the effluent accompanied by a plunge in aromatics yield. We proved that formaldehyde (HCHO) elimination of over CaO species accounts for this phenomenon and its role during MTO process was systematically studied.

**Experimental/methodology.** To suppress secondary reactions, a home-made low pressure catalytic reactor was employed, which combined with in situ synchrotron radiation photoionization mass spectrometry (SR-PIMS) allows the unambiguous detection of intermediately generated HCHO [1].

**Results and discussion.** Ca-modified ZSM-5 exhibited higher yield of olefins (Figure 1a) during the methanol to olefins (MTO) process. The FT-IR spectra of pyridine adsorbed indicated a reduced Brønsted acid site (BAS) concentration after Ca-modification, which would hinder consecutive reactions of olefins to form aromatic species and thus contributing to lifetime enhancement and promotion of olefin-based cycle [2]. Interestingly, unusual high CO and $H_2$ concentration in the effluent was observed for the Ca-modified samples (Figure 1b), which is accompanied by a decrease in aromatics yield. Such phenomenon is more prominent for samples treated via impregnation method, which introduces much more CaO species compared with those treated via ion exchange method. Further evidence was provided by $CO_2$-TPD, for samples treated via impregnation show higher basicity compared with the one treated with ion exchange method, indicative of higher CaO content. Several metal oxides have been identified to be efficient in decomposing HCHO during MTO process in some previous works [3-4], which triggered our interest into investigating the role of CaO.

Physically mixing HZSM-5 with CaO has also led to enhanced lifetime and the obvious decrease of HCHO was observed (Figure 1c) using PIMS method. The decrease of HCHO yield was accompanied by the decreased yields of butadiene and aromatic species, since HCHO acts as crucial intermediate that involves in the formation of dienes and aromatics. Therefore, the olefin-based cycle was favored via HCHO elimination, leading to higher propylene yield. The mechanistic insight into CaO species supplemented the understanding of Ca-modified HZSM-5, providing guidance for catalyst design of MTO process.

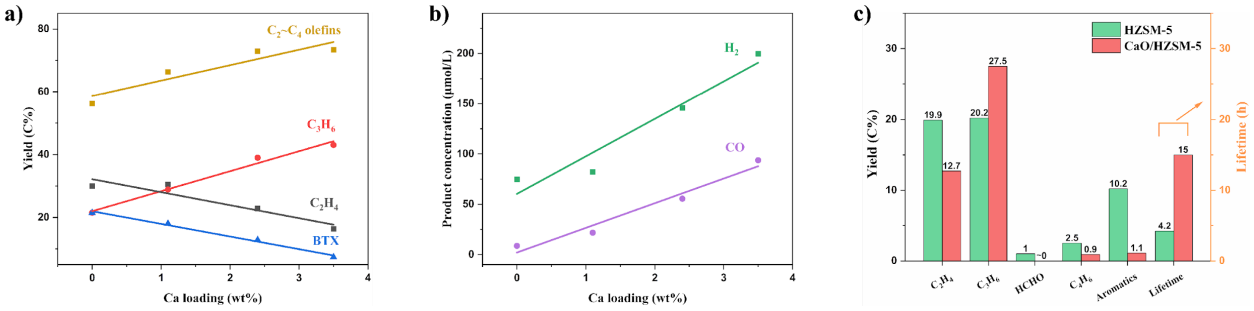

**Figure 1. Yield of main products (a) and product concentration of $H_2$ and CO versus Ca loading (b). Yield of main products and lifetime for HZSM-5 and CaO/HZSM-5 (c).**

# Palladium-catalyzed allylation of *N*-$CF_3$ secondary amines

Leibing Wang,[1] Wenbin Yi[1*]

[1]Nanjing *University of Science and Technology, Nanjing, P.R. China*
[*]*Corresponding Author's E-mail: yiwb@njust.edu.cn*

**Keywords:** Palladium Catalysis, *N*-$CF_3$ Secondary Amines, Allylbenzene.

**Introduction.** Recently, the synthesis of *N*-$CF_3$ derivatives has attracted more and more attention because of the role of trifluoromethyl in changing the lipophilicity, conformation, membrane permeability and enhancing the metabolic stability of the parent molecule. *N*-$CF_3$ secondary amines (R-$NHCF_3$) are excellent precursors for the construction of *N*-$CF_3$ derivatives, but due to the strong electron-withdrawing and steric bulk of trifluoromethyl moiety, their N-H bonds are more inert compared to the non-alpha-fluoro-substituted amines. In addition, the easy elimination of hydrogen fluoride by *N*-$CF_3$ secondary amines also makes it difficult to be exploited. Therefore, it is highly imperative to develop derivative reactions of *N*-$CF_3$ secondary amines with catalytic systems, which will fill the research gap of R-$NHCF_3$ catalytic reactions. In this study, *N*-$CF_3$ allyl compounds were synthesized by the palladium-catalyzed system.

**Experimental/methodology.** Under nitrogen atmosphere, a 10 mL Schlenk flask equipped with a magnetic stir bar was charged with the *N*-$CF_3$ secondary amine (0.5 mmol), palladium chloride (0.05 mmol, 0.1 equiv.), allylbenzene (0.75 mmol, 1.5 equiv.), dimethyl benzoquinone (0.75 mmol, 1.5 equiv.) and dry DMSO (1.5 mL). The mixture was stirred at 100℃. After 18 h, the reaction mixture was cooled to rt. The crude mixture was filtered and concentrated under reduced pressure. The residue was purified by column chromatography on silica gel using the indicated solvent system to give the corresponding products.

**Results and discussion.** In this work, we successfully coupled with *N*-$CF_3$ secondary amines with the assistance of palladium chloride/dimethyl sulfoxide catalyzed allylic C-H activation to obtain novel products. Under standard reaction conditions, the range for the preparation of *N*-$CF_3$ cinnamic compounds from *N*-$CF_3$ secondary amines was investigated. Taking allylbenzene as the olefin substrate, we found that it is compatible with electron-rich or electron-deficient aromatic amines as well as a wide range of functional groups. The respective yields are influenced by electron effect. The secondary amines with strong electron-withdrawing groups (cyano, trifluoromethyl) were transformed to products in moderate yields (55% and 60%). In contrast, substrates with strong electron-donating group (methoxy) were obtained in lower yields (28% and 31%). Halogen atoms on the aromatic ring including fluoro and iodo could be well compatible. It is worth to mention that aliphatic *N*-$CF_3$ secondary amines are poorly tolerated (13%-18%), most probably because of their worse stability.

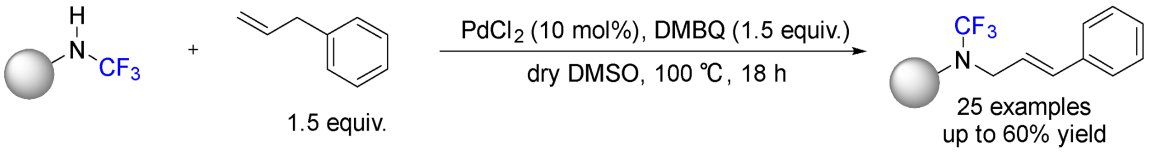

**Figure 1.** The preparation of *N*-$CF_3$ cinnamic compounds from *N*-$CF_3$ secondary amines

# Role of formaldehyde in promoting aromatic selectivity during methanol conversion over gallium-modified zeolites

Tianci Xiao[1], Wu Wen[1], Chengyuan Liu [1*], Yang Pan [1*]

[1]*National Synchrotron Radiation Laboratory, University of Science and Technology of China, Hefei, China*
[*] *lcy2012@ustc.edu.cn; panyang@ustc.edu.cn*

**Introduction.** We proposed that formaldehyde (HCHO) derived from the direct dehydrogenation of methanol over gallium species in HZSM-5 zeolite, promoted aromatic selectivity during methanol conversion through a HCHO-induced aromatic formation pathway[1].

**Experimental/methodology.** To capture the intermediately generated formaldehyde, an in situ low-pressure catalytic reactor combined with in situ synchrotron radiation photoionization mass spectrometry (SR-PIMS) was employed to perform the catalytic conversion of methanol[2].

**Results and discussion.** We found that formaldehyde (HCHO) was remarkably boosted over Ga-impregnated HZSM-5, along with the enhanced selectivity to aromatics. The higher Ga loadings, the higher productions of HCHO and aromatics (Fig. 1a). After eliminating HCHO into CO and $H_2$ by physically mixing $Y_2O_3$ with Ga-impregnated HZSM-5, aromatic production decreased to the level of parent HZSM-5. It indicated that there existed a new pathway to generate aromatics involving formaldehyde participation, which is called as HCHO-induced aromatic formation pathway. Previous works suggested that HCHO can react with olefins to form dienes via Prins reaction (HCHO + olefins ⟶ dienes + $H_2O$), and dienes react stepwise with HCHO to form H-poor products, aromatics and eventually cokes[3].

We verified that the direct dehydrogenation of methanol over $Ga_2O_3$ clusters contributed the more HCHO production. Cationic $GaO^+$ species had no activity to generate HCHO but promoted the dehydrogenative aromatization process of alkenes. In addition, an interesting phenomenon was observed in which the HCHO yield sharply increased after reduction-oxidation treatment of Ga-impregnated HZSM-5. It can be attributed to the migration of gallium from the external surface of the zeolite crystallites to their intracrystalline volume after reduction-oxidation treatment, leading to higher cationic $GaO^+$ concentration and redispersed $Ga_2O_3$ (Fig. 1b). Thus, both the LAS-induced and HCHO-induced aromatic formation pathways were enhanced, resulting in higher aromatic selectivity and faster deactivation. The above perspectives supplement the single LAS-induced aromatic formation mechanism with new insights into the HCHO-induced aromatic formation pathway over Ga-modified zeolites and provide a new thought to manipulate the MTH reaction.

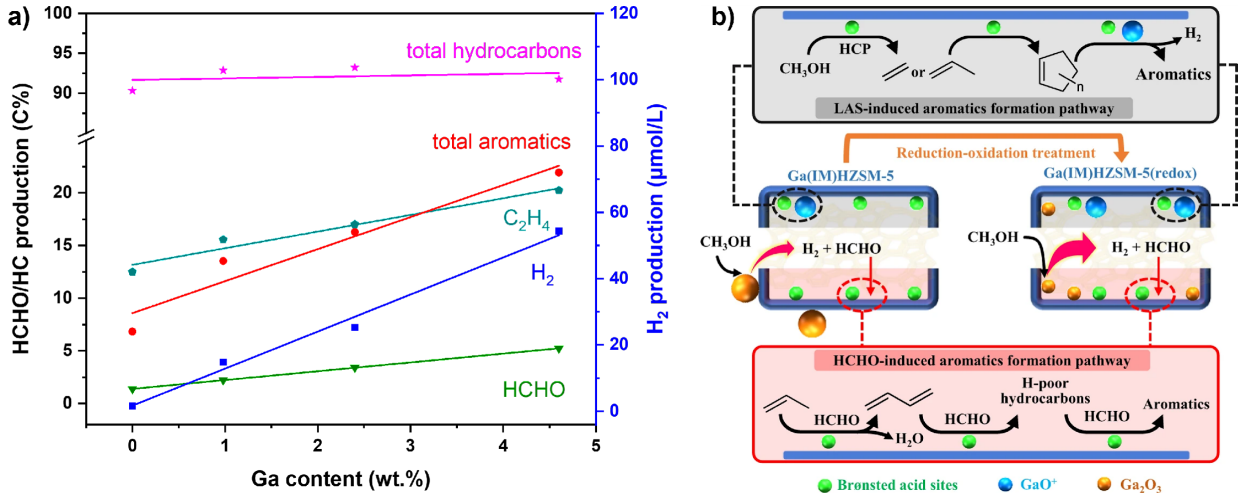

**Fig 1.** The production of HCHO, $C_2H_4$, total aromatics, total hydrocarbons and $H_2$ versus Ga content (a). Proposed evolution mechanisms of catalyst and aromatic formation (b).

**Keywords:** Cyclohexane oxidation, copper complex, catalysis, catalytic mechanism.

**Introduction.**

Due to the high dissociation energy of C–H bonds in saturated hydrocarbons, harsh conditions are required to oxidize this bond. However, the economic importance of this conversion for both chemical industry and environmental aims has led to extensive research to address the activation of C–H bonds under mild conditions (room temperature and ambient pressure) using catalysis.[1,2]

To this end, we are developing copper-based homogeneous and heterogeneous systems as catalysts for the oxidation of alkanes.[3] These systems were inspired by metallo-enzymes belonging to the pMMO (particulate methane monooxygenase) and LPMO (lytic polysaccharide monooxygenase) families in bioorganism. They oxidize methane and polysaccharides, respectively, into corresponding oxygenated species with high turnover rates.[4–7]

In this study, the peroxidative oxidation of cyclohexane to the corresponding alcohol and ketone over selected tetradentate *N,N,N,N*-Cu complexes was investigated.[3] The substrate cyclohexane offers a symmetric source of C–H bonds and is of paramount importance as precursor for adipic acid and nylon production.[8,9]

**Experimental/methodology.**

Catalytic tests were performed in closed vials as well as in a high-pressure PARR reactor. GC-MS was utilized to analyze samples at different time intervals after applying work-up steps, along with a parallel NMR in-situ analysis to establish the mass-balance. Reactivity of Cu(I) and Cu(II) initial oxidation states were compared and screened over different reaction conditions. Computational studies were performed to establish a reaction cycle corresponding to the experimental results. This model was further supported by UV-Vis and XAS studies.

**Results and discussion.**

NMR analysis showed mass-balance of 98 ± 0.03 % during the first 4 h, suggesting high selectivity to alcohol/ketone without over-oxidation products. Testing results showed higher reactivity when the Cu(I) complex is used. UV-Vis analysis of the reaction mixture at different time intervals revealed some interesting features. A change in catalyst resting state, from Cu(I) to Cu(II), was observed with time on stream, indicative of a change in the catalytic system that alters the relative rates of Cu oxidation and reduction; respectively. This observation was corroborated by UV-VIS measurements, which showed a shift in the absorption frequency of the Cu(II) d-d transition band upon oxidation from the Cu(I) state during reaction, compared to the Cu(II) version of the parent complex. GC-MS and UV-Vis data also suggest a double-role of water in these systems, i.e.; as an catalyst activator, yet simultaneously a source of catalyst degradation. These findings were further supported by XAS measurments to investigate the mechanism as well as Cu(I)/Cu(II) cycle stability over time between the two complexes. Both experimental and computational studies suggest a redox Cu(I)/Cu(II) cycle during the first 4 hrs.

# Unraveling the reactivity of metastable active sites in methane dehydroaromatization

Iqra Ahangar[1], and M. Ali Haider[1*]

[1]*Department of Chemical Engineering, Indian Institute of Technology Delhi, Hauz Khas, New Delhi, India*

**Corresponding authors: haider@iitd.ac.in*

**Keywords:** MDA, Mo/ZSM-5, metastable active sites, kinetics.

**Introduction.**

Molybdenum (Mo) impregnated on zeolite ZSM-5 is the most studied and promising bifunctional catalyst for directly transforming methane to aromatics in a non-oxidative environment. The molybdenum carbides formed during the progress of the reaction exhibit notable catalytic behavior in methane activation and formation of crucial intermediate [1]. The high-energy metastable Mo carbide structures are more reactive and play a vital role in cluster catalysis as numerous isomers of the cluster become accessible under different reaction atmospheres. This indicates the dynamic nature of the catalyst and suggests that the active site might not be just one. So, this gives an intuitive idea that at high temperatures, these metastable structures do all the turnovers [2]. In the present study, using the DFT studies, two different forms of Mo carbide having the same stoichiometric ratios of Mo: C anchored in the zeolite cage have been investigated to gain an insight into the mechanism of methane activation to the formation of possible intermediate for benzene formation. Furthermore, the Mars Krevelen type mechanism has been postulated in the MDA (methane dehydroaromatisation), considering direct ethene formation without undergoing ethane formation on both metastable and global minima carbide cluster active sites.

**Experimental/methodology.**

To investigate methane to $C_2$ conversion, we have utilized electronic structure methodology based on the Density Functional theory (DFT). The software package DMol3 code implemented in Material Studio program package 2020 (Biovia, San Diego) was used in the current study. Spin-polarized DFT calculations were performed to comprehend methane dehydrogenation to ethane, ethylene, and acetylene on a $Mo_2C_6$ cluster encapsulated in zeolite ZSM-5.

**Results and discussion.**

In the present work, the metastable and most stable $Mo_2C_6$ cluster was separately anchored on a single Al atom binding through only one Mo atom in 10 MR ring of ZSM-5. The first C-H bond of methane is activated on the metastable Mo carbide active site with a barrier of 72 kJ/mole, which is reduced by half what is observed in the most stable active site (133 kJ/mol). The active site for another methane is methyl metal. The second C-H bond is activated at a distance of 4.92 Å with an activation barrier comparatively higher than the first C-H activation. The C−H activation of ethylene ($C_2H_4$) to form vinyl ($C_2H_3$) and acetylene ($C_2H_2$) are found to be unfavorably owing to high activation barriers (103 kJ/mol and 125 kJ/mol, respectively). Ethane ($C_2H_6$) and ethyl ($C_2H_5$) dehydrogenation, having a considerably lower barrier of 81 kJ/mol and 90 kJ/mol, respectively, would be a preferred route; hence the acetylene formation is considered unlikely in this reaction mechanism. A similar trend was observed in the most stable molybdenum carbide active site. Haider and co-workers also demonstrated that the dehydrogenation of ethane to ethylene and further dehydrogenation to acetylene on bare $Mo_2C_6$ clusters is difficult [2]. It is not worth mentioning that these metastable active sites are equally helpful in C-H activation and C-C coupling. Furthermore, a possible alternative route for intermediate formation, considering the dynamic nature of the active site, has been explored using DFT simulations where the proposed pathway takes the carbon of the active site in intermediate formation.

# Performance of a Mn catalyst for the ozone oxidation of methyl ethyl ketone and by-products formation at room temperature

Hae-Young Ahn, Jin-Soo Jeon, JiHyeon Song
Department of Civil and Environmental Engineering, Sejong university, Seoul, South Korea

**Keywords:** Manganese oxide catalyst, Ozonation, Methyl ethyl ketone, By-products

**Introduction.**
Organic solvents used in gravure printing processes commonly contain high concentrations of methyl ethyl ketone (MEK). Ketones, such as MEK, are known to be difficult to remove by conventional adsorbents such as activayed carbon. Therefore, as an alternative, catalytic oxidation processes at room temperature have been studied and applied. This study was conducted to develop a pilot-scale system to oxidize MEK in the presence of ozone using a manganese oxide catalyst at room temperature and to determine ozone oxidation efficiencies and oxidation by-products.

**Experimental/methodology.**
Gamma alumina was selected as a support for the Mn catalyst. Manganese acetate ($(CH_3COO)_2Mn{\cdot}4H_2O$) was used to impregnate manganese on the surface of the support. The support was immersed in the Mn solution for 10 minutes, dried at 105°C for 2 hours, and calcinated at 800°C for 6 hours. A cylindrical column was filled with 50 mL of the ozone-active Mn catalyst at room temperature, and an air stream mixed with MEK at the inlet concentration of 500 ± 50 ppm was continuously introduced at a gas hourly space velocity (GHSV) of 18,000 $hr^{-1}$. The ozone oxidation of MEK is $C_4H_8O + 11O_3 \rightarrow 4CO_2 + 4H_2O + 11O_2$, and the stoichiometric $O_3$/MEK ratio is 11:1 for the complete oxidation. This study was to investigate the oxidation efficiency of the catalyst at different ozone ratios; therefore, the $O_3$/MEK ratios of 3, 7, and 11 were tested.

**Results and discussion.**

The concentrations of MEK, ozone, and $CO_2$ after the catalytic oxidation were measured in the column outlet. More than 99.9% of ozone was removed by the catalytic reaction at all the $O_3$/MEK ratio of 3, 7, and 11. The MEK removal rates were 23.9%, 91.3%, and 97.8%, respectively. It is interesting to note that the MEK removal rate was greater than 90% at the $O_3$/MEK ratio of 7, which is less than the stoichiometric ratio required for the complete oxidation. Consequently, the Mn catalyst prepared in this study showed the MEK and ozone removal rates greater than 90% at room temperature, even though the $O_3$/MEK ratio was less than the stoichiometric complete oxidation. However, the $CO_2$ conversion rates were found to be 27.7%, 59.3%, and 97.7% at the $O_3$/MEK ratio of 3, 7, and 11, respectively, showing that the $CO_2$ conversion rate decreased with decreasing the $O_3$/MEK ratios.

By-products generated from the catalytic ozonation of MEK were qualitatively analyzed, and 2,3-butanedione was the most abundant compound. Methyl acetate, acetaldehyde, and acetic acid were also found after the ozonation of MEK. As the $O_3$/MEK ratio increased, the conversion of 2,3-butanedione to fewer carbon compounds including methyl acetate, acetaldehyde, and acetic acid was prompted. Further studies on the oxidation mechanisms and catalyst poisoning by the accumulation of the by-products are required under various $O_3$/MEK ratios.

**Abstract:**

RuNPs stabilised by an amino-decorated imidazolium-based polymer immobilized ionic liquid is a remarkably efficient catalyst for the dimethylamine borane mediated reduction of quinolines to 1,2,3,4-tetrahydroquinoline (THQ) via 1,2-dihydroquinoline (DHQ). The initial TOF of 610 mol of quinoline converted mol $Ru^{-1}$ $h^{-1}$ for the reduction of quinoline is among the highest to be reported for a metal nanoparticle-based catalyst. Under optimised conditions, a wide range of substituted quinolines were reduced to a mixture of the corresponding 1,2-dihydroquinoline and 1,2,3,4-tetrahydroquinoline in short reaction times and ultimately to the 1,2,3,4-tetrahydroquinoline as the major product by extending the reaction time accordingly. Remarkably, the reduction of 3-substituted quinolines occurred with 100% selectivity for the corresponding partially reduced 1,2-dihydroquinoline, which wwas obtained as the sole product in near quantitative yield. Hot filtration experiments showed that the active species was heterogeneous and post reaction analysis of the catalyst using TEM revealed that the nanoparticles remained monodisperse with an average diameter of 1.8 nm which is similar to that of a freshly prepared sample of catalyst.

**Keywords:** Oxidation, Metal Organic Framework, Modified UiO-66, Kinetic Modeling, Complex Reaction

**Introduction.** As improving deep desulfurization is essential for producing ultra-clean sulfur-free fuel, Catalytic Oxidation Desulfurization (CODS) is a practical approach for removing planar sulfur compounds.[1] CODS process includes oxidation and the extraction step for the removal. The porous zirconium terephthalate UiO-66 provides a significant contribution to catalytic purposes because of its large surface area, tunable porosity, and reusability.[2] The insertion of functional groups into organic linkers affect on the ODS performance of UiO-66(Zr) due to electron induction effect.[3] Introduction of nitro-group in BDC linker can reduce the electron density of Zr sites in UiO-66 via the benzene ring conduction and thus enhance the ability to gain electrons and therefore increasing the Lewis acidic nature of zirconium clusters. Ultimately leading to stronger interaction with aromatic sulfur containing compounds. UiO-66-$NO_2$ exhibited superior catalytic activity in CODS reactions because it has a strong ability to gain electrons.[3] In this study, a systematic procedure[4] is applied to derive the overall rate equation expressions for reactant/product molecules cooperated in the reaction networks based on the theory of complex reactions for DBT removal in CODS reaction over UiO-66-$NO_2$.

**Experimental/methodology.** Heterogeneous catalytic oxidation is a multi-component reaction procedure that goes through elementary reaction steps. The mathematical procedure of the overall reaction has been employed by MATLAB to justify the overall items of complex kinetic mechanisms. The approach of overall reaction has been applied for this study to investigate the mechanism of CODS of Dibenzothiophehe (DBT) over MOF. The proposed combined mechanism consists of 11 elementary reaction steps. CODS reactions were conducted in a 22 mL reactor. For the model fuel (MF), 1000 ppm of DBT was dissolved in n-dodecane, and with the volume ratio 1:1, acetonitrile was added to the reactor as the polar phase. According to the experiment design, the specified amount of MOF was added to the reactor; then, hydrogen peroxide was supplied after heating the reactor to a predefined temperature. The aqueous and fuel phase was collected after the reaction had been completed and then analyzed.

**Results and discussion.** Predicted values of component yield including DBT, its sulfone and, sulfoxide were in appropriate accordance with the experimental data. Eventually, this study smooths the way for similar research toward the joint of complex reactions and multiple reaction/component mechanisms.

Figure 1. Procedure employed to derive the overall rate equation expressions for CODS network

Table 1. Obtained reaction routes (RR) and overall reactions for CODS over UiO-66-$NO_2$

| Reaction Route | Expression | Overal Reaction | |
|---|---|---|---|
| RR1 | S1-S3+S10 | $DBT + H_2O_2 == Sulfoxide + H_2O$ | N(1) |
| RR2 | S9-S5+S10 | $Sulfoxide + H_2O_2 == Sulfone + H_2O$ | N(2) |
| RR3 | S4-S9+S10-S6 | $RS + Sulfone == 2Sulfoxide$ | N(3) |
| RR4 | S3-S5+S7-S8 | - | N(4) |
| RR5 | S2+S4+S10 | $DBT + H_2O_2 == Sulfoxide + H_2O$ | N(5) |
| RR6 | S11+S7-S5+S2 | - | N(6) |

# First Principles Investigation of Interwoven Electronical and Energetical Properties of $Pt_1O_x/CeO_2$ Single Atom Catalysts towards CO oxidation

Sarah Bernart[1], Jelena Jelic[1], Felix Studt[1,2]

[1]*Institute for Chemical Technology and Polymer Chemistry (ITCP), Karlsruhe Institute of Technology (KIT), Karlsruhe, Germany*
[2]*Institute of Catalysis Research and Technology (IKFT), Karlsruhe Institute of Technology (KIT), Eggenstein-Leopoldshafen, Germany*
[*]*felix.studt@kit.edu*

**Introduction .** In this study we focus on Pt single sites supported on the ceria surface facets {100}, {110} and {111} and the accordingly activity towards CO oxidation related to the environmental conditions by means of temperature and oxygen pressure. The catalyst is investigated by DFT methods on a GGA+U level of theory and the Bader analysis. The Mars-van Krevelen and the Langmuir-Hinshelwood mechanism were studied to describe the surface oxygen chemistry of the ceria supported noble metal. The temperature dependence between the competing rate-limiting steps characteristic for each of the mechanisms were found to result in a change of the rate-limiting barriers heights by increasing temperature.

**Methodology.** The DFT calculations were performed using the Vienna Ab initio Simulation Package (VASP) [1,2] in connection with the Atomic Simulation Environment (ASE) [3]. A plane-wave basis set with a cut-off energy of 415 eV [4], the projector augmented wave method [5, 6] and the Bayesian error estimation functional with van der Waals (BEEF-vdW) [7] exchange correlation functional were used. Due to the localized Ce 4f orbitals in ceria, we applied the generalized gradient approximation (GGA) + U (U = 4.5 eV for the 4f electron of ceria in the implementation of Cococcioni and de Gironcoli. [8, 9]

**Results and discussion.** The Langmuir-Hinshelwood mechanism investigated in this study involves no surface lattice oxygen vacancy. The first step is a dissociation of a $O_2$ molecule adsorbed directly on the Pt single site leading to a $Pt^{+IV}O_2$ species. The Mars-van Krevelen mechanism investigated in this study involves one surface lattice oxygen vacancy.

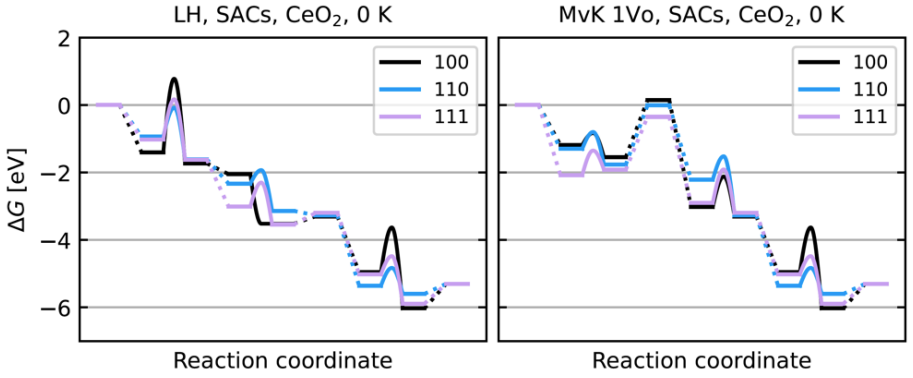

**Figure 1: Potential energy diagrams of the Langmuir-Hinshelwood and the Mars-van Krevelen mechanism for the CO oxidation on the ceria surface facets {100},{110} and {111}.**

**Keywords:** heterogeneous catalysis, ORR, magnetism, DFT+U, segregation

**Introduction.** In the last years the relationship between magnetism and heterogeneous catalysis has regained substantial attention since the pioneering works of Selwood[1] and Hedvall[2] in mid-20$^{th}$ century. An outstanding example of this relationship is represented by Pt-bimetallic alloys containing ferromagnetic metals like Fe, Co and Ni, which have been experimentally investigated as good candidates for cathode materials in Proton Exchange Membrane fuel cells[3]. Since the electronic structure-atomic structure-catalytic activity correlation is at the root of catalysis, the possibility of the influence of magnetic properties in the catalytic activity of these compositions cannot be neglected. Here we present a computational study on the influence of magnetism in the structural, chemisorption and stability properties of multilayered $Pt_3M$ (M= Fe, Co, Ni) (111) compositions.

**Experimental/methodology.** The work is performed by PBEsol + U method (U= 2.4 eV)[4,5]. Spin- and non-spin calculations are carried out to understand the influence of spin potentials in the atomic arrangement, chemisorption and resistance against segregation of $Pt_3M$ (M=Fe, Co, Ni) (111) alloys[4,5].

**Results and discussion.** The study begins with a detailed structural screening of $Pt_3M$ (M= Fe, Co, Ni) slab models with different atomic distributions. The global minima for all the three compositions are found to be ordered structures with multilayer organization among the magnetic 3*d*-metals and the non-magnetic metal Pt (see Figure 1)[4,5]. The chemisorption enthalpy values of O* atoms on these magnetic (FM and AFM A-type) multilayered models show a weaker binding of about 0.16-0.22 eV in comparison with the non-magnetic isostructural ones[4]. Moreover, magnetic multilayered $Pt_3Fe(111)$, $Pt_3Co(111)$ and $Pt_3Ni(111)$ also show a general good resistance against the segregation of FM 3*d*-metal atoms under vacuum and oxygen environment[4]. In the case of the non-magnetic isostructural slabs such stability is preserved under vacuum only, while the lack of magnetic interactions favours the segregation of 3*d*-metals when oxygen atoms are chemisorbed onto their surfaces[4]. These results show that a complete and realistic treatment of the electronic structure-atomic structure−activity relationships in heterogeneous catalysis relies on the correct evaluation of orbital magnetism.

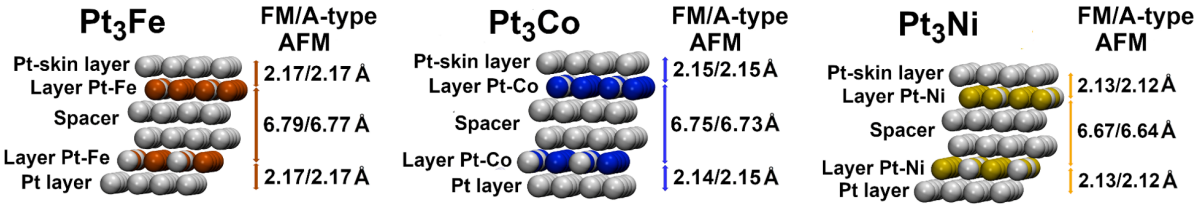

**Figure 1.** Multilayered organization of the global minima $Pt_3Fe(111)$, $Pt_3Co(111)$, and $Pt_3Ni(111)$ nanostructures with estimated distances (in Å) between the layers for the FM (right) and A-type AFM (left) orderings, respectively.

# Interpretation of transient effects on $NH_3$ oxidation over $Pt/Al_2O_3$: an experimental and modelling study for automotive applications

R. Bono*[1,2], R. Uglietti[2], G. Keitl[2], A. Scheuer[2], A. Dreizler[1], M. Votsmeier[1,2]

[1]*Reaktive Strömungen und Messtechnik, Technische Universität Darmstadt, Darmstadt, Germany*
[2]*Umicore AG & Co. KG, Hanau, Germany*
**bono@rsm.tu-darmstadt.de*

**Introduction.** To decrease tail-pipe emissions of $NH_3$, the implementation of the Ammonia Slip Catalyst (ASC) in the vehicles after-treatment systems has become of primary relevance. The ASC consists in a $Pt/Al_2O_3$ bottom layer responsible for $NH_3$ direct oxidation, and a top layer responsible for the Selective Catalytic Reduction (SCR) of the $NO_x$ formed in the bottom layer. Focusing on the bottom layer, although extensive research on the mechanisms has been carried out, some significant open questions remain. In particular, the activity of the bottom layer at low temperatures (< 300 °C) has been proven to depend on the catalyst history [1], but no detailed mechanistic explanation has been given. In this study, we propose an interpretation of such phenomenon, ascribing it to the oxide formation on the Pt surface, which is known to be particularly stable at low temperatures [2]. To accomplish the task, transient experiments on $NH_3$ oxidation have been carried out, together with modelling the catalyst activity.

**Experimental/methodology.** The $NH_3$ oxidation activity of a $Pt/Al_2O_3$ wash-coated monolith, at different stages of hydrothermal aging (0 to 100 h), has been tested at different temperatures (from 150 to 300 °C), using a synthetic gas test bench and an FTIR gas analyser. For each temperature, the test has been run until steady conversion was reached. Additionally, a 1D+1D monolith model has been used to fit the transient profile of $NH_3$ conversion by including the reactions for Pt oxide formation and depletion.

**Results and discussion.** Figure 1 shows the first 5 minutes of the $NH_3$ conversion trend against time for each investigated temperature, with respect to the fresh sample. At the beginning of the test, no oxygen is fed in the system and no oxide is present on the Pt surfaces. Then, $O_2$ is fed to the reactor, initiating the $NH_3$ oxidation. Around 30 seconds, an initial maximum is reached, which has been ascribed to the conversion on an oxide-free Pt surface. Afterwards, above 260 °C, a stable catalyst activity is observed. Instead, at lower temperatures, the catalyst shows a progressive deactivation, until a steady conversion is achieved. This effect has been ascribed to the slow formation of detrimental Pt oxides over time, hindering the conversion. Afterwards, we have applied this concept to a 1D+1D monolith model, and the simulations of both fresh and aged states are ongoing.
As a whole, this work provides new insights on the Pt bottom layer activity at low temperatures, which are of primary interest in the automotive industry.

**Keywords:** electrochemical hydrogenations, $H_2$ evolution, surface coverages, catalyst design, DFT.

**Introduction.** Industrial hydrogenations of platform chemicals often employ organometallic catalysts and organic solvents.[1] One way to cut down the associated chemical waste is the electrification of such processes by replacing organometallic reagents with electrodes based on earth-abundant elements, and organic solvents with $H_2O$ and alcohols.[1] However, the use of aqueous electrolytes is hindered by the competition with the hydrogen evolution reaction (HER).[2] As HER activity is reduced under alkaline conditions,[2] we propose that the ideal catalyst for electrochemical hydrogenations (ECH) should work efficiently at basic pH, hydrolysing $H_2O$ to source the H atoms for the subsequent hydrogenation steps. H atoms should also be retained on the surface with close to thermoneutral binding strength ($\Delta G_{*H}$) at the applied potential, and the catalyst should be based on abundant and cheap elements. With these premises, we computationally guided the design of cost-efficient metal cathodes for the ECH of acetophenone (AC) to 1-phenylethanol.

**Methodology.** Periodic DFT calculations with the Bayesian error estimation functional (BEEF)[4] were carried out using the Vienna Ab Initio Simulation Pacakge (VASP, version 5.4.4) [3] and an energy cut-off of 500 eV for the plane waves. The Brillouin zone was sampled with a Γ-centered 5×3×1 k-point mesh.

**Results and discussion.** As $H_2O$ hydrolysis is unfavourable on AC,[5] a catalyst exhibiting a H coverage was sought to achieve this model ECH. To prove our hypothesis, we employed metal cathodes covering a wide range of $\Delta G_{*H}$, *i.e.* Ag, Au, Cu, In, Ni and Pt. Calculations indicated that Ag(111) and Au(111) exhibited 25% of the *fcc* sites occupied by H atoms with moderately endergonic $\Delta G_{*H}$ values under relevant ECH conditions. On the other hand, Cu(111) featured 75% of such sites covered with H atoms and moderately exergonic $\Delta G_{*H}$, while Ni(111) and Pt(111) presented all those sites terminated with H atoms and highly exergonic $\Delta G_{*H}$ (*Fig. 1a*). Finally, we predicted the In(101) surface to be clean due to the highly endergonic $\Delta G_{*H}$ (*Fig. 1a*). Based on these findings, we envisioned the best ECH activity with Ag, Au and Cu, and poor conversions with In, which lacked the H coverage, Ni, which had to pay a higher energy penalty for H desorption and AC hydrogenation, and Pt, due to its outstanding HER activity.[2] These predictions were confirmed both experimentally (*Fig. 1b*) and computationally with detailed mechanistic studies, which unveiled the role of solvent $H_2O$ molecules which shuttle H atoms from the surface coverage to AC (*Fig. 1c*). Overall, this work demonstrates the importance of assessing the surface coverage of electrocatalysts under relevant conditions, and highlights the power of joint computational and experimental studies in guiding the discovery of materials to electrify industrial chemical syntheses.

# Theoretical modeling of pathways for the transformation of glucose and fructose to levulinic acid using sulfuric acid.

A. Kącka-Zych[1], N.Sobuś[1], I.Czekaj[1*]

[1] *Faculty of Chemical Engineering and Technology, Cracow University of Technology, Warszawska 24, 31-155 Krakow, POLAND*

**Keywords:** sulfuric acid; glucose, fructose, DFT; Biomass; Levulinic acid

**Introduction**

Levulinic acid (LA) has been identified as a promising biocompound derived from biomass. It is a platform molecule that is used as a precursor for pharmaceuticals, plasticizers and various other additives (Figure 1) [1,2]. LA arises as a result of depolymerization and dehydration of the cellulose fraction [3]. Theoretical modeling involved understanding the changes that occur during the conversion of glucose to levulinic acid (LA) proceeding in the presence of an $H_2SO_4$ catalyst.

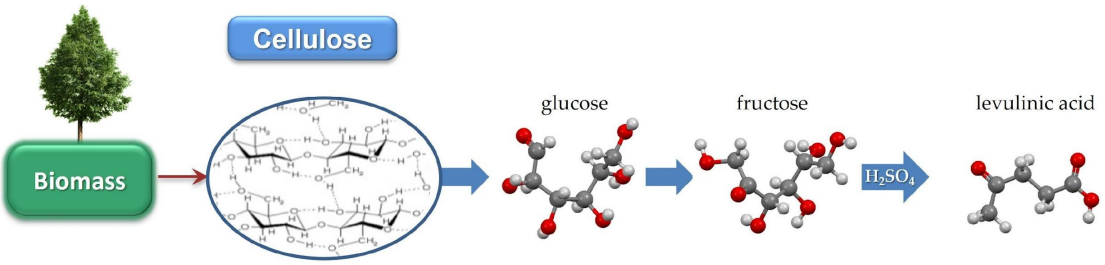

Fig. 1. Reaction pathways of biomass into glucose and levulinic acid.

**Experimental/methodology.**

All calculations associated to the conversion of sugars to levulinic acid were performed using: the Gaussian (PBE0 functionals, 6-31G(d,p) and 6-311+G(d,p) basis sets), the (QST2) algorithm for TSs. the conceptual density functional theory (CDFT) for global reactivity indices (GS, B3LYP/6-31G(d) level), the TopMod for Electron Localization Function (ELF).

**Results and discussion.**

Modeling included the conversion of glucose to fructose, fructose to hydroxymethylfurfural (HMF), and then HMF to levulinic acid without/with $H_2SO_4$ and in different temperatures (298 and 493K). Two mechanisms of glucose to fructose conversion were considered: cyclic and open chain mechanism. Cyclic mechanism is forbidden from kinetic point of view at low temperature. At higher temperatures both paths are allowed. Conversion of fructose via HMF to LA involves the steps of protonation/deprotonation and dehydration reactions as well as formic acid desorption.

**Introduction.**

Transition metal exchanged Si-rich zeolites are promising materials for redox-catalysis [1]. The periodic DFT methodology allows a modeling of the reactivity of transition metals exchanged in zeolites [2]. Periodic DFT calculations of the reactivity of two cooperating transition metal cations in zeolites were essential for the discovery of a new type of the active sites capable of the M(II) to M(IV) redox cycle able to activate small low reactive molecules [3,4].

**Methodology.**

Periodic DFT employing the VASP program.

**Results and discussion.**

In this contribution, we report on our study of the reactivity of vanadium V(II) cationic sites with small molecules as, for example, dioxygen. We describe the redox behavior and show that vanadium V(II) cationic sites exhibit desired redox properties for the selected catalytic reactions.

**Keywords:** Biofuels, Carboxylic acids, Ketonisation, Zirconia, DFT.

**Introduction.** Production of liquid fuels from biomass have gained increasing industrial and academic attention as alternative energy source to fossil-based fuels. Biofuels are usually obtained as a mixture of organic species with high content of oxygenated derivatives, which required chemical upgrading for improvement of its physicochemical properties prior to their use as fuels.[1] Acid–base bifunctional catalysts are particularly desirable in this context, which can be tuned by different approaches in order to optimise their activity and selectivity.[2] Here, we investigate how distinct dopants can affect the acid-base properties of zirconia based catalysts and their effect over the ketonisation of organic acids.

**Experimental/methodology.** All calculations were performed using the VASP package within the framework of periodic density functional theory and at RPBE-D3+U ($U_{Ti(d)}$ = 4.0 eV) level. The Zr $4s^2 4p^6 4d^2 5s^2$ and O $2s^2 2p^4$ orbitals were explicitly included as valence electrons. Brillouin zone sampling was performed using the Monkhorst–Pack scheme with a k-point grid of 5 × 5 × 1 together with a Gaussian smearing broadening of 0.02 eV. Forces and electronic SCF convergence were set at $10^{-2}$ eV $Å^{-1}$ and $10^{-5}$ eV, respectively. All surfaces were previously constructed and characterised regarding their acid-base properties.[2,3]

**Results and discussion.** The ketonisation reaction has been proposed to occur via several putative mechanisms. Currently, the β-ketoacid mechanism is the most plausible one based on previous experimental and computational results.[1] The two most important steps of the β-ketoacid mechanism are investigated here: enolisation of the adsorbed organic acid and C-C coupling step to afford α-hydroxy γ-carboxy alkoxide intermediate (**Table 1**). According to the computed energy profile, the rate-determining step for the acetic acid reaction over clean c-$ZrO_2$ (111) is the enolisation step ($E_{barrier}$ = 36.1 kcal $mol^{-1}$). Similar results were computed for propionic acid. The computed energy barrier for the C-C homo- and cross-coupling step presented only slight variations, ranging between 16.7 and 20.3 kcal $mol^{-1}$.

**Table 1.** Energy profile for enolate formation and C-C coupling of acetic acid over c-$ZrO_2$ (111). Reactivity of acetic acid is compared for selected examples of modified zirconia surfaces. Energies are given in kcal $mol^{-1}$.

| *Acetic acid* | $HAc_{ads}$ | $TS_{enol}$ | Enolate | $2^{nd}$ $HAc_{ads}$ | $TS_{C-C}$ | Interm. |
|---|---|---|---|---|---|---|
| c-$ZrO_2$ (111) | -38.4 | -2.3 (36.1) | -22.3 | -43.1 | -26.4 (16.7) | -38.9 |
| t-$ZrO_2$ (101) | -43.9 | -16.2 (27.7) | -33.4 | -67.9 | -46.6 (21.3) | 64.6 |
| Ca-doped c-$ZrO_2$ (111) | -53.2 | -30.6 (22.6) | -37.1 | -74.8 | -35.5 (39.3) | -59.0 |
| Y-doped c-$ZrO_2$ (111) | -52.4 | -29.4 (23.0) | -38.4 | -72.6 | -51.1 (21.5) | -60.3 |

Two examples of modified surfaces investigated here are also shown in **Table 1**: Ca- and Y-doped c-$ZrO_2$ (111). Interestingly, a significant drop in the energy barrier for enolisation was computed for both doped surfaces. On the other hand, the computed barriers for the C-C coupling step were distinctly modified for these same systems: reduction over Y-doped c-$ZrO_2$ (111) and increase over Ca-doped c-$ZrO_2$ (111). The origin of such effect is shown to be due to distinct strength of acid-base pairs and adsorption modes, as well as resulting changes to TS structures. These findings are used in the rationalisation of the role of distinct dopants over the ketonisation reaction of organic acids. Furthermore, they provide insight into the identification of more eficient and selective catalysts for the chemical upgrading of biofuels.

**Keywords:** MTO-process, aromatic cycle, paring mechanism, DFT calculations

**Introduction.** The methanol-to-olefins process is a possible way to convert sustainably produced methanol into valuable chemicals, without relying on fossile resources. It is catalyzed by acidic zeolites such as H-ZSM-5 or H-SAPO-34 [1]. The mechanism constists of two competing cycles using either olefins or aromatic species as co-catalysts. The aromatic cycle also consists of two possible sub-cycles, namely the paring and the side-chain mechanism [2]. The paring mechanism was in previous literature considered to be unfavorable because of its antiaromatic intermediate and therefore high reaction barrier [2]. Recently, we presented a new possible paring mechanism with significantly lower reaction barriers on the H-SSZ-13 model catalyst [3]. In this work, we employ this revised paring mechanism to the industrially relevant H-SAPO-34 and H-ZSM-5 zeolites.

**Methodology.** H-ZSM-5 and H-SAPO-34 were used as model catalysts. Periodic DFT calculations were carried out with the Vienna Ab Initio Simulation Package (VASP) version 5.4.1 in the atomic simulation environment (ASE) using the PBE-D3 functional and the projector-augmented wave method. Transition state searches were performed with automated relaxed potential energy surface scans (ARPESS) [4]. Energy corrections at the CCSD(T)-level of theory were employed by single-point calculations on smaller clustermodels of the active site, as described previously [5].

**Results and discussion.** In both investigated zeolites, a similar paring mechanism as described in [3] was observed. The crucial step that distinguishes the newly proposed mechanism from the mechanism described in the literature is the propene elimination step, which occurs in our mechanism from a neutral isopropyl fragment, involving also protonation of the zeolite's acid site, as shown in fig. 1. This step was found to be comparable for both H-SAPO-34 and H-ZSM-5, with barriers being lower than the respective H-SSZ-13 barrier (< 142 kJ/mol). This indicates, that the proposed new paring mechanism is more feasible also in industrially employed catalysts.

**Keywords:** WGS performance, oxygen storage capacity, OSC and performance relation

**Introduction.** There has been a profound research interest in the design and development of active, steam tolerant, non-pyrophoric, robust Platinum-group metal (PGM) based and metal oxide supported WGS catalysts to be used in a fuel processor (FP) producing PEM grade hydrogen for PEM fuel cells. The current work mainly focuses on developing a reliable methodology for determination of oxygen storage capacity (OSC) of the catalysts through the use of operando IGA-MS analysis and establishing a relation between WGS activity and OSC.

**Experimental.** Pt-Re-V/$CeO_2$ catalysts were prepared, characterized and tested in WGS performance tests for two realistic feed compositions, which have $H_2O/CO$ ratio 6.7 and 16.2, at 300, 350, 400 and 450°C for fixed GHSV at 120,000 ml $gcat^{-1}$ $h^{-1}$. The OSC values of the samples were determined through a novel operando IGA-MS methodology under two diluted realistic feed (DRF) compositions at 350°C. Experiments conducted with pure He flow over each catalyst at all temperature levels were used to determine the "structural" oxygen that already exist in the catalysts/their structure (S-OSC). However, the experiments conducted upon DRFs display not only the oxygen stored in lattice and located on surface in the form of surface groups as formate, carbonate and/or carboxyl-carboxylate like intermediates, but also the oxygen emanating from reaction; which in all can be called as "total" OSC (T-OSC). Effective OSC (E-OSC) was obtained as the difference between T-OSC and S-OSC for a specific reaction temperature.

**Results and discussion.** The catalysts showed their highest performances at 350 and 400 °C and the highest net $H_2$ production values were achieved over 1Pt-1Re-1V and 0.5Pt-0.5Re-0.5V catalysts at 350 and 400 °C, respectively under feed flow having low $H_2O/CO$ ratio. Figure 1 represents three types of OSC values obtained for each catalyst subjected to diluted realistic feed flows, which have $H_2O/CO$ ratio 6.7 and 16.2 at 350°C. The combined evaluation of WGS performance and OSC results indicates that S-OSC including surface groups have key role in water activation at the time when reactive mixture first contacts with the catalyst, while E-OSC becomes primary factor affecting WGS activity after the surface concentrations reach steady state.

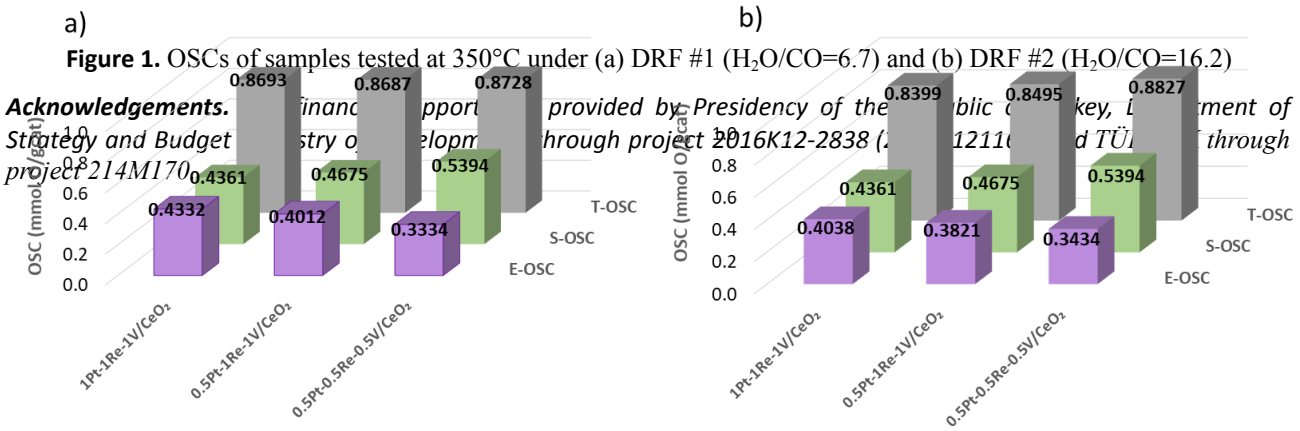

**Figure 1.** OSCs of samples tested at 350°C under (a) DRF #1 ($H_2O/CO$=6.7) and (b) DRF #2 ($H_2O/CO$=16.2)

# Ethane dehydrogenation in the presence of $CO_2$ over Co/BEA catalyst: effect of cobalt precursors and catalytic performances

Safaa ESSID*,Roman Bulánek

*University of Pardubice, Faculty of Chemical Technology, Department of Physical Chemistry, Studentská 573, CZ53210 Pardubice, Czech Republic*
*safaa.essid@upce.cz

**Keywords:** ethane, $CO_2$, ethene, cobalt, BEA

**Introduction.** The conversion of ethane into ethene with economically significant activity and stability is an advance from an industrial point of view and would add value to ethane a reliable source of more valuable chemical products. Ethylene is one of the most important and adjustable intermediates for synthesis of various chemical industry. Another big challenge of the chemical industry is utilization of $CO_2$, which considered as the main cause of global warming. Accordingly, the tandem $CO_2$-assisted dehydrogenation of ethane to ethylene is a potential way, since the reaction equilibrium can be shifted as a result of $H_2$ consumption via reverse water-gas shift reaction ($H_2 + CO_2 \rightarrow H_2O + CO$), and contribute to decrease the rate of coke formation reaction ($C + CO_2 \rightarrow 2CO$)[1].

**Experimental/methodology**. Giving the fact that, Co-zeolites performances in $CO_2$ ethane dehydrogenation were poorly investigated in the literature [1] [2], our goal was to contribute to enrich the discussion and to understand the role of cobalt oxidation states in the $CO_2$-ethane dehydrogenation into ethene.

Here, a series of Co/BEA catalysts were prepared by solid state ion exchange using differents cobalt precursors (cobalt chloride, cobalt nitrate, cobalt acetate and cobalt acetylacetonate) exchanged with BEA zeolite (Si/Al=12.5). Worthily, a deep chracterization was performed using temperature programmed reduction, FT-IR and DR UV-vis spectroscopy in order to shed light into the distribution of cobalt species on the zeolite surface and in the cationic sites.The prepared catalysts were tested in $CO_2$-ethane dehydrogenation performed at 575 ◦C in a fixed-bed through flow microreactor at atmospheric pressure. 200 mg catalyst (35~60 mesh) was activated in situ under He flow at 575◦C for 2 h before dehydrogenation. The gaseous reactant contained (3% ethane, 6% $CO_2$ with the balance helium) at a total flow rate of 30 mL/min. The products were analyzed using an on-line gas chromatograph (GC) equipped with flame ionization detector (FID) and a thermal conductivity detector (TCD) .

**Results and discussion**. Various cobalt species were formed in zeolites materials, including isolated cationic $Co^{2+}$, $CoO_x$ clusters , $[Co(III)O]^+$ and $Co_3O_4$ particles depending on the cobalt precursors used. In fact, the cobalt distribution in the zeolite surface was highly affected by variyng the cobalt precursors. Mainly, in the case of Co/BEA prepared with cobalt chloride, we noticed the relatively high occupation of cobalt $Co^{2+}$ in the zeolite cationic sites and cobalt oxo-species $[Co(III)O]^+$, revealed by UV-Vis spectroscopy. This catalyst was the most active one in this work exhibiting an ethane conversion of 15% with around 82% selectivity toward ethene at 575◦C. In the case of Co/BEA catalyst prepared with cobalt nitrate, where TPR and UV-vis spectroscopy revealed that cobalt was present mainly in the form of $CoO_x$ clusters, was observed negligible activity in the $CO_2$- ethane dehydrogenation, but high activity in the $CO_2$ reduction to CO. Although, cobalt acetate and cobalt acetylacetonate, showed the presence of $Co_3O_4$ and $CoO_x$ reduced at lower temperature when compared to TPR results of Co/BEA catalyst prepared with cobalt chloride, these catalyst where selective to ethene as main product. In brief, it should be pointed out, that cobalt in the oxides forms ($Co_3O_4$ and $CoO_x$) with particular sizes could be reduced in situ to Co(II) during the $CO_2$-ethane dehydrogenation and lead to high activity and selectivity into the desired product.

# Cu-based double metal cyanides for phosphoramidate synthesis via aerobic oxidative coupling of amines and phosphites

Alejandro Fonseca, Kwinten Janssens, Carlos Marquez*, Dirk De Vos*
*cMACS, Celestijnenlaan 200F, 3001 Leuven, Belgium.*
* carlos.marquez@kuleuven.be, dirk.devos@kuleuven.be

**Keywords:** Double Metal Cyanides, Heterogeneous catalysis, Green Chemistry, Phosphoramidates

**Introduction.** Phosphoramidates are common and widespread backbones of a great variety of fine chemicals, pharmaceuticals, additives and natural products.[1,2] Conventional approaches to their synthesis make use of toxic chlorinated reagents and intermediates, which are sought to be avoided at an industrial scale.[3] A more environmentally friendly approach to the phosphoramidate synthesis is the metal-catalyzed aerobic oxidative coupling of phosphites and amines, with homogeneous Cu salts showing promising results.[4] Here we report the first heterogeneously catalyzed aerobic oxidative coupling of phosphites and amines promoted by a $Cu_3[Co(CN)_6]_2$-based double metal cyanide (Cu-Co DMC), using $I_2$ as additive and $O_2$ as reactant. This represents an efficient, environmentally friendly alternative to the synthesis of these valuable compounds.

**Experimental/methodology.** Cu-Co DMCs were prepared following previously reported procedures.[5] Reactions were performed in a sealed glass vial with magnetic agitation containing Cu-Co DMC (3 mol%), 2 ml of solvent, the corresponding phosphite (2 mmol), 2 ml of a 15 mol% $I_2$ solution and 4 mmol of the respective amine (4 mmol), connected to an $O_2$ filled balloon, bubbling into the reaction medium through a syringe. The reaction products were analysed using GC-FID, GC-MS and NMR.

**Results and discussion.** Preliminary experiments proved that catalytic amounts of $I_2$ could greatly improve the outcome of the transformation, in combination with bubbling of $O_2$ into solution. When the Cu-Co DMC was tested, yields up to 99% were obtained for the coupling of 2phenylethylamine and dibutyl phosphite under optimal conditons, outperforming other heterogeneous (CuO, $Cu/SiO_2$, Cu-BTC and Cu-Mg Al mixed oxides) and homogenous Cu catalysts ($Cu(OAc)_2$ and CuI). Interestingly, characterization by PXRD, FTIR and XAS confirmed a change in the internal crystalline structure of the DMC and the formation of different phases during its reuse, with Cu adopting an octahedral, tetrahedral and square planar coordination (Fig. 1). However, the observed changes did not have an impact on the remarkable activity of the catalyst, which could also be used for 5 iterations without any loss of activity. The scope of the reaction was also extended to the synthesis of different phosphoramidates using bulkier primary amines, secondary amines and even amides. Preliminary mechanism studies suggest that the reaction proceeds by a change in the oxidation state of the Cu metal, induced by a $O_2/I^-$ redox cycle.

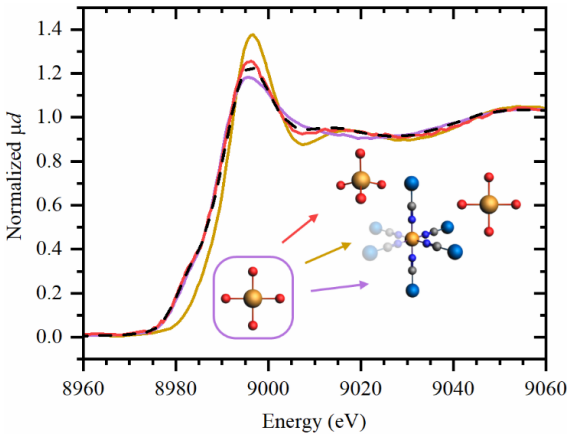

**Fig. 1. Experimental Cu K-edge XANES spectra for initial (dark yellow), spent (purple) and washed (red) catalyst. The dashed line corresponds to the linear combination fit of the spectrum of the washed state using three experimental spectra (initial, spent, and tetrahedral $Cu_2O$)**

**Keywords:** heterogeneous catalysis, DFT, free energy of activation, energy span concept, catalytic cycles

**Introduction:** Valorization of biomass and other renewable resources is one of the major research directions in green chemistry. Dehydration of butanols to butenes catalyzed by acidic zeolites is a key step for production of longer hydrocarbon chains that can be used in further industrial processing. In experimental studies[1,2] a unexpectedly high selectivity for conversion of isobutanol to linear butenes has been demonstrated, and these results motivate our computational study. In this work, we have performed simulations of the monomolecular dehydration mechanisms that are likely at the core of the high linear butene selectivity, starting from isobutanol.

**Methodology:** Periodic DFT calculations were performed using the VASP code with PBE functional and D2 correction to dispersion interactions. The energy span concept, specifically designed to describe catalytic cycles[3], was used to analyze the importance of the particular transformation routes that were obtained. The critical steps were explored by *ab initio* molecular dynamics with the Blue Moon Ensemble method with a sophisticated description of reaction coordinate.

**Results and discussion:** In addition to conventional dehydration mechanisms, we have revealed a network of monomolecular reaction transformations of isobutanol to butenes transformations involving also isobutanol isomerizations to other butanols, and synchronous isomerization and dehydration reaction mechanisms [4]. The reaction pathway in which isobutanol is converted directly into linear butene has previously never been reported in the literature. While the static approach, based on crudest statistical mechanics approximation is useful for qualitative analysis, its accuracy is often insufficient for realistic predictions[5]. This problem is resolved by explicit sampling of configuration space via *ab initio* molecular dynamics for the some of the most important pathways identified by the energy span concept. With the aid of *ab initio* molecular dynamics, free energies of activation and ultimately also the rate constants, are determined using the transition state theory. Our results suggest that the so far overlooked isobutanol isomerizations might be of a key importance for explaining the isobutanol to linear butenes selectivity. The *a posteriori* butene isomerizations, on the other hand, are shown to be rather unlikely under the relevant experimental conditions.

# Hydrogenation of Acetone to Isopropanol over Fixed-Bed Raney-Type Nickel Catalyst

Y. Gherib, P. Kukula, J. Padevět*

*Ranido, s.r.o., Thákurova 531/4, 160 00 Prague, Czech Republic*
** jaroslav.padevet@ranido.cz*

**Keywords:** Hydrogenation, Raney-type nickel, Fixed-bed

**Introduction.** The catalytic hydrogenation of acetone is an important catalytic process to produce highly demanded isopropanol used for fine chemical synthesis [1, 2]. The utilization of acetone produced from $CO_2$ and green hydrogen from solar energy and water can then provide an access to renewable isopropanol and other downstream products [3]. **Experimental.** An experimental study on acetone hydrogenation was performed by using Raney-type nickel alloy as a catalyst. Catalytic hydrogenation experiments were carried out in a fixed bed continuous flow reactor [4] and reaction parameters such as space velocity, temperature and pressure were investigated.

**Results.** It was found that Raney-type nickel catalyst efficiently converted acetone (>99%) to isopropanol with excellent selectivity. No traces of by-products were detected. Further studies towards improving the efficiency of the process were performed with an emphasis on the scalability to deliver a larger amount of product.

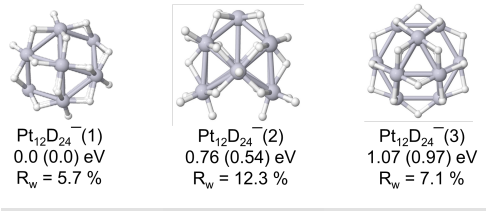
# Quantum chemical calculations of $Pt_nD_{2n}^-$ clusters

Siddhi Gojare[1], Dennis Bumüller[1], Manuel Kraft[1], Detlef Schooss[1], Karin Fink[1]



[1]*Institute of Nanotechnology, Karlsruhe Institute of Technology (KIT), 76344, Germany*

**Keywords:** Pt hydrides clusters, structure, spin-orbit coupling, density functional theory.

**Introduction.** The Pt-based heterogeneous catalysts have quite versatile catalytic properties and are applied in automotive catalytic convertors, in the catalytic oxidation and reduction reactions, and for emission control [1]. The nanoclusters of Pt show high catalytic activity and thorough study of the structure of Pt clusters in the gas phase is base in order to understand the underlying mechanisms of the surface reactions. One of the important reactions is the reaction with hydrogen. Therefore, we aim to investigate the structures of Pt-hydride cluster anions by combining trapped ion electron diffraction (TIED) techniques with DFT computations. In general, such clusters show high diversity in structures in a small energy range. This makes the task difficult to predict the global minimum structure. Heavy elements such as Pt, require to take into account the SOC which influences the relative energetic ordering of the isomers [2]. Therefore, we investigated the effect of SOC on $Pt_nD_{2n}^-$ clusters.

**Experimental/methodology.** The $Pt_nD_{2n}^-$ clusters were generated in the TIED experiment described in detail in ref. [3]. The scattering intensity obtained in the TIED experiment was compared with the scattering function calculated using several structure models. The structural models were obtained using combination of different methods such as semiempirical potentials within a modified genetic algorithm [4]. The best fitting structures were further optimized performing DFT calculations with the program package TURBOMOLE [5] using TPSS/def2-TZVP basis set. SOC contributions were included by relativistic two-component (2C) calculations with TPSS/dhf-TZVP-2c basis set [6].

**Results and discussion.** The structures and the relative energies of several isomers of $Pt_{12}D_{24}^-$ and $Pt_{13}D_{26}^-$ were investigated and were compared with the experimental data by the profile factor ($R_w$). The spin-orbit coupling plays a critical role in regulating the relative stability between the structural isomers of the cluster. In the case of $Pt_{12}D_{24}^-$ isomers (Figure 1), the SOC decreases the differences in the relative energies of the isomers compared to the one-component calculations. In contrast to the bare $Pt_n^-$ clusters, inclusion of SOC did not affect the energetic ordering of the isomers. The structural motifs did not change after geometry optimization with inclusion of SOC, only a slight elongation of the Pt-Pt bond lengths was observed. Thus, it can be deduced that hydrogens stabilize the structure of Pt cluster. With the help of Nudged elastic band (NEB) method, we calculated the barrier of 1.23 eV for the transformation between isomer (1) and (2) of $Pt_{12}D_{24}^-$. In future, we want to investigate other cluster sizes, reaction with $O_2$, and the role of the support in catalysis.

# Development of HTC-supported non-noble metal catalysts for ammonia reforming

M. Guci[1*], F. Rümmele[1], F. Nestler[1], M. Poschmann[2], R. Szolak[1]

[1]*Fraunhofer Institute for Solar Energy Systems, Freiburg, Germany*

**Keywords:** non-noble metals, nitrogen-doped carbon, ammonia reforming, hydrogen storage/transportation

Hydrogen ($H_2$) is a key molecule to enable a carbon dioxide ($CO_2$)-neutral energy infrastructure. While the production of $H_2$ via renewable energy-driven water electrolysis has already achieved a high TRL, its transportation and storage remain key challenges for the implementation of the hydrogen economy [1]. Due to its beneficial storage properties, a high volumetric and gravimetric energy density and the already existing transport infrastructure, ammonia ($NH_3$) is a promising candidate as a $H_2$ carrier molecule [2]. Whereas $NH_3$ synthesis is today among of the best known chemical processes, the reverse, $H_2$ releasing reaction, i.e. $NH_3$ reforming, requires an energy and cost efficient thermochemical process. In particular, development of an active, stable, sustainable and cheap catalyst is needed to enable large scale $H_2$ production from $NH_3$ [3].
In the research project AmmoRef (03HY203A), Fraunhofer ISE investigates together with other academic and industrial partners the viability of nickel-, iron-, and cobalt-based catalysts for $NH_3$ reforming, employing an environmentally friendly biomass-derived Nitrogen-Doped Carbon (NDC) support. Besides their sutainability, NDC materials have proven their beneficial material tuning capabilities defined by selection of precursor materials, applied hydrothermal methods, doping agents, impregnation methods and post thermal treatments [4].
This contribution tends to outline the impact of metal-support interactions on the catalyst performance. Several characterization techniques, including XPS (X-ray Photoelectron Spectroscopy), XRD (X-ray Diffraction), physi- and chemisorption measurements, SEM (Scanning Electron Microscopy), were applied to understand the catalyst's structural and chemical properties with the perspective to optimize those for $NH_3$ reforming reaction. Experimental results revealed the highest activity for iron (Fe). Moreover, it will be shown, how the interplay of the Nitrogen (N)- precursor, post thermal treatment conditions and N-amount impact both the surface area and the activity of a Fe-based of the catalyst. Further, the influence of adding Cobalt (Co) as a second metal or promoters as Potassium or Cesium to the catalytic system will be indicated. A decline in activity for the Fe-based system was observed as the carbonization temperature of the support was raised to 800 °C. However, this trend was less when the same temperature increase was applied to a bimetallic (Fe-Co) catalytic system. This led us to the assumption that a higher graphitization degree is more beneficial for Co than Fe.
Furthermore, investigations focused on evaluating the potential of synthesizing NDC materials and its variations for coating methods are shown, aiming to assess their suitability for future industrialization.

# The role of surface silanols in the initiation of olefin metathesis on $MoO_x/SiO_2$ and $WO_x/SiO_2$ catalysts: a computational perspective

J. Handzlik*, M. Gierada, K. Kurleto

*Faculty of Chemical Engineering and Technology, Cracow University of Technology, Kraków, Poland*
**jhandz@pk.edu.pl*

**Keywords:** alkene metathesis, molybdenum, tungsten, silica, active site, mechanism, DFT.

**Introduction.** Metathesis of light olefins enables for regulation of olefin stocks in petrochemical industry [1]. Large-scale processes involving olefin metathesis are carried out over tungsten or molybdenum oxides supported on high-surface-area materials [1,2]. In these systems, metal alkylidene sites, being active in olefin metathesis, are formed *in situ* from the surface metal oxide species upon contact with olefin [2-5]. However, the mechanism of the transformation of the metal oxide precursors into the active sites is not well recognised, although several routes were proposed [2-5]. In this work, we attempted to determine the most feasible initiation mechanisms for olefin metathesis catalysed by the $MoO_x/SiO_2$ [6] and $WO_x/SiO_2$ systems, taking into account the possible participation of the surface silanol groups.

**Computational models and methods.** Cluster models based on the periodic amorphous structure of dehydrated silica surface [7] or β-cristobalite structure were built to represent the $MoO_x/SiO_2$ [6] and $WO_x/SiO_2$ catalysts. Geometry optimization on the PBE0/def2-SVP level was followed by PBE0-D3/def2-TZVPP single point energy calculations. The Gaussian 09 set of programs was used.

**Results and discussion.** A number of potential reaction pathways for generation of the molybdenum and tungsten alkylidene species from the metal oxide precursors and propene were calculated. It is shown that surface silanol groups interacting with metal species and constituting Brønsted acid sites can play a key role in reduction of the dioxo M(VI) species (M = Mo, W) to the monooxo M(IV) species by propene, through M(VI) isopropoxy species, and in subsequent formation of the M(VI) isopropylidene species. An alternative activation pathway avoiding the reduction step is also possible. The reactivity of the metal oxide sites is significantly affected by their geometry and the local structure of silica. The proposed initiation mechanisms are kinetically preferred over non-silanol-assisted formation of the active sites. They are also in line with the reported experimental data [3-5,8]. The predicted activation barriers for the generation of the W alkylidene species are higher than in the case of the Mo alkylidene sites. This is consistent with the fact that a higher temperature is required for olefin metathesis catalysed by the $WO_x/SiO_2$ system, compared to the $MoO_x/SiO_2$ catalyst.

# Analysis of the Adsorption Rate on Catalysts for Ammonia Synthesis

Simon I. Hansen[1], Anker D. Jensen[1] and Jakob M. Christensen[1*]

[1]*Department of Chemical and Biochemical Engineering, Technical University of Denmark, 2800 Kgs. Lyngby, Denmark*

[*]*jmc@kt.dtu.dk*

**Keywords:** Haber-Bosch, Iron catalyst, Adsorption/desorption kinetics

**Introduction.**

The synthesis of ammonia is an important chemical process, but despite the maturity of the Haber-Bosch technology, the process is not fully understood. It is widely accepted that the rate determining step is the dissociative breaking of the N≡N triple bond [1-2]. However, studies have shown that an $H_2/D_2$ isotope effect exists, where $D_2$ gives a three-four times faster reaction rate than $H_2$ [3-4]. This is interesting since $H_2$ is not part of the rate determining step in the dissociative mechanism. Thus, a deeper understanding of the dissociative $N_2$ adsorption is necessary in order to clarify these discrepancies in the mechanism.

**Experimental**

An iron-based catalyst promoted with K and Al was used to carry out experiments on $N_2$ adsorption. The catalyst particles (150-300 µm) were placed in a glass-lined packed bed U-tube reactor with the adsorption carried out in a 100 NmL/min flow at 673 K, 1 bar with 25% $N_2$ and varying $H_2$ content (balance Ar). The adsorption times were varied by applying a quenching method developed in our research group [5]. $N_2$-TPD with a 2 °C/min ramp was then performed to analyze the surface coverage. The data were modelled to describe the adsorption and desorption rates of nitrogen.

**Results and discussion**

The model includes a quadratically decreasing heat of adsorption with increasing coverage on the basis of electrostatic arguments, and the validity of this dependence has been verified by comparison with experimental data reported in the literature [6]. The model was fitted to experimental TPD data in order to obtain an expression describing the ad- and desorption rates of nitrogen. The model fit is shown in Figure 1 along with a comparison with previously reported data on $N_2$ desorption from Fe(100) [7].

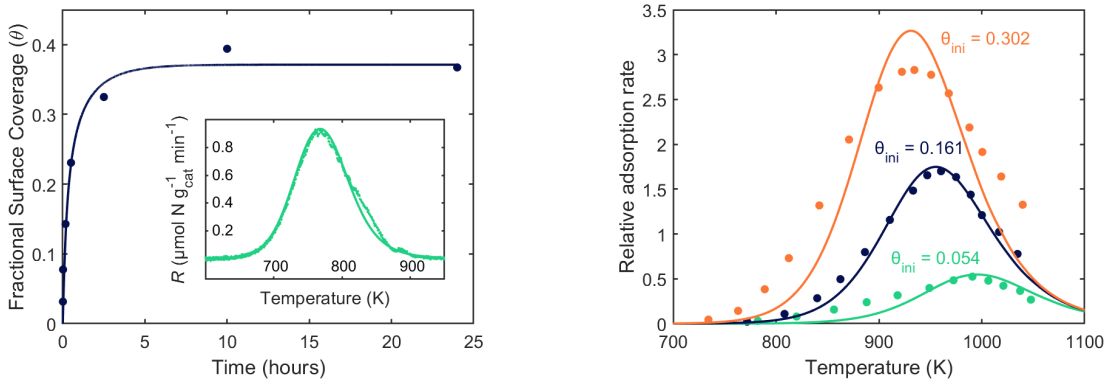

**Figure 1. Left: Experimental and fitted fractional coverage of N as a function of adsorption time. Insert: TPD after adsorption at 10 hours. Right: The fitted model compared to previously reported $N_2$ TPD data from Fe(100) [7].**

**Keywords:** Core-shell nanomaterials, heterogeneous catalysis, DFT, $TiO_2$, gold

**Introduction.** Surface-supported gold nanoclusters are of increasing interest in heterogeneous catalysis due to the possibility to design unique and efficient photocatalysts by adapting the structure and complexity of the reactive interface. Recent experimental studies by Ghazzal and co-workers [1,2] have demonstrated that core-shell $SiO_2$@Au@$TiO_2$ nanostructured photocatalyst shows increased photocatalytic hydrogen production efficiency for low amount of gold nanoparticle loading. To understand the enhanced reactivity of these core-shell catalysts, computational methods are applied to simulate the electronic structural properties of the nanostructures. The study to be presented here will focus on the effect of size, shape, and structure in determining the electronic structure of Au nanoparticles on $TiO_2$(101) surface, which in turn influences the catalytic efficiency.

**Methodology.** Electronic structure calculations are performed using the open source software package CP2K with the dispersion corrected generalized gradient approximation (GGA) and Hubbard-*U* potential correction. Known geometries of stable gold nanoclusters ($Au_n$ for $n$ = 13, 19, 28, 32, 38, 55, …) will be used for adsorption on $TiO_2$(101) surface for generating the catalyst structures. Gold nanoparticles sandwiched between $TiO_2$ layers and embedded in thin $TiO_2$ shell will also be studied and the atomic charge density and projected density of states analysis will be used to compare the catalytic activities of the $TiO_2$(101) layer vs core-shell nanostructure.

**Results and discussion.** The density of states at the Fermi level is expected to change with variations in shape, size and orientation of nanoclusters [2]. Previous results from similar systems have shown that the charge density on metal nanoclusters can affect the selectivity of overall water splitting [3]. The electronic structure calculations using periodic density functional theory methods are underway for the $Au_n$:$TiO_2$ systems, and the results are expected to identify the active sites and explain the experimental observations regarding the photocatalytic activity of core-shell nanostructures. In addition to the size of the nanocluster, the shape and thickness of the surface will also be studied for simulating the experimental conditions.

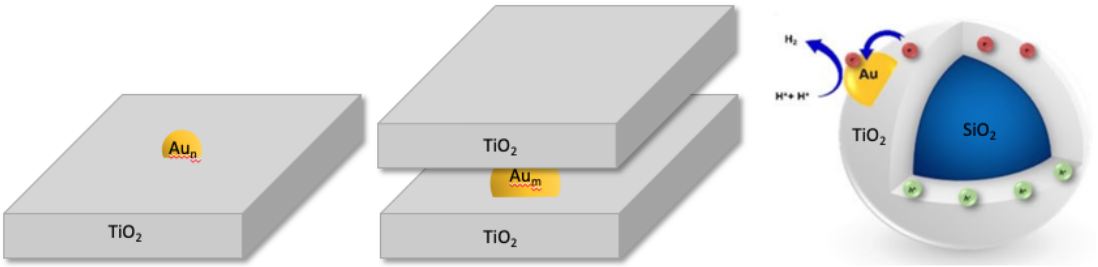

Figure 1: Systems of interest. Au nanoparticles of different sizes on different $TiO_2$(101) surfaces

**Keywords:** Periodic density functional theory (DFT), Hydrogenolysis, Ruthenium, Methanol

**Introduction.**

Polyols from lignocellulosic biomass are a promising alternative to chemicals from fossil resources. Their conversion to short-chained polyols offers a variety of applications in chemical and pharmaceutical synthesis as well as food industry. However, despite numerous kinetic studies the mechanism of hydrogenolysis of these polyols is still not fully understood.[1,2] Therefore, the decomposition of the $C_1$ alcohol methanol was investigated as a simple model compound for mechanistic insights into the surface-catalyzed reaction.

**Experimental/methodology.**

Periodic DFT calculations were carried out using VASP, with the PBE exchange-correlation functional within the generalized-gradient approximation (GGA) and complemented by the Grimme D3 correction with BJ damping to account for dispersion.

**Results and discussion.**

The reaction mechanism to methane on a Ru(0001) surface was elucidated under realistic reaction conditions including solvation effects and coverage of the catalyst surface. A modeling of the catalyst surface revealed that the Ru surface covered with hydrogen is the most stable system. On the H-saturated Ru surface, the pathway via O H formation of the intermediate $CH_2O$ and subsequent C O cleavage is the most favorable (Figure 1, x-xi). This study emphasizes the importance of modeling reactions under realistic conditions to obtain results that are more accurate.

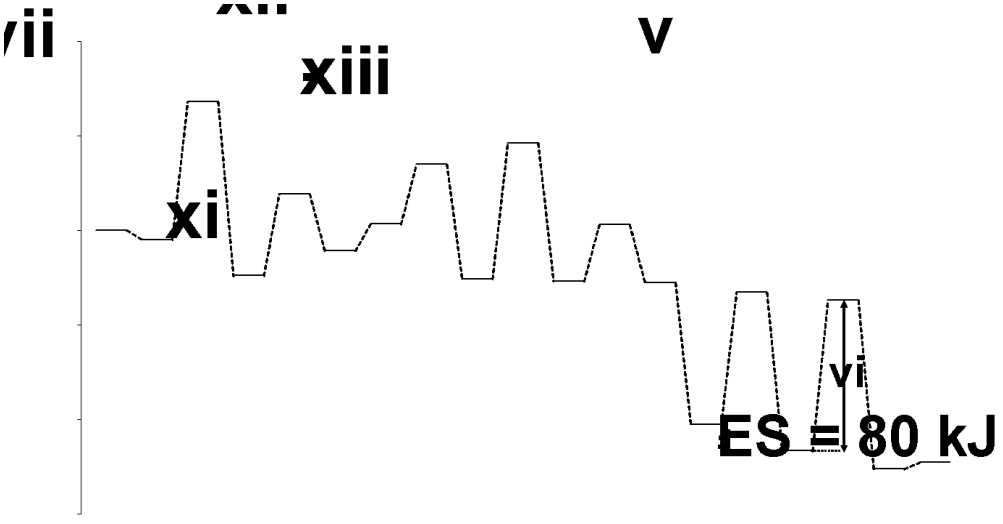

**Figure 1. Decomposition of methanol to methane and water on a hydrogen covered Ru surface.**

**corresponding author: m.higham@ucl.ac.uk*

**Introduction.** Ammonia ($NH_3$) synthesis is an essential yet energy-demanding industrial process[1][2]. Hence, there is a need to develop $NH_3$ synthesis catalysts that are highly active under milder conditions[3]. Metal nitrides are promising candidates, with the η-carbide structured $Co_3Mo_3N$ having been found to be more active than the industrial Fe-based catalyst[4][5]. The isostructural $Fe_3Mo_3N$ catalyst has also been identified as highly active for $NH_3$ synthesis[6]. Recent experimental work has also suggested that promotion of $Fe_3Mo_3N$ by chromium can enhance activity. In the present work, we apply computational techniques to investigate the catalytic ammonia synthesis mechanisms in $Fe_3Mo_3N$[7], which we compare and contrast with the previously studied $Co_3Mo_3N$[8-15].

**Methodology.** Plane-wave Density Functional Theory (DFT) as implemented in the VASP code was applied to investigate surface N vacancy formation in $Fe_3Mo_3N$, and two distinct ammonia synthesis mechanisms. In line with the previous studies on $Co_3Mo_3N$, a thin-film 2x2 surface supercell interleaved by 30Å of vacuum was used to model the $Fe_3Mo_3N$ surface. The revised PBE XC functional was used throughout in conjunction with the D3 dispersion correction. Inner electrons were replaced with PAW, with the valence states expanded in plane waves up to a cut-off of 650 eV. A Γ-centred (4x4x1) Monkhorst-Pack k-point sampling mesh was used to sample the Brillouin zone. Electronic self-consistency was deemed to have been achieved for total energies converged to within $10^{-5}$ eV. All structures were optimised until atomic forces were converged to within 0.01 eVÅ. Transition states were identified using the climbing image nudged elastic bands (CI-NEB) and dimer methods, with vibrational analysis confirming that a saddle point had indeed been located.

**Results and Discussion.** The calculations reveal that whilst N vacancy formation on $Fe_3Mo_3N$ is experimentally found to be more thermodynamically demanding than for $Co_3Mo_3N$, the calculated formation energies are comparable, suggesting that surface lattice N vacancies in $Fe_3Mo_3N$ could facilitate $NH_3$ synthesis. $N_2$ activation was found to be enhanced on $Fe_3Mo_3N$ compared to $Co_3Mo_3N$, for adsorption both at and adjacent to the vacancy. The calculated activation barriers suggest that, as for $Co_3Mo_3N$, the associative Mars van Krevelen mechanism affords a much less energy-demanding pathway for ammonia synthesis, especially for initial hydrogenation processes. It is intended that the present work will inform future studies investigating quaternary nitride systems and the role of Cr-promotion in $Fe_3Mo_3N$.

# Distance effect in bifunctional metal-acid catalysis

Kang Cheng,[1,2*] Ye Wang,[1] Krijn P. de Jong[2]

[1]*State Key Laboratory of Physical Chemistry of Solid Surfaces, College of Chemistry and Chemical Engineering, Xiamen University, Xiamen 361005, China*

**Keywords:** Bifunctional catalysis, shape selectivity, C1 chemistry, proximity, hydrocarbon chemicals

**Introduction.** Bifunctional catalysts composed of metal (oxide) and zeolites have been widely applied in the catalytic conversions of C1 molecules, short-chain hydrocarbons, and biomass-based feedstock.[1,2] The performance of bifunctional catalysts is influenced not only by the physical and chemical properties of the metal and zeolite but also by the distance between them. The distance factor also affects the catalyst stability, regeneration, and recovery of the spent catalyst. However, up to now, deep investigation and understanding of the distance factor for bifunctional catalysis are still lacking.

**Results and discussion.** We have investigated the distance-dependent performances from the aspects of the accessibility of functional sites, the local concentration of intermediates, and the transfer mechanism of reaction intermediates.[3-5] It is noteworthy that under harsh reaction conditions of high temperature, exothermicity, reduction, and the presence of water, metals are highly prone to migrate into the zeolite channels thus poisoning the zeolite.[6] Sometimes, this phenomenon was superficially attributed to the speculative distance effect. For the hydrogenation of $CO/CO_2$ to olefins by oxide-zeolite catalysts excluding metal migration, we found that gaseous methanol as an intermediate can diffuse fast and randomly between the dual active sites and therefore is not sensitive to the distance factor. In contrast, for $CO/CO_2$ to aromatics, metal oxide and zeolite must be integrated closely because the last aromatization step requires the fast removal of hydrogen species through the oxide-zeolite interface (Figure 1). Our work not only provides insights into emerging metal−acid catalysis for C1 chemistry but also guides the rational arrangements of functional sites and the design of reactor shapes for specific tandem reactions.

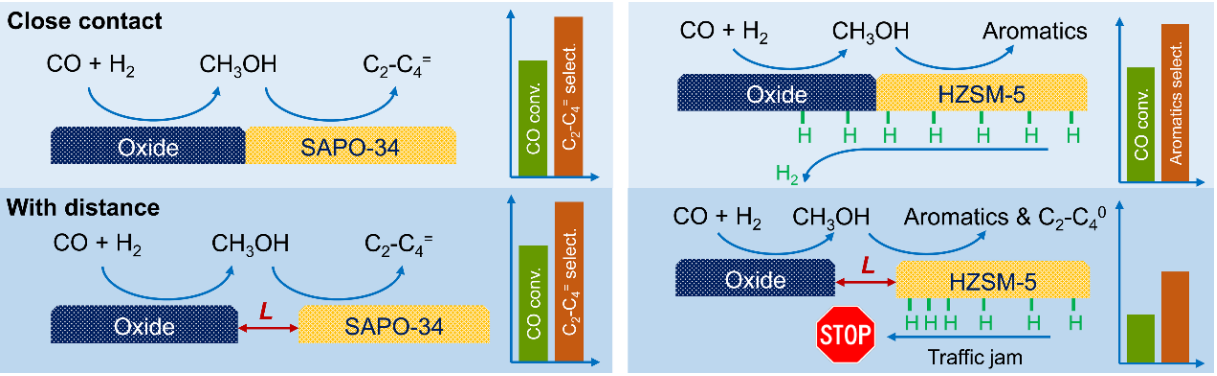

Figure.1 Distance effect of bifunctional catalysts on the performance of syngas to olefins and aromatics.

# Kinetic & mechanistic study of the complete oxidation of volatile organic compounds (VOCs) on $Co_3O_4$ catalysts

Y. Georgiou[1], N. Apostolopoulos[1], P. Dimitropoulos[1], M. Smyrnioti[1], C. Zhang[2], A.M. Efstathiou[2], T. Ioannides[1,*]

*E-mail: theo@iceht.forth.gr*

**Introduction.** Catalytic oxidation of volatile organic compounds (VOCs) is an important reaction for abatement of VOC emissions from industrial sources. Transition metal oxides, such as $Co_3O_4$, are active catalysts for VOC oxidation and it is generally accepted that the reaction takes place via a redox (Mars-van Krevelen) mechanism, whereas the VOC gets oxidized by surface lattice oxygen leading to reduction of the catalyst surface which is subsequently reoxidized by gaseous oxygen closing the cycle [1]. In such a simplified mechanism, the kinetics of the surface reoxidation step are independent of the type of VOC and, as a consequence, kinetic analysis of the oxidation of various VOCs should result in identical rate constants for surface reoxidation regardless of the VOC type. The validity of this hypothesis was scrutinized in the present work by a kinetic and mechanistic study of oxidation of propylene, butane and toluene over two $Co_3O_4$ catalysts differing in specific surface area by almost two orders of magnitude.

**Experimental/methodology.** The prepared $Co_3O_4$ catalysts were characterized by SEM, PXRD, XPS, $H_2$-TPR, Raman spectroscopy and $N_2$ physisorption. Kinetic measurements were performed at four different temperatures as a function of VOC and oxygen partial pressures. The interaction of VOCs with the catalyst surface was investigated by temperature-programmed desorption (TPD, helium carrier gas) and surface reaction (TPSR, $O_2$/He carrier gas) following adsorption of the respective VOC at room temperature. Experiments of transient oxidation of carbonaceous species deposited after VOC reaction with lattice oxygen were also carried out aiming to probe differences in the rates and amounts of carbonaceous species deposited and oxidized by lattice oxygen or gaseous oxygen for the two $Co_3O_4$ catalysts.

**Results and discussion.** The two $Co_3O_4$ catalysts were of pure spinel oxide phase with similar $Co^{2+}/Co^{3+}$ surface atomic ratios and had specific surface areas of 77 and 2.4 $m^2g^{-1}$, respectively. The kinetic behavior could be described in all cases by a Mars-van Krevelen rate expression, albeit with a reaction order of $n$~0.25 with respect to $O_2$ partial pressure, which does not have an obvious physical meaning. In addition, the determined kinetic rate constant for the surface reoxidation step differed significantly among the examined VOCs, which implies that the Mars-van Krevelen rate expression could be considered as an empirical description of catalyst behavior with no direct mechanistic relevance. The kinetic observations are discussed in the light of the extensive transient studies carried out in the present work which provided mechanistic information of the surface processes during VOC oxidation over $Co_3O_4$ catalysts towards the development of a relevant mechanistic model for this reaction.

# DFT study of acetaldehyde (AcH) and methyl acetate (MeOAc) formation on $HCo(CO)_4$ catalyst

J. Jelic[1], Kalim A. Sheikh[1], Thomas A. Zevaco[1], Felix Studt[1]

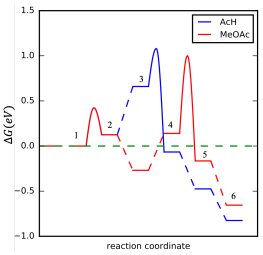
*jelena.jelic@kit.edu*

**Introduction.**

Acetaldehyde dimethyl acetal (AADMA) is a promising substance for the synthesis of pharmaceuticals, fragrances and can be efficiently used as a diesel additive to increase the cetane number. Not only used as a raw material, it is also an important intermediate for the synthesis of various oxygen-containing organic materials, such as higher acetals, resins, solvents and adhesives. The direct synthesis from CO, $H_2$, and methanol has not been studied extensively, and reports on the heterogeneously catalyzed synthesis of AADMA from methanol and syngas are scarce. Here we present a DFT study on the formation of acetaldehyde (AcH) and methyl acetate (MeOAc) on the $HCo(CO)_4$ catalyst to support the experimental results.

**Experimental/methodology.**



Density Functional Theory (DFT) calculations were performed using the Vienna Ab Initio Simulation Package (VASP) in connection with the Atomic Simulation Environment (ASE). The Bayesian Error Estimation Functional with van der Waals correlations (BEEF-vdW) with the projector augmented wave method (PAW). The choice of the BEEF-vdW functional is motivated by its performance with respect to adsorption energies and transition states on transition metal surfaces. Due to the presence of delocalized Co d orbitals, we applied GGA+U (U = 4.0 eV) method.

Large 12x12x12A unit cells were used to represent isolated $HCo(CO)_4$ species. Transition states are obtained using constrained optimizations and Nudge elastic band (NEB) calculations. Entropic contributions to the free energy were calculated within the harmonic approximation.

**Results and discussion**

DFT calculations were performed to complement the experimental work and to support some assumptions regarding the mechanisms, in solution and on the surface.

As a first step, we tested the stability of a $Co_2(CO)_8$ cluster (the most stable form of cobalt carbonyl) in the presence of $H_2$. Upon $H_2$ dissociation, the $Co_2(CO)_8$ dimer became unstable and dissociated into two $HCo(CO)_4$ monomers. Barrier for the whole process is 0.86 eV. In the liquid phase, a proton transfer from the $HCo(CO)_4$ cluster to methanol can take place. Using a single MeOH molecule to simulate the process requires overcoming a barrier of 1.7 eV in the Gibbs free energy diagram. Using more than one MeOH molecule to simulate the liquid phase for easier proton transfer was necessary and we used three MeOH molecules around $HCo(CO)_4$. This significantly lowered the barrier for the $CH_3Co(CO)_4$ formation. After creation of cobalt methyl tetracarbonyl, the formation of acetaldehyde (AcH) and methyl acetate (MeOAc) was studied and compared. The results show that the barriers for both processes are of similar magnitude and that both could take place equally. Increasing the hydrogen pressure decreases the barrier to AcH formation. The formation of $CH_4$ as a by-product was also taken into consideration.

# Mechanistic Insights into the Catalytic Hydrogenation of Muconic Acid in Aqueous Phase

Haseena K V[1], M. Ali Haider[*]
[1]*Indian Institute of Technology Delhi, Delhi, India*
[*]*haider@iitd.ac.in*

**Keywords:** Hydrogenation, Aqueous Phase, Proton Coupled Electron Transfer, Density Functional Theory

**Introduction.**

The transition metal catalysed hydrogenation of unsaturated functionalities, such as alkenes, primarily occurs via the Langmuir-Hinshelwood mechanism. The presence of solvents often tend to alter the conventional mechanism of hydrogenation, promoting alternate routes which are energetically more favourable.[1,2] In the present study, catalytic transfer hydrogenation (CTH) of trans,trans-muconic acid (TTMA) to adipic acid (AA) is explored in different solvents. Complete conversion is observed in the presence of water in 120 mins reaction time, whereas reduced conversion is observed in THF and cyclohexane. It is hypothesised that the hydrogen-bonded network of water molecules assists the hydrogen transfer to the C=C bond via a proton coupled electron transfer mechanism (PCET). Herein, density functional theory (DFT) simulations are employed to capture the energetics of the possible reaction pathways in solvents to develop a mechanistic understanding of the hydrogenation reaction.

**Experimental/methodology.**

CTH of trans,trans-muconic acid is carried out in an Anton Paar reactor equipped with a stainless steel heating jacket and integrated pressure and temperature control system. The chromatographic analysis of the reaction mixture is performed using the HPLC supplied by Agilent Technologies (1260 infinity II series), and the compounds are separated on a Hiplex-H column. Plane-wave DFT calculations, as implemented in Vienna ab-initio Simulation Package (VASP 6.2.0) is employed to study the mechanism of hydrogenation on different facets of a Pd surface. An explicit solvation model is used to simulate the solvent environment.

**Results and discussion.**

The hydrogenation reaction of TTMA is performed using Pd/C (10%) catalyst and formic acid as hydrogen source at 70°C and autogenous pressure. Nearly 100% conversion with 82% selectivity to AA is observed in water in 120mins (Table 1). Appreciable conversion is observed in polar protic solvents such as ethanol and methanol (Table 1). However, in THF, the activity is seen to reduce to half, and in cyclohexane, the conversion drops to 9% (Table 1). A detailed mechanistic study is therefore carried out using DFT simulations to understand the observed shift in conversions in different solvents. Figure 1. Shows the most stable binding mode of TTMA on Pd(111) and Pd(100) surfaces. The activation barriers for the hydrogen transfer in the presence of explicit water would be captured to develop mechanistic insights into the hydrogenation pathways.

**Table 1. Effect of Solvents in CTH of TTMA**

| S. No | Solvent | Conversion (%) | Adipic Acid (%) Yield |
|---|---|---|---|
| 1 | Water | 100 | 82 |
| 2 | Ethanol | 98 | 87 |
| 3 | Methanol | 88 | - |
| 4 | THF | 50 | - |
| 5 | Cyclohexane | 9 | - |

# The efficiency of nickel-containing catalysts for the transformation of carbon monoxide and methane into graphite-like carbon allotropes

A. Kaporov*, O. Shtyka, R. Ciesielski, A. Kedziora, W. Maniukiewicz, J. Albinska, T. Maniecki

**Keywords:** nickel-containing catalysts, Boudouard reaction, methane cracking, nanostructured carbon allotropes, greenhouse gases transformation

**Introduction.** It is widely recognized that greenhouse gas emissions, such as CO2 and CH4, are alarmingly high and cause serves damage to the environment despite international efforts to mitigate emissions of these gases [1]. In this regard, lots of scientific efforts have been put into the investigation of the possibility of conversion of them into valuable materials, such as carbon nanotubes, graphene, fullerenes, diamonds, etc., due to their cheapness, abundance, and relative safety [1-5]. One specific process that utilizes these gases is the dry methane reforming (DRM), during which side reactions (i.e., the Boudouard reaction and methane cracking) occur to form different types of carbon deposits [6-8]. The presented project aimed to study the effect of the type of catalytic support (CaO, Al2O3, MgO) on the performance of Ni catalysts in the Boudouard reaction and methane cracking.

**Experimental/methodology.** Ni catalysts supported on CaO, Al2O3, and MgO were prepared using the impregnation method. The catalytic measurements were performed using continuous flow reactor under atmospheric pressure at 450 and 700 °C for the Boudouard reaction and methane cracking, respectively. The gases composition was measured using online gas chromatographs with thermal conductivity detectors (TCD). The physicochemical properties of samples were analyzed using atomic adsorption spectroscopy (AAS), Brunauer-Emmett-Teller method (BET), temperature-programmed reduction/oxidation and desorption of NH3 and CO2 (TPR, TPO, NH3- and CO2-TPD), total organic carbon analysis (TOC), and X-ray diffraction (XRD).

**Results and discussion.** The experimental results showed that graphite-like carbon nanotubes were mainly formed on the surface of catalysts irrespectively of the investigated process. Also, it was evident that, the amount of carbon deposit depended on the physicochemical properties of catalytic systems, mainly, susceptibility to the reduction and concentration of acid-base sites. In particularly, the highest amount of graphite-like carbon was observed on the surface of Ni/CaO and Ni/Al2O3 (15-20%). These catalytic systems characterized by highest concentration of strong acid-base sites and relatively good reducibility. At the same time, the lowest carbon content was determined in the case of Ni/MgO (5-10%). This catalyst did not undergo complete reduction due to the formation of NiO-MgO solid solution. The mechanisms of formation of graphite-like carbon species during the Boudouard reaction and methane cracking were suggested.

**Keywords:** heterogeneous catalysis, multiscale approach, DFT, automatization

Industrial production of fuels and chemicals would not be possible without catalysts. Different processes require different catalytic materials though. With the now changing reality, where new feedstocks are developed, an efficient way to discover materials active and selective in given reaction is needed. Over the last years, the materials' performance assessment was done at the molecular scale using Density Functional Theory (DFT) calculations. This approach, however, does not give any insight on the performance of the material under various reaction conditions. To gain it, we need to extend our studies on additional time and length scales.[1]

Together with our academic partners from Institute of Chemical Research of Catalonia (ICIQ) in Tarragona (Spain) we approached this problem. Multiscale modelling workflow, together with Automated Multiscale Simulation Environment (AMUSE) tool, was created to address catalytic reactions on multiple scales.[2]

The starting point for the workflow are DFT calculation results. They can be produced from scratch in house, or they can be retrieved from databases, like ioChem-BD,[3] or existing literature. Then, they are automatically treated with the AMUSE tool to: i) retrieve the molecules structures and energies, ii) transform the structures into molecule graphs, iii) find the connections between these graphs and build the full reaction network, iv) ascribe the appropriate reaction energies to the elementary steps. These previous steps enable to proceed to microkinetic modelling. This approach allows us to get first insight, comparable with the experimental output, into catalysts' performance. We can anticipate the material efficiency, in terms of conversion and selectivity, under various temperature, pressure, and substrates concentration conditions. That can serve as the first filter for the promising materials selection. Yet, to be even closer to the reactor scale physics, we need to include transport phenomena, which is possible with Reactive Fluid Dynamic calculations.

For benchmark the workflow was tested with two reactions: $CO_2$ hydrogenation to methanol on $Pd/In_2O_3$, and isopropanol dehydrogenation on Co(0001) and Co(11-20) facets. The obtained simulation results are in line with the experimental observations, by which the proof of concept was achieved.

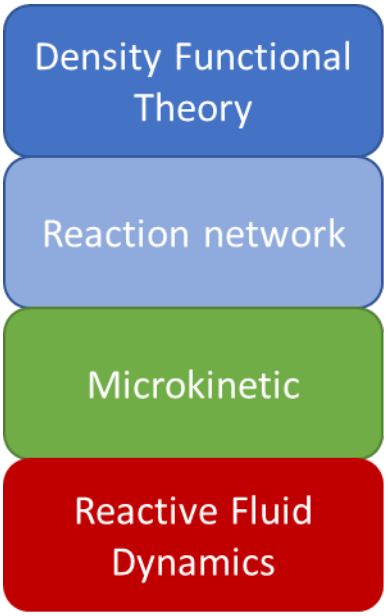

**Figure 1. Schematic illustartion of our automated multiscale modelling workflow for heterogeneous catalysis.**

**Keywords:** furanics, metal-organic frameworks (MOFs), selectivity control, DFT.

**Introduction.** Biomass valorization to generate green fuels and value-added chemical products is a promising way to mitigate the demand on fossil fuels and diversify feedstocks. The context of biomass-derived furanics dominates the research because of their intrinsic reactive nature which connects between aliphatic and alicylic compounds. In upgrading processes, ring-opening oxidations are particularly sensitive and difficult to control. A series of side-products could be obtained along with the target product, thus selectivity control is necessarily required. In the concept of heterogeneous catalysts, metal organic-frameworks (MOFs) are promising porous materials with highly catalytic properties for biomass conversion. Recent research demonstrated that the zeolitic-imidazolate framework (ZIF-8) MOF can act as selectivity mediator for the conversion of dimethylfuran (DMF) to 3-hexene-2,5-dione.[1] A reaction mechanism was proposed, however, a comprehensive study on how ZIF-8 controls the product selectivity was not fully addressed. To tackle these issues, we apply computational simulations at atomic level.

**Methodology.** Calculations were performed at periodic Density Functional Theory (DFT) level using the Vienna Ab-Initio Simulation Package (VASP) 5.4. The PBE exchange-corelation density functional was employed. NCIPLOT program was used to reveal non-covalent interaction between reactants, intermediates, products, and ZIF-8. An automatic search for efficient binding sites on ZIF-8 was carried out by xTB and CREST in combination with GFN-FF.[2] All values correspond to Gibbs energies at 333.15 K.

**Results and discussion.** We report the thermodynamics reaction pathway of DMF conversion with and without ZIF-8. After 3-hexen-2,5-dione is formed, the next step involving a second $H_2O_2$ molecule affects selectivity by promoting overoxidation side-processes. To the best of our knowledge, this is the first mechanistic study on interactions between large adsorbates and bulk ZIF-8 at periodic model. With automated searching tools for geometry structures, we systematically search the configurational space to obtain the most stable binding sites on ZIF-8. Unraveling the main interactions between intermediates and MOFs provides atomistic information on how and why ZIF-8 promotes selective for DMF conversion. With that knowledge at hand, other MOFs could be test to further improve the process.

# Changes of Oxygen Species on the Surface of Manganese Catalysts and their Effects on Acetaldehyde Ozonation

Yoon-Kyoung Lee[1], Eun-Chae Doh[1], Jun-Pyo Cho[2], JiHyeon Song[1*]

[1]*Sejong University, Seoul, South Korea*
[2]*FST corp., Gyeonggi-do, South Korea*
[*]*songjh@sejong.ac.kr*

**Keywords:** Manganese catalysts, Oxygen species, Acetaldehyde, Ozonation

**Introduction.**
Acetaldehyde is one of the volatile organic compounds (VOCs) that requires stringent regulations. Catalytic oxidation is commomly applied to reduce and control acetaldehyde emissions. In this study, an oxidation reaction of acetaldehyde using manganese catalysts and ozone was studied at room temperature. Active oxygen species formed on the surface of the catalyst are known to have high oxidizing power resulting in an increase of the oxidation rate. Therefore, the support of the catalysts was pretreated with strong acid to change the specific surface area and the ratio of oxygen species, and the effect of the surface modification on the acetaldehyde ozonation was investigated.

**Experimental/methodology.**
A cordierite support in a honeycomb shape was applied in this study, and its suface was pretreated with strong acid for 0, 30, 60, and 90 minutes. After the surface modification, manganese oxide catalysts were preapred at 5 wt% using the wet impregnation method. The oxygen species form on the Mn catalysts surface was confirmed through X-Ray Photoelectron Spectroscopy (XPS), which indicated $O_{vac}$, an oxygen vacancy and $O_{lat}$, a lattice oxygen in a manganese oxide bond.
The Mn catalyst was packed in a stainless-steel column, and the ozone oxidation efficiency of acetaldehyde was tested in the column study at the space velocity of 3,600 $hr^{-1}$. The total flow rate in the column was fixed at 3 L/min by adjusting a mass flow controller. The concentration of gaseous acetaldehyde in an air stream was set to be 100 ppm, and the molar ratio of ozone/acetaldehyde (5:1) required for the complete oxidation of acetaldehyde was selected as a reference condition.

**Results and discussion.**
The specific surface area and the oxygen vacancies ($O_{vac}$) on the surface of the Mn catalysts were compared as the acid pretreatment time changed. At the acid-pretreatment times of 0, 30, 60, and 90 minutes, the average specific surface areas were found to be 0.1, 35.6, 82.4, and 104.3 $m^2/g$, respectively. The analyses of the oxygen species on the surface of Mn catalysts revealed that the ratio of $O_{vac}$ were 84%, 86%, 88%, and 92%, respectively. As result, the specific surface area and the $O_{vac}$ of the Mn catalysts increased proportionally with increasing the acid pretreatment time.
The column study showed that the average ozone removal rates were 11%, 34%, 47%, and 54% at the acid pretreatment times of 0, 30, 60, and 90 minutes, respectively. In addition, the average acetaldehyde degradation rates were 49%, 98%, 100%, and 100%. Therefore, the higher the $O_{vac}$ ratio on the Mn catalyst surface, the higher the ozone activity, and therefore, the acetaldehyde removal efficiency was also improved. It is necessary to optimize the pretreatment method and to investigate the oxidation mechanisms of acetaldehyde on the various Mn catalysts with different oxygen species.

**Introduction**

This work is focused on the transformation of ethanol to more valuable chemical compounds via heterogeneous catalysis in a flow reactor. One of the desired products is butanol, which is important chemical compound, which can be used such as solvent or as feedstock for production of other chemical compounds, e.g., hexanol, butyl acrylate, iso-butene (additive to polymers). The transformation of ethanol to butanol can be achieved by the Guerbet reaction, which is self-condensation of two primary alcohols to the beta-alkylated dimer alcohol and consist of four steps [1].

Mixed metal oxides of lithium, aluminum, and transition metal (copper) were used as heterogeneous catalysts for the Guerbet reaction [2]. Lithium, aluminum mixed metal oxides from layered double hydroxides precursors (LDH) were chosen as one of the possible alternatives to more common magnesium, aluminum mixed oxides. The influence of different amount of transition metal in mixed oxides on ethanol transformation was studied and catalytic data were obtained, i.e., conversion of ethanol and selectivity of reaction to butanol (and other products). Mixed metal oxides were also deeply characterized by several experimental techniques.

**Experimental/methodology**

Mixed metal oxides were obtained via decomposition of LDH precursors prepared by the urea method (co-precipitation with urea) in a batch reactor with reflux condenser at atmospheric pressure and 105 °C. Alumina, lithium and copper nitrates were weighed at specified molar ratios of metals and were dissolved in redistilled water. Solution of metal ions was transferred into batch reactor and heated to 105 °C and urea was added to adjust pH and start the co-precipitation. Obtained LDH precursors were calcinated to mixed metal oxides and characterized by various methods: ICP-OES, X-ray diffraction, $N_2$-Physisorption, TPR and TPD. Catalytic studies were performed in a micro flow reactor with catalyst bed, at various temperatures (300–400 °C) in a mixture of 10 % ethanol and helium gas and atmospheric pressure.

**Results and discussion**

The properties of mixed oxides were determined for better understanding of the catalytic activity. Characterization data were statistically analyzed and correlated with catalytic data to determine the most suitable composition of heterogeneous catalysts for the reaction. Addition of transition metal had a positive influence on the ethanol conversion, on the other hand higher basicity and acidity had positive influence on butanol selectivity. Tuning of heterogeneous catalysts for the Guerbet reaction can provide relatively simple, cheap, and sustainable method of production not only bio-butanol.

## Introduction

Reaction kinetics information is crucial to determine the size of the commercial catalytic reactor and to improve the catalyst [1]. Regarding HDO kinetics of model molecules such as anisole, authors have reported three major pathways, (a) demethoxylation (DMO) [2,4], (b) demethylation (DME) [3-5], and (c) primary hydrogenation/secondary deoxygenation (HYD) [3,4]. However, there are aspects of this mechanism that remain unsettled and require further analysis. Therefore, a Langmuir-Hinshelwood-type kinetic model was proposed to describe the HDO of anisole over a Ru-based catalyst. The objective of this study is to obtain kinetic parameters that allow us to provide a quantitative framework to interpret data and to elucidate HDO reaction mechanisms for high aromatic selectivity.

## Experimental/methodology

Rate expressions were derived based on a conventional Langmuir-Hinshelwood model, considering 2 types of catalytic sites: the first, where the anisole molecule and each of the products of the reaction network are absorbed (Figure 1), the second, where hydrogen is adsorbed and dissociated.

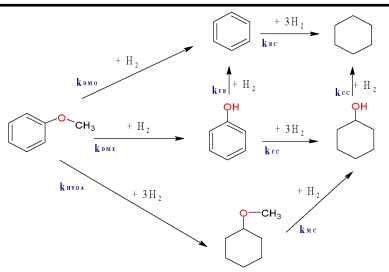

Figure 1. Anisole conversion reaction network over Ru/$TiO_2$ (T = 200-300 ° C, P = 30-50 bar).

The rate expression for anisole is:

$$r_A = \frac{k_A K_A C_A}{1 + \sigma K_i C_i} \quad , \quad k_A = k'_A \left[ \frac{\left[ \overline{K_{H_2} C_{H2}} \right]}{1 + \left[ \overline{K_{H_2} C_{H2}} \right]} \right] \qquad (1)$$

Where i: represents anisole and each of the products of the reaction network.

## Results and discussion

A temperature of 300ºC favored the obtention of products of interest (benzene). The formation of methylcyclohexane was not observed, thus its adsorption was neglected. From the kinetic and absorption constants calculated for each compound, benzene and cyclohexanol are the most strongly adsorbed compounds. Cyclohexanol and phenol reacted faster than the other products, cyclohexanol showed a reaction constant of 2.8 times and phenol, 2.2 times that of anisole. These values are consistent with the small yields to phenol and cyclohexanol as compared with benzene. Figure 2 shows the concentration of anisole versus WHSV. The predicted data from the proposed model gave a fair fit to the data observed experimentally for de hydrodeoxygenation of anisole over the Ru/$TiO_2$ catalyst.

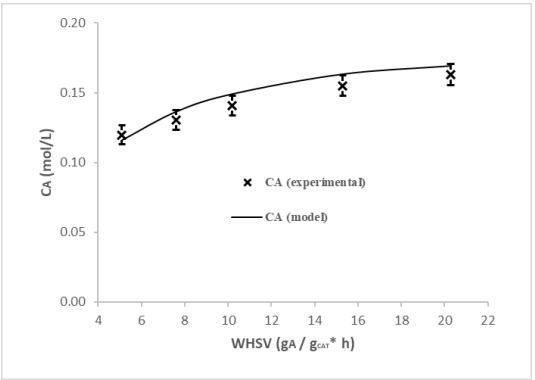

Figure 2. Comparison between the estimated and experimental data for the concentration of anisole as a function of WHSV (T = 300 ° C, $P_{H2}$ = 40 bar).

From the estimated kinetic parameters it can be said that the DMO pathway (to produce benzene) is preferred over the DME pathway, and the conversion step of Cyclohexanol to cyclohexane is the fastest. This leads to a higher yield of deoxygenated compounds.

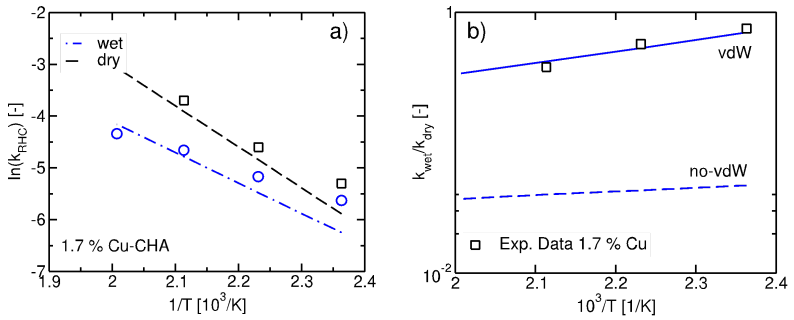
# First-Principles insights into the Reduction Half Cycle of the LT $NH_3$-SCR over Cu-CHA under wet conditions

G. Contaldo[1], M. Ferri[1], C. Negri[1], I. Nova[1], M. Maestri[1,*] and E. Tronconi[1,*]



[1]*LCCP, Dipartimento di Energia, Politecnico di Milano, via La Masa 34, 20156, Milano, Italy*

[*] *matteo.maestri@polimi.it* [*]*enrico.tronconi@polimi.it*

**Introduction.** The $NH_3$-assisted selective catalytic reduction (SCR) is the leading technology for the $NO_x$ abatement from lean burn engines. In this context, Hu et al. [1] proposed a DFT-derived mechanism for the LT reduction half cycle (RHC) under dry conditions which identifies the oxidative activation of NO to HONO as the kinetic relevant step of the reduction cascade, consistent with the experimental observations that reveal a rate proportional to NO pressure and a quadratic dependency on Cu(II). Furthermore, Gramigni et al. [2] reported that the inclusion of $H_2O$ in this reacting system affects the thermodynamic and kinetic parameters by decreasing the apparent activation enthalpy of the RHC to half of its dry counterpart while on the other hand inhibiting the reaction rate, even with the same rate dependency with respect to the dry conditions. A clear explaination to these effects is still lacking, therefore here we examine the role of $H_2O$ in the RHC of the $NH_3$-assisted SCR in order to provide a detailed mechanistic interpretation of such phenomena and improve the actual knowledge of the detailed chemistry that regulates the RHC under wet conditions.

**Experimental/methodology.** We performed hybrid density functional theory (DFT) calculations that account for van der Waals interactions with the Grimme $D_3$ method in a 12T-sites unit cell of Cu-CHA. The TS structures in wet and dry conditions are identified using the climbing-image nudge elastic band methodology (CI-NEB) in combination with statistical thermodynamic formalisms for the evaluation of entropy, enthalpy and Gibbs free energy. Vibrational frequency calculations are performed by using a finite-difference approximation of the Hessian matrix implemented in ASE.

**Results and discussion.** The experimental evidences reported by Gramigni et al. [2] indicate that the RHC under wet conditions follows the same kinetic scheme observed in the dry system and suggest that $H_2O$ does not affect the dinuclear nature of Cu(II). For this reason, we introduce one $H_2O$ molecule in the proximity of Two-P and NO inside the cage of CHA. According to our results, the presence of $H_2O$ influences the Gibbs free energy of the kinetically-relevant TS structure producing strong enthalpic stabilization effects which result in the net decrease of the apparent activation enthalpy by 20 kJ/mol with respect to the dry case, from 62 to 42 kJ/mol, in analogy with experiments. However, the entropic penalties gained after the addition of one $H_2O$ molecule are predominant and prevail over the enthalpic stabilization effects producing the experimentally observed inhibition of the reaction rate, blue curve in Fig.1(a). In particular, the ratio between the wet and dry rate constants is shown in Fig.1 (b) and it decreases at high temperature because in this range the entropic losses more than compensates over the enthalpic stabilization. As a result, the inhibition effects produced by $H_2O$ on the RHC are more strongly evident when temperature increases. It is relevant to notice that such stabilization effects vanish when vdW contributions are excluded from the calculations (dashed blue line), in analogy with the catalysis by confinement effects observed in voids of molecular dimensions [3].

**Keywords:** $CO_2$ Utilization, $CO_2$ Methanation with excess $H_2$ from a PEMFC

**Introduction.** Fuel processor (FP) technology is an applicable way to produce on-site $H_2$ for a PEM-Fuel Cell (PEMFC) in order to overcome the difficulty of high volume need of $H_2$ in direct usage [1, 2]. $CO_2$ is produced in addition to $H_2$ through an FP while produced $H_2$ is not fully converted in a PEMFC. In this case, $CO_2$ methanation emerges as a plausible solution for both utilizing produced $CO_2$ and beneficial use of excess $H_2$. The main concern for this application is low $H_2$ concentration, therefore, low $H_2/CO_2$ ratio to be used as a feed for $CO_2$ methanation. In this study, catalytic $CO_2$ methanation tests are conducted over Ni-La/$Al_2O_3$ system at low $H_2/CO_2$ feed ratios via using Box-Behnken experimental design, which makes further modelling studies possible.

**Experimental.** Temperature, $H_2/CO_2$ feed ratio, La promoter loading and GHSV are selected as factors for a Box-Behnken experimental design for both experimental comparisons and possible further modelling studies in ranges of 300-400 °C, 0.5-1.5, 1%-5% and 40,000-60,000 $ml.h^{-1}.g^{-1}$, respectively. In addition to widely used performance indicators of $CO_2$ conversion and $CH_4$ selectivity, $H_2$ conversion is also used to compare experiments since low $H_2/CO_2$ is far below the ideal stoichiometry of 4.

**Results and discussion.** The effect of each factor is observed at minimum and maximum levels of another factor in a Box-Behnken design. Increasing temperature mostly causes a slight increase in $CO_2$ conversion and a slight decrease in $CH_4$ selectivity. $H_2$ conversion significantly rises with temperature at low level of La loading and high level of GHSV whereas it slightly decreases or slightly increases with an increase in temperature at other conditions. Figure 1 shows effect of the temperature as a sample demonstration. Moreover, higher $H_2/CO_2$ feed ratio has a significant positive effect on both $CO_2$ conversion and $CH_4$ selectivity; however, the increase in $H_2$ conversion in response to an increase in $H_2/CO_2$ feed ratio is slight. In general, $CO_2$ conversion, $CH_4$ selectivity and $H_2$ conversion slightly increases with increasing La loading percentage and decreasing GHSV, except low temperature comparison indicating more significant changes.

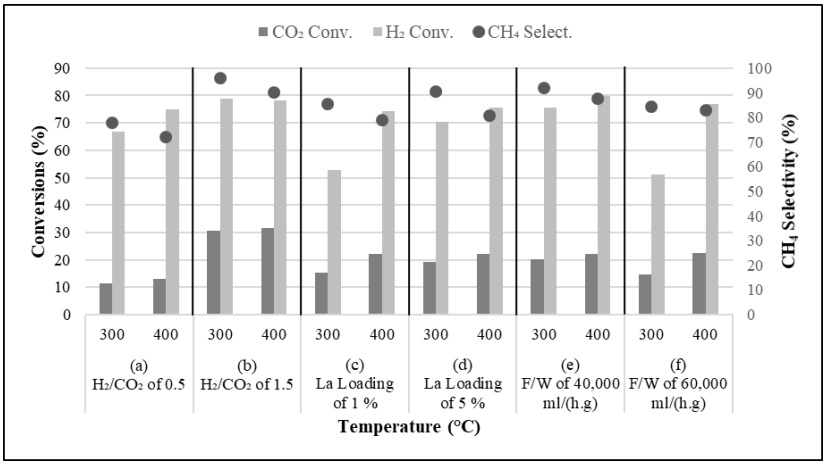

**Figure 1.** Effect of the temperature on $CO_2$ and $H_2$ Conversions, and $CH_4$ Selectivity

# Dry reforming of methane under microwave-assisted heating: *Operando* thermal analysis

J.Palomo, D. Cette, A. Urakawa*

*Catalysis Engineering, Department of Chemical Engineering, Delft University of Technology, Delft, 2629 HZ, The Netherlands*

* A.Urakawa@tudelft.nl

**Keywords:** DRM, Microwave heating, *operando* thermal analysis, Ni-catalyst.

**Introduction.** Dry Reforming of Methane (DRM) has attracted much attention as an effective route to convert two of the main greenhouse gases, namely methane and carbon dioxide, into syngas. Due to the high stability of methane, together with the thermodynamic limitations affecting the process, DMR has to be conducted at high temperatures. In addition, the high endothermicity of the reaction demands an intense energy supply. Furthermore, conventional Ni-based catalysts suffer severe deactivation with time on stream due to the formation of coke on the active sites of the catalyst. On the other hand, microwaves have been proved to be very efficient in driving heterogeneous catalytic reactions [1], having the interesting feature of being able to selectively heat up the solid catalyst rather than the catalyst and gas phase. In this contribution, the effect of microwave heating on DMR is analysed.

**Experimental/methodology.** Ni-based catalyst were prepared by incipient wetness impregnation (10 $\%_{w/w}$ Ni) of three different supports, namely: $ZrO_2$, $Al_2O_3$ and $Fe_2O_3$. The resulting materials were fully characterized and used catalyst in the DRM reaction, under conventional resistive and microwave assisted heating conditions. Thermal phenomena taking place in the catalyst bed were experimentally evaluated using a customized microwave system, which allows to incorporate different analytical tools under operando conditions.

**Results and discussion.** XRD results showed the presence of NiO crystal phases when $ZrO_2$ and $Fe_2O_3$ were used as support. In the case of $Al_2O_3$ supported catalyst, only Ni aluminate species were detected. $H_2$-TPR profiles evidenced that Ni species were reducible in all the prepared catalyst. Catalytic results (Figure 1a) showed that operation under microwave heating conditions resulted in a higher methane conversion than the one obtained using conventional resistive heating. *Operando* thermal visualization analyses, revealed a totally isothermal catalyst bed when using conventional resistive heating. On the other hand, the presence of thermal gradients and hotspots in the catalytic bed was observed under microwave-assisted heating conditions (see Figure 1b). This localized heating was a key aspect in achieving a higher methane conversion.

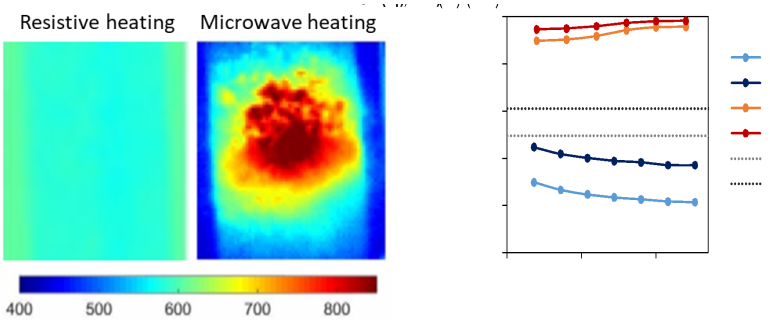

Figure 1. a) Catalytic resulst and b) IR thermography of Ni-$Al_2O_3$ catalyst bed, under microwave and resistive heating conditions. Reation T = 600 ºC, $CH_4$:$CO_2$ = 1, $P_{CO2}$ = 25 %, $F_{total}$ = 150 mL/min.

# Molecular insight into Propane dehydrogenation catalysed by Pt sub-nanoclusters on g-$C_3N_4$.

J. Pan[1], E. Strugovshchikov[1], A. Salom[1], J. J. Carbó[1], D. Curulla-Ferré[2], K. Kaźmierczak[2], C. Godard[1*], J. M. Ricart[1*]

Today, the increasing demand of propylene requires the development of more efficient ways of production, such as direct propane dehydrogenation (PDH).[1,2] Platinum-based materials are one of the most suitable catalysts for PDH due to their remarkable activity and selectivity for C-H bond breaking. However, the energetic cost of propene desorption on Pt surfaces, and the deep dehydrogenation leading to coke formation are big challenges.[3] It has been shown that the selectivity of platinum could be improved using disperse Pt small particles on different supports.[4] Herein, we present a theoretical study of PDH catalysed by platinum supported on g-$C_3N_4$,[5,6] from single atom catalyst[7] to small sub-nanoclusters, paying attention to the effect of cluster size on the activity and selectivity. We have also analysed the diffusion of platinum into the support.

All static calculations were performed with the Vienna Ab Initio Simulation Package (VASP) [8] using the Perdew−Burke−Ernzerhof (PBE) functional. For molecular dynamics, the in house parametrized ReaxFF reactive force field [9] was used in addition to VASP. We considered four layered slabs of the (001) g-$C_3N_4$ and a p(2x2) supercell. Pt atoms, dimers and trimers were situated on one side of the slab.

$Pt_1$, $Pt_2$ and $Pt_3$, anchored on the support, are stable even at high temperature. Furthermore, the diffusion study of $Pt_n$ clusters on g-$C_3N_4$ has shown that $Pt_1$ diffuses easily below the first layer of g-$C_3N_4$, but $Pt_2$ and $Pt_3$ are more stable on the surface due to stronger interactions with the support. We show the energy profiles at 873K, 1atm for the PDH mechanism over the $Pt_n$/g-$C_3N_4$ (n =1, 2, 3) catalysts. The single-atom $Pt_1$/g-$C_3N_4$ catalyst is the most favourable for adsorbing propane and propene but also for desorbing hydrogen. On $Pt_2$ and $Pt_3$ the activation of the second C-H bond and propene desorption are favoured.

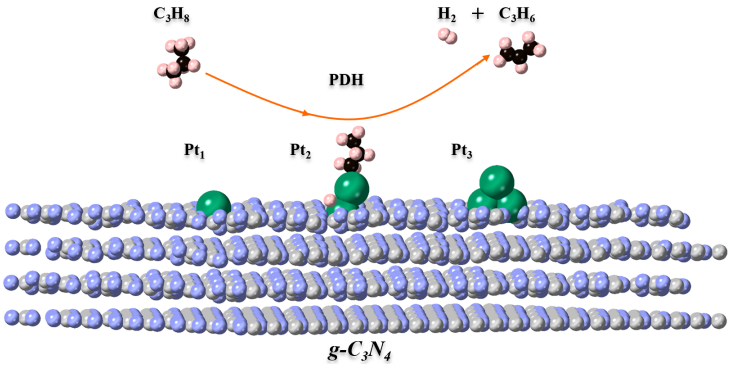

**Figure 1.** Pictorial representation of PDH catalysed by small Pt clusters anchored on g-$C_3N_4$.

**Keywords:** water-gas shift, platinum, ceria, DFT

**Introduction.** Ceria-supported Pt is an active catalyst for the low-temperature water-gas shift (WGS) reaction employed in the production of pure $H_2$. However, it suffers from sintering problems, forming large nanoparticles (NPs) with low surface area.[1] The catalytic performance is strongly structure-sensitive, favoring small Pt NPs for CO oxidation.[2] Several strategies have been considered to minimize aggregation, including optimizing the Pt concentration and doping the support. Alternatively, the problem can be tackled by using the structural dynamics under operating conditions to tune the NP size. Oxidative treatments at ~500 °C promote nanoparticle redispersion and might prove useful to obtain optimal catalysts.[3] In this work, we propose a density functional theory (DFT) study to gain atomic-level insight into the redispersion of Pt NPs.

**Computational details.** DFT calculations were performed using the VASP code. We consider various stages of Pt redispersion namely (1) A NP of ~1.5 nm representing the sintered catalyst, modeled as a $Pt_{147}$ cluster in its most stable high-symmetry homotope, a strongly-irregular truncated octahedron, (2) small 2–13 atoms Pt oxide clusters obtained via global optimization by a combination of genetic algorithms and sampling with a velocity rescaling thermostat, (3) single Pt atoms constituting the final state of the full redispersion. All $Pt_xO_y$ systems were adsorbed on the $CeO_2$(111) surface.

**Results and discussion.** We find that single atoms are not accessible under the conditions of the oxidative treatment, since $\Delta G > 0$ for all the $Pt_1O_y$ systems considered, indicating the treatment at 500 °C cannot redisperse Pt into single atoms. Instead, $Pt_{13}O_{12}$ species are found to be the most stable at 500 °C among the ones considered. This is in line with previous studies showing that Pt atoms are stabilized on $CeO_2$(111) by oxygen vacancies,[4] which are mostly unavailable under oxidizing conditions. Stable highly oxidized Pt single atoms are found at low temperatures, but the kinetics limit the redispersion under these conditions. At $T$ > 800 K larger nanoparticles are preferred on $CeO_2$(111), although sufficiently large temperatures might induce a reconstruction of the support stabilizing single atoms.[5]

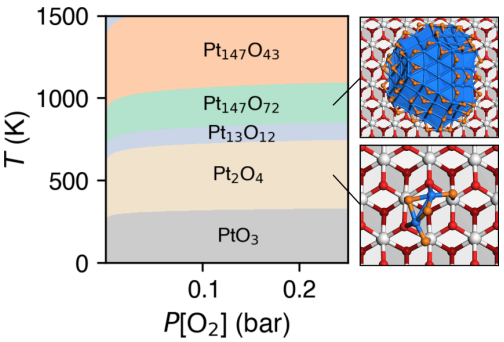

**Figure 1.** Ab initio thermodynamic map indicating the most stable species as a function of temperature and partial pressure of $O_2$.

Vibrational frequencies were also calculated to validate the cluster models by comparison with Raman spectra, identifying the main peaks associated with Pt–O and Pt–O–Ce bonds.

Overall, this study explores the stability of $Pt_xO_y$ species supported on ceria and advances the understanding of the sintering and dispersion of Pt for catalytic applications.

**Keywords:** Structure Sensitivty, Gold Catalysis, Oxidation of Glucose

**Introduction.** The excellent biodegradable and biocompatable properties of aldonic acids have made them broadly applied in cosmetics, pharmaceuticals, food ingredients and detergents. They are classically produced by oxidation of glucose with molecular oxygen on noble metal catalysts, however hydrogen peroxide has been proven to exhibit excellent oxidant properties showing similar selectivities but with doubled reaction rates. The focus of previous studies has mainly been on reaction conditions and process intentisification. To illucidate the dependency on the catalyst properties and structure, a variety of catalysts with varying supports, metals and nanoparticle sizes were synthesised and tested in this work.

**Experimental/methodology.** The catalytic testing was performed in a 250 ml glass reactor fitted with a heating jacket and a teflon stirrer. The reaction was performed at low temperatures between 303-343K and ambient pressure with a starting concentrations of 0.2 M of glucose and 1.5M of hydrogen peroxide. Gold catalysts with varying nanoparticle sizes (2.5nm-38nm) and different supports were prepared. In addition, a series of catalysts with varying metals (Fe, Pd, W) were synthesised.

Among the metals, gold on alumina showed the best performance, however tungsten based has shown promising results as an alternative in the future. At a standard reaction temperature (343K), catalysts with higher nanoparticle size showed higher reaction rates while maintaining the same selectivity. The oxidation rate had a maximum around 6.5 and 7 nm, which is significantly higher than the classical rate-structure dependency observed for oxidations using oxygen on gold. However, at temperatures close to room temperature this dependency shifts its maximum to 2.5 nm. The determination of the apparent activation energy revealed an increase of the apparent activation energy with an increasing nanoparticle size with no significant change above 20 nm (Figure 1). The obtained apparent activation energy vs. particle size curves showed an excellent agreement with the theoretical model assuming differences in the adsorption energies on edges and terraces for a Langmuir-Hinshlewood-type reaction with first order for both reactants [1].

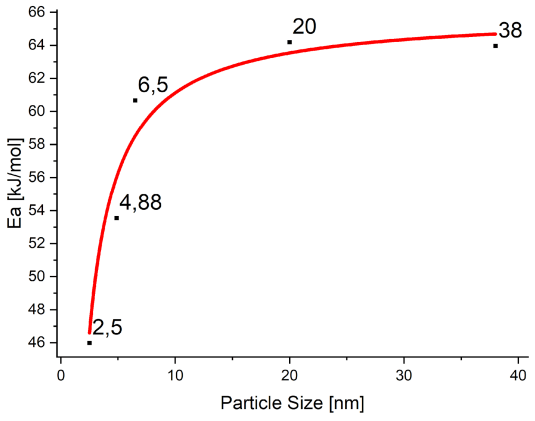

**Figure 1. Fit of the theoretical model for the apparent activation energies for different gold cluster sizes.**

**Introduction.** The direct synthesis (DS) of hydrogen peroxide (HP) is a hot topic in heterogeneous catalysis, as it represents a sustainable approach to produce this green oxidant for chemical industries.[1] The DS, catalyzed by supported Pd nanoparticles, suffers from the issue of selectivity, because water is the favored product and this is an obstacle for technological application. Well-established selectivity enhancers are chloride or bromide ions, but their application in industrial scale is prevented by corrosion problems.[2] A well-known feature of inorganic halides is their ligand properties towards Pd(II) to form palladium complexes, a feature which is shared with some common coordinating organic solvents. Starting from this, this work presents the use of a coordinating solvent as novel corrosion-free promoter for the DS reaction, thanks to their coordination properties.

**Experimental/methodology.** Pd catalysts supported on an ion-exchange resin based on a novel mesoporous polymer (Ps/SpDVB) [3] were investigated in the DS, both with a semi-batch reactor (SBR) and a trickle bed reactor (TBR). Further zeolite supported catalysts were investigated, together with commercial Pd on carbon as benchmark. The effect of acetonitrile (ACN) as coordinating solvent was studied by using a 10% vol ACN solution in methanol as the reaction mixture. The promotion effect of ACN is proposed by comparing DS experiments and characterization of fresh and spent catalysts, mainly with XPS, TEM and XAS.

**Results and discussion.** The results of the DS experiments with SBR setup are showing a selectivity enhancement as well as an increase in the production of HP when ACN is present in the reaction mixture (Figure 1). This effect is obtained only when the catalyst is supported on ion-exchange materials. In this case, the reconstruction of the metal phase occurs under reaction conditions, according to the formation of smaller Pd nanoparticles when compared to the fresh catalyst. Moreover, XPS and XAS show an increase of the Pd(II)/Pd(0) ratio after the catalytic experiment. This is further enhanced by the presence of ACN, together with the modification of the structural properties of the metal nanoparticles. This suggests a *release-and-capture* mechanism of the active metal, which starts from the formation of $[Pd(ACN)_4]^{2+}$ complexes that are then grafted to the support by ion-exchange. Their later reduced to form metal Pd nanoparticles; with this mechanism Pd species that are more active towards the DS are formed. By comparing the results with SBR and TBR setups, it is clearly seen that this mechanism and therefore the promotion effect depends on the reaction conditions used in the catalytic experiments.

**Keywords:** Y zeolite, fluidized catalytic cracking, $H^+$ transfer.

**Introduction.** Different approximations to determine the kinetic of reactions involved in fluidized catalytic cracking have been developed. Given the high complexity of this process, model compounds representing the real mixtures are selected. Results for experimental catalytic cracking of methylcyclohexane (MCH) have been reported in several papers due to its importance in the formation of aromatic compounds. However, detailed mechanism, and thus chemical kinetics for the specific reaction, is not well understood. This study describes the catalytic cracking for MCH over Y zeolite based on electronic structure simulations, considering different important steps such as: adsorption, $H^+$ transfer from zeolite's active site to hydrocarbon and C-C bond cleavage, both for the ring opening and for the cracking reaction.

**Methodology.** MCH catalytic cracking reaction was evaluated employing *Gaussian 09* software [1]. Initially, isolated MCH and possible product molecules were fully optimized in their electronic ground state multiplicity using the density functional theory [2,3] with the hybrid functional B3LYP [4] and the 6-31G basis set. These calculations were followed by the evaluation of the adsorbed molecules on a cluster model of the Y-zeolite, which consists of 260 atoms, while the unit cell contains 576 atoms. All silicon atoms in the zeolite cluster have tetrahedral environments and one silicon atom, located in the zeolite cage, was replaced by an Al atom, which generates a Brønsted acid site. Interactions between the zeolite model and intermediate molecules were optimized employing the ONIOM method [5].

**Results and discussion.** Only unimolecular cracking reaction was considered, since hydrocracking, isomerization, coking, or any other secondary reaction are not considered. Isobutylene formation is shown as an example (Figure 1 left), since it has been reported as a product of cracking reaction [6]. A possible transition state for $H^+$ transfer from zeolite active site to MCH giving rise to the carbocation formation and subsequent C-C bond cleavage can be seen at the right side of Figure 1.

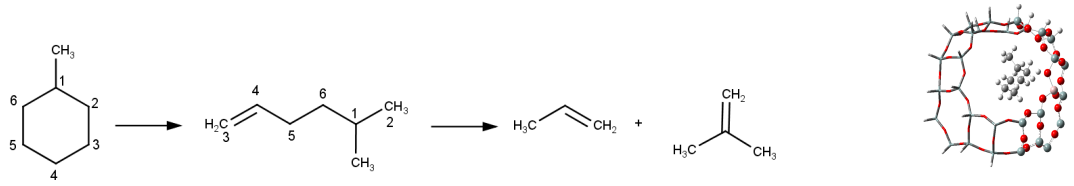

Figure 1. Left: MCH cracking reaction to produce propene and isobutylene $\Delta G_{800}$ = - 32.5 kcal/mol. Right: Activated complex for $H^+$ transfer from zeolite active site to MCH. $\Delta G^*_{800}$ = 37.4 kcal/mol.

Thermodynamics and detailed properties are obtained for reactant adsorption, olefin formation, as well as isobutylene and propene formation through cracking reaction, and finally desorption products allowing to propose a reaction mechanism in good agreement to the experimental reported results.

**Keywords:** Microwave-assisted catalysis, Electrification of chemical engineering,

**Introduction.** Microwave-assisted catalysis holds great promise for enhancing sustainable industrial processes [1].By leveraging efficient energy transfer and localized heating, microwave heating can improve conversion and selectivity [2]. However, challenges related to catalytic materials, reaction kinetics, heating mechanisms, microwave emission, and scalability need to be addressed [3]. Overcoming these hurdles through further research will unlock the full potential of microwave-assisted catalysis, revolutionizing industrial processes for a greener future

**Experimental/methodology.** The magnetron power output control was modified to keep the desired temperature in the catalytic bed. Given the significant temperatures attained and the inherent challenge of point measurements within the catalytic bed, thermal homogeneity verification in the challenging catalytic bed involved grounded K-type thermocouples. An extensive experimental campaign included distributed thermal measurements using a quartz reactor (20 mm ID) with a Ni-based catalyst for methane reforming, mixed with SiC particles. Local thermal gradients were investigated in inert and reaction conditions. Microwave heating effectiveness was examined under transient and stationary regimes. A comparative analysis of energy balance between microwave and resistive heating highlighted the potential for innovative energy sources to replace conventional methods.

**Results and discussion.** Experimental campaign demonstrated the presence of resonance nodes in the cavity and reactor resulted in significant temperature gradients. Methane Dry Reforming reaction was studied. **Figure 1** showed that despite the temperature gradients, the catalyst's performance in terms of reactant conversion remained comparable to conventional heating methods. Both microwave and conventional heating achieved exceptional performance within the required temperature range (T > 900°C), with $CO_2$ and $CH_4$ conversions exceeding 95%. This indicates that microwave heating can effectively support the endothermic reaction and reduce reliance on fossil fuels. However, further investigation is needed to optimize the reactor design and improve selectivity due to the significant temperature variation across the reactor.

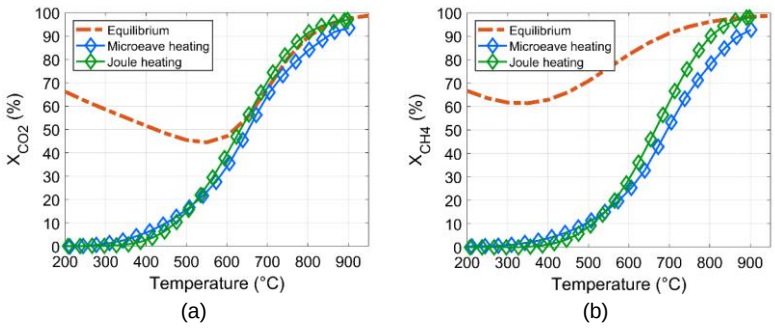

**Figure 1: Comparison between microwave oven and conventional oven: (a) $CO_2$ conversion and (b) $CH_4$ conversion as function of controlling temperature**

**Introduction.**

Catalysts based on redox oxides of transition or rare earth metals are very relevant in multiple processes such as pollutant elimination due to their capacity of oxygen exchange. Among them, perovskites, which are mixed oxides with general formula $ABO_3$, are very promising because of their high thermal stability, chemical versatility, and redox capacity. In these materials, position A of the structure is occupied by a large cation, generally of a rare or alkaline-earth element, while in the B-site hosts a cation of a transition-metal element with redox capacity, which mainly determines the catalytic performance. However, since the synthesis of perovskites requires high temperature, perovskites usually present very low surface area (<10 $m^2.g^{-1}$) and this can limit their catalytic efficiency.

Catalytic decomposition of $N_2O$ into harmless $N_2$ and $O_2$ is a very suitable technology for controlling this powerful greenhouse gas released by industrial sources. Besides, this process is very suitable to explore the role of oxygen vacancies in catalytic processes because it does not yield any secondary product. Accordingly, in this work, we have tested for first time the catalytic activity of several $CaMn_{1-x}Fe_xO_{3-\delta}$ perovskites (x= 0.1 and 0.3) for the decomposition of $N_2O$ in inert gas streams. These materials were selected for this study because thermodynamics of the oxygen vacancies formation have been experimentally determined in great detail, turning them ideal systems for thoroughly investigating the role of these defects on the catalytic removal of $N_2O$.

**Experimental/methodology.**

The catalytic activity of $CaMn_{1-x}Fe_xO_{3-\delta}$ perovskites (x= 0.1 and 0.3) for the decomposition of $N_2O$ (1000 $ppm_v$) in an Ar stream (GHSV=50330 $h^{-1}$) was assayed at temperatures in the 350-850 °C range. Catalysts were characterized by XRD, and Raman spectroscopy, while Near Ambient Pressure (NAP) XPS was used to monitor redox processes on the surface.

**Results and discussion.**

For these catalysts, the temperature of 50 % conversion of $N_2O$ was around 745 °C, independently of the Fe content. These values are comparable to those previously reported for other Mn and Fe perovskites under similar operation conditions. However, the activity of those materials declines moderately with time on stream. Thus, for $CaMn_{0.9}Fe_{0.1}O_{3-\delta}$ conversion of $N_2O$ decreases from 55 % to 46% after 18 hours at 745 °C. Interestingly, an excess of oxygen release with regards to the expected considering only the $N_2O$ decomposition stoichiometry was detected initially during the temperature rise. This reveals that the stoichiometry of the perovskite quickly changes in response to the increment of temperature, liberating oxygen. Since this process occurs simultaneously to $N_2O$ decomposition, formation of $N_2$ was also observed but as expected, time evolution of this molecule does not show the maximum detected in the case of oxygen. Variation in δ of the perovskite and, accordingly, the evolution of $O_2$ concentration in the gas phase are entirely reversible with respect to the temperature in the presence of $N_2O$. This behavior suggests the existence of two independent routes leading to the release of oxygen in this perovskite. Thus, the thermodynamic mechanisms control non-stoichiometry of the solid by capturing/liberating $O_2$ from the surrounding atmosphere in response to the changes in temperature and oxygen partial pressure. This process has been further investigated by NAP-XPS. Simultaneously, some surface vacancies can assist to the rupture of the N-O bond of $N_2O$, as a part of a concurrent regenerative catalytic cycle yielding $N_2$ and $O_2$.

**Keywords:** #1 MOFs, #2 selective hydrogenation, #3 hydride formation, #4 *operando* spectroscopy

**Introduction.** Metal-organic frameworks (MOFs) are a unique class of materials in terms of the tuneability of their pore geometry, chemistry, and flexibility, which makes them desirable from fundamental and application viewpoints. Furthermore, the size regime of the typical MOF pores (*ca.* 0.5-3 nm) coincides with size ranges in which other interesting physical phenomena take place. An example of such a phenomenon is the formation of interstitial hydride in Pd.[1] This is of relevance as Pd is a prolific catalyst for hydrogenation reactions but the phase activity and selectivity, *i.e.* whether the metallic ($\alpha$) or the interstitial ($\beta$) phase is more active and/or more selective, has been subject of significant debate.[2]

With the help of the microporous non-flexible $NH_2$-UiO-66(Zr) framework we were able to nanoconfine Pd particles, as previously reported[3], in its pores and demonstrated that the so-obtained Pd nanoclusters cannot form the $\beta$-phase. We selected the butadiene hydrogenation reaction as model for the phase activity and selectivity test.

**Experimental/methodology.** We will discuss a combined theoretical-experimental approach, including structural optimisation and finite-size effects. Catalyts testing was carried out in a flow-reactor ($H_2$:$C_2H_4$:He=150:30:225) at ambient temperature, monitoring the exhaus stream using a GC-MS. The phase and chemical state of the Pd catalyst (which is *ca.* 1 nm, *i.e.* too small to diffract) was tested using a combintion of *operando* XAS, *in-situ* inelastic neutron scattering and, thermal desorption spectroscopy.

**Results and discussion.** Using the above approach, we demonstrate that the $\beta$-phase does not form.

Importantly, using this strategy, we were not only able to design a highly active, stable (Figure 1, and as shown through *operando* and *in-situ* characterisation), and selective catalyst but we were also able to relate this performance to the prevalence of the $\alpha$-phase. In fact, we were able to produce fundamental insight into the ability of nanoconfined Pd nanoclusters to form hydrides or indeed absorb hydrogn in the first place. Our data, as opposed to previous suggestions[4], strongly suggests not only does the intersitial hydride phase not form on but even the absorption of sub-surface hydrogen (which is necessary for solid-solution formation) is unfavourable.

**Keywords:** Heterogeneous catalysis, magnetism

**Introduction.** Catalysts containing 3d transition metals have recently gained interest due to their inexpensive cost and abundance. Heavy and 3d transition metal alloys are utilized in electrochemical reactions like the oxygen reduction reaction (ORR) and the oxygen evolution reaction (OER). Another advantage of using such materials is that they introduce a new parameter that may be exploited to control the chemical reactions: The spin moments of 3d transition metals. From the theoretical point of view in heterogeneous catalysis the trend of the chemical reactivity is often explained in terms of the so-called d-band center model. We propose a generalized d-band center model where the chemical reactivity of the majority and minority spin-band electrons are separately evaluated [1]. We demonstrate that to understand the catalytic properties of spin-polarized materials one has to consider the d-band center model reformulated by us. Oxygen-based electrochemical reactions are the most important processes for batteries, fuel cells, etc. In this work, we looked at the possibility if one can reduce the overpotential for the oxygen reduction reaction (ORR) by changing the orientation of the spin moments of the oxygen atoms by a magnetic field. We studied the paramagnetic oxygen atoms adsorbed on PdFe surfaces and showed that the oxygen reduction reaction can be controlled using magnetic fields, particularly the overpotential [2]. Finally, we discuss how the traditional adsorption energy scaling relationship fails in bimetallic magnetic surfaces [3], with surface magnetic moments serving as critical descriptors in understanding the negative slopes in adsorption energy scaling relationships [4].

# Size Effects in Transition Metal Catalyzed Ammonia Decomposition

Jihao Wang, Shilong Chen, Malte Behrens*

*Institute of Inorganic Chemistry, Kiel University, Kiel, Germany*
**mbehrens@ac.uni-kiel.de*

**Introduction.**

Hydrogen economy provides a promising solution to the current global energy emergencies. However, the storage and transport of hydrogen from renewable energies is one of the major challenges. Under such scenario, it is possible to store hydrogen into ammonia, which has a big advantage in its high energy density and fully-fledged transportant infrastructure world-wide. Most importantly, hydrogen production via ammonia decomposition is a carbon-free process. So far, the best performing catalysts for ammonia decomposition are Ru-based. Nickel- and cobalt-based catalysts have been widely reported as the most potential catalysts to replace expensive Ru for ammonia decomposition.[1] Size effect of metal catalyst plays an important role in heteroegenous catalysis.[2] So far, only the size effect of Ru catalysts on ammonia decomposition has been systematiclly studied.[3] This work aims at the investigation of the size effect for these two non-nobal metal catalysts and at providing insight for ammonia decomposition catalyst design.

**Experimental/methodology.**

Ni/MgO and Co/MgO catalysts with different metal loadings were synthesized by a computer-controlled co-precipitation of mixed $Mg_{1-x}M_x(OH)_2$ hydroixdes with M = Co, Ni. The M/MgO catalysts were obtained by calcination followed by reduction. Kinetic measurements were carried out in a flow reactor (3%$NH_3$/Ar) with Micro-GC for detection. Structural analysis of the catalysts was performed by XRD and STEM.

**Results and discussion.**

Pre-catalysts are the solid solution of $Mg_{1-x}Ni_xO$ or $Mg_{1-x}Co_xO$, obtaining from the calcination of the hydroxide precurors. After reduction of the pre-catalysts, the size of metal particles increased from highly dispersed clusters to around 9 nm with the metal loading increased from 1 to 20 at.% ($0.01 < x < 0.20$). For increasing Ni loading, the reaction rate increased from 1 at.%-Ni/MgO (10 $mmol_{H2}$ $mol^{-1}_{Ni}$ $s^{-1}$) to 2 at.%-Ni/MgO (38 $mmol_{H2}$ $mol^{-1}_{Ni}$ $s^{-1}$) and then stayed at a similar value until 20 at.%-Ni/MgO (Figure 1a). Co catalysts showed a different behavior and the reaction rate continuesly increased from 1 at.%-Co/MgO (11 $mmol_{H2}$ $mol^{-1}_{Co}$ $s^{-1}$) to 20 at.%-Co/MgO (61 $mmol_{H2}$ $mol^{-1}_{Co}$ $s^{-1}$) (Figure 1b). 1 at.%-Co/MgO showed a much higher activation energy of 127.4 kJ $mol^{-1}$ compared to catalysts with higher loading (~90 kJ $mol^{-1}$) while 1-5 at.%-Ni/MgO catalysts showed a similar higher activation energy of ~95 kJ $mol^{-1}$ compared to higher loadings (~85 kJ $mol^{-1}$). Ni/MgO catalysts show high activity already at loading > 1 at.%, i.e. in the small clusters / particles range, while Co/MgO catalysts exhibit higher potential in the large particles range with an activity increasing with the loading / size. The kinetic results indicate that Co catalyst showed a distinctly sensitive size effect on ammonia decomposition as compared to Ni catalyst. Further experiments of $NH_3$-TPD for the nitrogen adsorption strength and H2-pulse-chemisorption for characterization of tiny metal particles are under way.

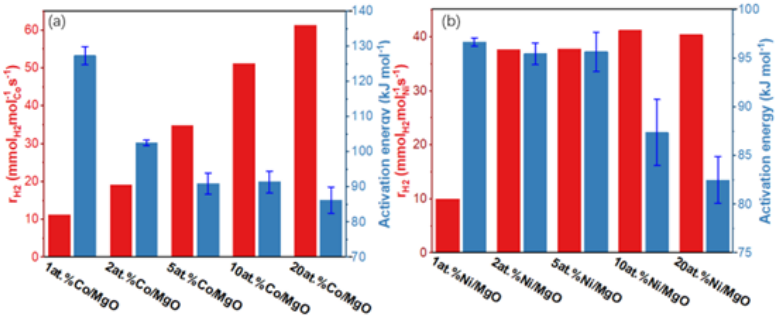

**Figure 1. Reaction rate of $H_2$ production during ammonia decomposition at 500 C of and the corresponding activation energy for Ni and Co catalysts with various metal loading.**

# Reactions of Organic Molecules at the Water/Platinum interface: Parametrization of Density Functional Tight-Binding (DFTB)

Q. Wang[1,2], T. Niehaus[2*], S.N. Steinmann[1*]

[1]*Univ Lyon, ENS de Lyon, CNRS UMR 5182, Laboratoire de Chimie, F-69342 Lyon, France*
[2] *Université Claude Bernard Lyon 1, CNRS, Institut Lumière Matière, Villeurbanne, France*

**Keywords:** DFTB, water/platinum interface, repulsive potential parametrization, biomass conversion

**Introduction.** The water/metal interface is ubiquitous in heterogeneous catalysis and electrocatalysis, especially in the context of biomass conversion. Therefore, it is of great importance to obtain a detailed understanding of the this interface and the modification of the interaction of organic adsorbates in the presence of water compared to vacuum. Limited by the large size and complexity of the system, classical molecular dynamics (MD) and/or QM/MM simulations with force-fields models [1-2] are the conventional approaches for explicit water simulation. However, the many-body effects of water at the interface are neglected by force-fileds, as are surface reconstructions and modifications of adsorption modes in explicit water compared to implicit solvents. Herein, we parametrize Density Functional Tight Binding (DFTB), which can overcome these issues with a computational cost that is several orders of magnitude lower than DFT. We start by the water/platinum interface and then supplement the necessary parameters for Pt-C in order to describe the adsorption and reactivity of organic molecules at this archetypical interface.

**Methodology.** The parametrization of repulsive potential ($E_{rep}$) is critical for the transferability and overall accuracy of DFTB but is tedious. We start by establishing a relevant training and test set at the DFT level of theory and generate Pt-O and Pt-H $E_{rep}$ parameters via the "DFTBparaopt" [3] and "CCS" [4] programs. These pair wise repulsive parameters are then augmented by many-body interactions as provided by the Chebyshev Interaction Model for Efficient Simulation (ChIMES) [5]. Finally, a large set of configurations are used to validate the method. This strategy is then applied to Pt-C and biomass molecules.

**Results and discussion.** The performance of different combinations of generated Pt-H and Pt-O $E_{rep}$ parameter pairs were tested on a set containing ~4000 single-water/platinum-surface adsorption configurations that covers the diversity of water/platinum interaction. The best root mean square deviation (RMSD) of DFTB-calculated adsorption energies ($E_{ads}$) is 3.6 kcal/mol compared to DFT. The analysis shows that, compared to the DFT-calculated results, the DFTB predicted $H_2O$-Pt binding strengh is under-estimated on high-coordination surfaces like Pt(111) and Pt(100) while rather correctly reproduced on low-coordination surface atoms, e.g., addatoms. The ChIMES corrective potential is found to lower the RMSD to 1.76 kcal/mol and to increase the transferability between extended crystal surfaces and nanoparticles.

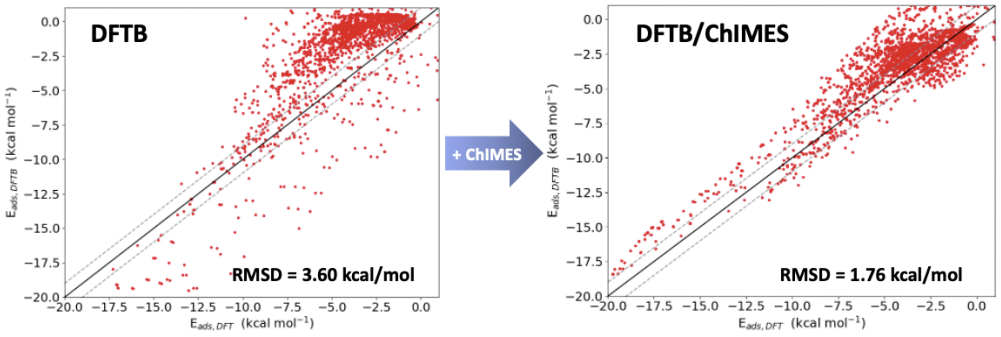

**Figure 1:** Parity plot of DFTB vs DFT adsorption energies of water on Pt surfaces, with/out and with ChIMES correction.

[2] *Korea Research Institute of Chemical Technology(KRICT), Daejeon, South Korea*
[*] *E-mail: cukim@krict.re.kr*
[**] *E-mail: ysyoon@postech.ac.kr*

**Keywords:** Kinetics, Ethylene, Butens, Dimerization, Ni-Al supported Silica based Catalyst

**Introduction.**
Butenes constitute an important commodity which can be used as an intermediate in the production of a wide range of chemicals.[1] Typically, butenes are produced from naphtha steam cracking as a by-product. In other ways, the dimerization of ethylene to butenes(ETB) is an attractive possibility, exploiting the availability of ethylene via methathesis step.

The dimerization of ethylene to butenes over Ni-Al supported ordered mesoporous silica SBA-15 catalysts with different morphologies have been investigated compared to the activities of the other catalysts in our previous study, but also faced severe deactivation with time on stream.[2]

In this study, a kinetic study inculding deactivation is discussed for ETB reaction over the Ni-Al supported silica based catalysts based on the molecular based lumped kinetic model.

**Experimental/methodology.**
The ethylene dimerization was performed in a fixed-bed reactor (i.d. 6 mm) using 0.25 g catalyst at the pressure of 2 to 20 bar and the temperature of 200 to 380 °C. Ethylene was supplied at the rate of 2 to 8 ml/min with $N_2$ as a carrier gas. The experimental data after reacting for 1.3 and 10 hours, respectively, were used due to fast deactivation of the catalysts.
The kinetic parameters were estimated using experimental data by use of a genetic algorithm and ODE15s solver offered by Matlab R2023a.

**Results and discussion.**
Ni-Al suppoorted mesoporous silica based catalysts were good catalysts for ethylene dimerization, but are still faced severe deactivation with time on stream.

The conversion of ethylene was increased with increasing of the space time, reaction temperature, and reaction pressure at the early stage of the reaction (1.3 hour with time on stream). The major products at the this time were as followes such as 1-butenes > butane > ethane ≒ propylene ≒ hexene, whereas the major products after 10 hour were changed such as 1-butenes > hexene > butane due to the drastic declines of ethane and proplyene.

From the expimental results, apparent activation energies of ethylene conversion were estimated 1.7 and 37.5 kJ $mol^{-1}$ at 1.3 and 10 hour, respectively.

**Keywords:** Activated carbon, adsorption, impregnation, catalytic modification

**Introduction**

Humic acid (HA) is a naturally occurring complex organic matter and plays a key role in water and wastewater treatment (Lipczynska-Kochany, 2018). HA reacts with chlorine and produces carcinogenic by-products like tri-halomethanes and haloacetic acids during disinfection processes in water treatment plants (Park et al., 2019). Various removal technology has been considered and adsorption by activated carbon (AC) is recognized as a feasible option. However, adsorption capacities of HA should be enhanced to expand its application. Catalytic reaction of iron impregnation on surfaces of AC has been investigated to improve adsorption capacities of HA. Two different raw materials, i.e., coal- and coconut- based AC were utilized.

**Experimental/methodology.** The original granular AC was purchased from Calgon Carbon Corp. (USA) for the coal-based AC and from Samchully (Korea) for the coconut-based AC. Surface modification for iron impregnation was performed by an ion-exchange technique and treated by heat in a tube furnace with a temperature of 900 ℃ at a rate of 5 ·min-1 for 1 h under helium gas flow. Surface characterization was conducted with field emission scanning electron microscopy, X-ray photoelectron spectroscopy (XPS), energy dispersive spectrometer (EDS), and zeta potential analysis. Isotherm experiments were also implemented to understand the adsorption properties.

**Results and discussion.** The surface modification increased iron contents of AC, which verified by EDS mapping images and XPS spectra analyses. The results of ion-exchange with different iron concentrations showed the increasing mean pore diameter and the decreasing specific surface area with increasing iron contents from 0.2 M to 2.0 M. The specific surface area was recovered by heat treatment and obtained approximately 5%~10% increases, which yielded the area almost similar to the original AC. However, the heat treatment decreased iron contents on the AC surfaces. Interplay between the catalytic component of iron and the active adsorptive sites were seemingly determined the adsorption capacities of humic acid. The isotherm equilibrium of humic acid showed that the maximum adsorption capacity was greater with high iron content AC than the original AC. The enhanced removal of HA was supported by the composition and spatial distribution of iron in the modified ACs. A reduction in the specific surface area and pore volume was observed with the modified AC. The increased adsorption capacity based on the accessible surface area revealed the importance of the catalytic surfaces of iron. The heat treatment largely recovered the pore structures and maintained a high adsorption capacity, which implied that particular strategies should be adopted to increase iron impregnated surfaces to improve HA removal.

**Introduction.** The electronic properties of metal oxide semiconductors can easily be tuned by light, temperature, and chemical interactions with the environment. The latter makes them suitable for the gas sensor applications such as monitoring and detecting VOCs, toxic and hazardous gases such as CO, $NO_x$, etc. $SnO_2$ is the most frequently used and investigated material for gas sensor applications. The sensor response is based on the electrical resistance change due to the electron transfer between the semiconductor and the surface species. The reactions and electron transfer over the semiconductor surface are quite complex and have the primary importance on the sensor response characteristics such as response time, sensitivity, selectivity, etc. The response mechanism mainly relies on the ionized oxygen species ($O^-$ and $O^{2-}$) over the surface and yet, the true nature behind the surface interactions with the oxygen species has not been adequately explained [1]. In this work, a comprehensive model is set-up to simulate the dynamic response of the thin film n-type $SnO_2$ gas sensor to CO in an air environment. For that reason, the ionization kinetics of oxygen over the surface, oxidation of CO and the mass transfer effects were incorporated into the mathematical model. The simulations were compared with the experimental results.

**Experimental/methodology.** The mathematical model consists of the diffusion of CO in 1D (through the thickness of the thin film), the oxygen adsorption and ionization over the surface, the reaction of CO with the ionized oxygen, electron transport between the adjacent grains and the electrical current transfer in 2D. The transient 2D simulations were performed by using the commercially available software COMSOL 6.0. The $SnO_2$ thin films were deposited on a glass substrate by using the sol-gel drop coating method. Under continuous dry air flow, DC resistance measurements of the sensor were obtained by using the digital multimeter GW Instek GDM-8255A. The gas sensor response was obtained with respect to step impulse of CO in air by using two six-port valves. The desired flow rates were adjusted by mass flow controllers.

**Results and discussion.** The effects of the temperature and film thickness on the dynamics of the sensor response were analyzed by simulations. The simulations were in good agreement with the experiments in terms of the response/recovery dynamics of the $SnO_2$ gas sensor having 7 µm film thickness to three different step changes in CO concentration in air (Figure 1). The increase in temperature results in an increase in $O^-$ and total ionized oxygen density, while a decrease in $O^{2-}$ density. Although faster response and recovery were obtained at high temperatures, response magnitude decreases with increasing temperature due to the faster replenishment rate of ionized oxygen species over the surface. The mass transfer limitations significantly decrease the sensor responses. In thick films, the current mainly flows near the external surface of the thin film as a consequence of the mass transfer limitations.

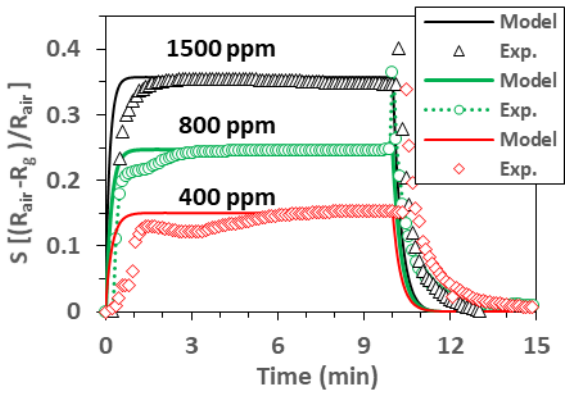

**Figure 1. Comparison between experimental and simulation results in terms of the response of $SnO_2$ sensor having 7µm film thickness at T=528K.**

**Introduction.** The beneficial use of zeolites as shape-selective catalysts in petrochemical and refinery processes has been widely demonstrated. In order to maximize the catalytic activity and selectivity and to minimize catalyst decay, it becomes crucial to control the pore diameter (intrinsic zeolite pore dimensions and shape), the zeolite's chemical composition (Si/Al ratio, acid site density) and crystallite size (pore length), which determine the number and distribution of the active sites as well as the diffusion pattern. Besides the well-documented effect of the crystallite size and acid site density, there is another variable that may influence reactivity and diffusion in zeolites with different pores running along different crystallographic dimensions, such as ZSM-5, which is related to the morphology of the crystallites.[1] The high propylene demand drives researchers and industrial companies to the search for easy, inexpensive on-purpose technologies for its production. When propylene is obtained by FCC, butenes are also produced, so the direct conversion of butenes to propene is of high interest. In this work, this is approached by means of an oligomerization-cracking process, where the main challenges are minimizing the formation of aromatics and paraffins, not only because of selectivity issues, but also because of catalyst life. Therefore, we have studied and controlled the zeolite variables that result inpropene yield maximization during the catalytic cracking of butenes in the presence of ZSM-5 catalyst.[2]

**Experimental/methodology.** On the one hand, ZSM-5 zeolites with Si/Al 400 were synthesized with different crystallite sizes and morphologies. On the other, ZSM-5 zeolites with small crystal size and a square morphology were prepared with Si/Al ratios in the range of 200-600. Butene cracking experiments were performed under continuous fixed-bed conditions at 550ºC, atmospheric pressure and 1-butene concentration in the feed of 0.16 vol.%.[2]

**Results and discussion.** Chemical composition, crystal size and crystal morphology were defined as the descriptors that should control activity, selectivity and catalyst life. Thus, ZSM-5 zeolites were synthesized so that these descriptors were varied one at the time while maintaining the rest of the catalyst features constant, allowing us to rationalize the relative impact of each descriptor and their interplay. We found that square-shaped crystals with sub-micron sizes and Si/Al~300 (Figure 1a) facilitate propylene diffusion and decrease the extension of consecutive reactions by shortening the length of both sinusoidal and straight channels. The number of channel intersections is also reduced and, as a result, the formation of aromatics and branched oligomers leading to coke precursors was minimized, resulting in longer catalyst life. On the other hand, coffin-type ZSM-5 crystals show crystal discontinuities[3] and higher diffusional restrictions resulting in successive reactions leading to lower propylene selectivity and faster catalyst decay. Interestingly, both propylene selectivity and catalyst life were enhanced for large coffin-shaped crystals with intergrown particles (Figure 1b). We believe that this unexpected behavior is due to the preferential orientation of the twinned subunits, which expose preferentially sinusoidal pores (Figure 1c) and hence increase the proportion of openings giving access to the zig-zag channels for the whole crystal.[4] This allows more recracking events, but also prevents the formation and/or diffusion of large (poly)alkylated aromatic molecules, reported to be formed preferentially in the straight pores.[4] Moreover, light hydrocarbons, such as propene, will preferentially diffuse through the sinusoidal channels without being further converted into bulkier products,[5] while they will be consumed in consecutive reactions along the straight channels. Thus, in this case, the product shape selectivity is affected by the preferential exposure of the intergrowth facets giving access to the sinusoidal channels wherein the aromatics production is limited. Consequently and both propylene selectivity and catalyst life are enhanced, even for these large crystallites.

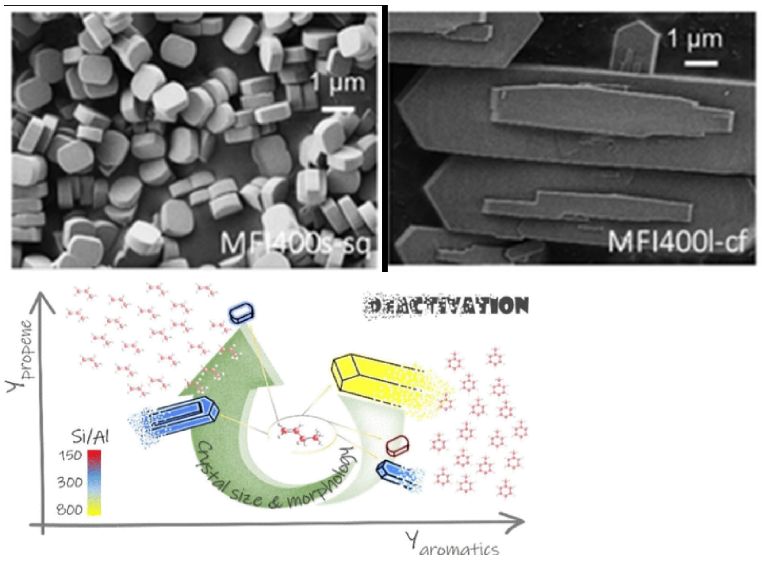

**Figure 1. (a, b) FESEM micrographs of two differently synthesized ZSM-5 and (c) balance of diffusional (crystal size and morphology) and compositional (Si/Al ratio) effects for maximizing propylene production and catalyst life.**

# The Role of Formaldehyde in the Methanol-to-Hydrocarbons Conversion

Vladimir Paunović[1,2*], Patrick Hemberger[2], Andras Bodi[2], and Jeroen A. van Bokhoven[1,2]
[1] *Institute for Chemical and Bioengineering, ETH Zurich, Zurich, Switzerland*

[*] *vladimir.paunovic@chem.ethz.ch*

**Introduction.** Formaldehyde ($CH_2O$) is an important intermediate that affects the performance of zeolite catalysts in the methanoltohydrocarbons (MTH) conversion.[1-3] This species, which is proposed to arise from Brønsted acid site (BAS)-catalyzed hydrogen transfer (HT) from methanol, readily transforms alkenes into dienes and methylated benzenes (MBs), thus favoring the products of the arene cycle.[1,2] Besides, $CH_2O$ facilitates the conversion of MBs into polycyclic aromatic hydrocarbons, which are the main deactivating species.[2] However, the $CH_2O$ reaction pathways and their dependence on the catalyst structure are still elusive, which is mainly caused by the challenging detection of this intermediate.

**Experimental/methodology.** The photoelectron photoion coincidence (PEPICO) spectroscopy combined with isotope labeling experiments and catalyst testing were used to investigate the formation and reactivity of $CH_2O$ in quartz and stainless steel reactors, over bed diluents (silicon carbide and quartz), and ZSM-5 catalysts with low (15, $Z_{15}$) and medium (40, $Z_{40}$) Si/Al ratios.[3]

**Results and discussion.** The PEPICO experiments revealed that stainless steel reactor walls and silicon carbide diluent exhibit methanol-to-formaldehyde conversion activities that are higher or comparable to those of the zeolite catalysts under similar conditions (**Fig 1a**). Their activity stems from methanol dehydrogenation over transition metal sites, which yields hydrogen and carbon monoxide as byproducts. Thus produced $CH_2O$ readily reacts in the MTH reaction, causing a decrease of the propenetoethene ratio and the reduction of the catalyst life-time (**Fig 1b**). Low activity of quartz enabled to study the $CH_2O$ reactions over ZSM-5 catalysts (**Fig 1a,c**). At low conversions, methane is generated in stoichiometric amounts with $CH_2O$, which along with low yields of $C_{2-4}$ alkenes and non-detectable formation of alkanes, arenes, and dienes implicates that HT between metoxy groups is the prevailing reaction in the first phase of the MTH conversion. This reaction displays the first order dependence with respect to methanol and moderate activation energy (ca. 80 kJ $mol^{-1}$). With increasing conversion, a decrease of $CH_2O$ yield coincides with the evolution of dienes and MBs, indicating the involvement of $CH_2O$ in their formation. This is corroborated by the $CH_2O$ cofeeding, which led to immediate decrease of alkene, and increase in production of MBs and methylated naphthalenes (**Fig 1d**). Thereby, identification of fulvene suggests that it may be the central species mediating the $CH_2O$-induced transformation of alkenes to arenes. Notably, the yield of $CH_2O$ shows faster decrease for less stable $Z_{15}$ than for more stable $Z_{40}$ catalyst (**Fig 1c**). These results provide a hint that lower activity of less acidic zeolites in the $CH_2O$-mediated reactions may be the central source of their lower coking propensity. Such relationships between the $CH_2O$ activity and catalyst stability are tackled in our ongoing research.

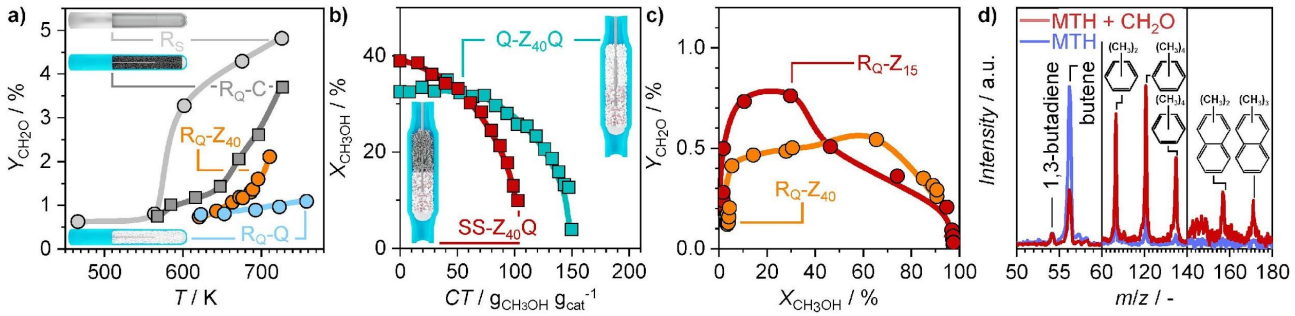

**Fig. 1.** a) $CH_2O$ yield in stainless steal (Rs) and quartz reactors ($R_Q$) filled with SiC (C), quartz (Q) and $Z_{40}$ zeolite. b) Conversion vs. cummulative turnover in the MTH reaction in the presence of steal and quartz. c) $CH_2O$ yield vs. conversion over $Z_{15}$ and $Z_{40}$ zeolites. c) Change of product distribution in the MTH reaction upon $CH_2O$ co-feeding.

# Application of Ga-based catalysts for the non-oxidative dehydrogenation of methanol to formaldehyde and hydrogen

M. Merko, S. Delsing, W. Busser, M. Muhler*

[1] *Ruhr-Universität Bochum, D-44780 Bochum, Germany*
**muhler@techem.rub.de*

**Introduction.** The non-oxidative dehydrogenation of methanol ($CH_3OH$) to formaldehyde ($CH_2O$) is an alternative to the classical oxidative dehydrogenation/partial oxidation applied in the industrial production of $CH_2O$. Its advantage is the production of anhydrous formaldehyde required for the synthesis of polyoxymethylene dimethyl ethers and $H_2$ as a coupled valuable product. In spite of intense reseach[1] an industrially relevant process has not been established yet. The promising catalytic performance of bulk β-$Ga_2O_3$[2] as well as an enhanced yield of $CH_2O$ as a reaction intermediate over Ga/HZSM-5[3] were recently reported.

**Experimental/methodology.** Supported catalysts with varying Ga content were prepared by wet impregnation of fumed $SiO_2$ and γ-$Al_2O_3$ followed by calcination in air. The characterization of the materials included $N_2$ physisorption, ICP-MS, XRD, Raman spectroscopy, TEM/SEM-EDS, XPS, $NH_3$ TPD, DRIFTS, and TPO. The activity of the materials was tested in a home-made laboratory set-up using a fixed-bed reactor in the temperature range of 200-650 °C while applying a flow of 2.6-2.7% $CH_3OH$ in 300 mL $min^{-1}$ $N_2$.

**Results and discussion.** Figures 1a demonstrates that both the choice of the support material and of temperature had a significant impact on the product distribution. Formation of $CH_2O$ was favored above 550 °C for 8 wt% Ga/$SiO_2$ with DME being a major byproduct at lower temperatures. The latter was due to the intrinsic activity of the support in case of γ-$Al_2O_3$ and possibly accompanied by the formation of new active sites upon interaction of gallia with the support for $SiO_2$. Additionally, variation of the Ga content and the support affected the deactivation rate (Fig. 1b) as well as the amount, composition and thermal stability of the carbon deposits formed at the catalyst surfaces. Deactivation was reversible for all catalysts, which was fully regenerated by a treatment with $O_2$. By applying reaction-regeneration cycles, prevention of rapid deactivation was achieved resulting in a stable performance of the catalysts (25 wt% Ga/$SiO_2$, Fig. 1c).

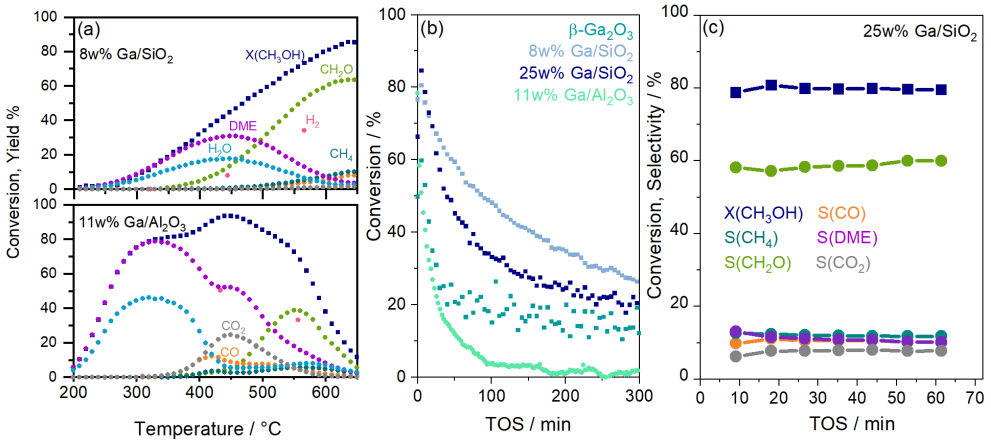

**Figure 1. (a) Effect of temperature on the product distribution over 8 wt% Ga/$SiO_2$ and 11 wt% Ga/$Al_2O_3$; (b) change of conversion with TOS at 550 °C; (c) catalytic performance of 25 wt% Ga/$SiO_2$ at 550 °C obtained when periodic regeneration of the catalyst was performed using a ratio of reaction time to regeneration time of 2.7:1.**

# Second-generation approaches for the production and distribution of green $H_2$

G. Centi* and S. Perathoner

*The University of Messina and the European Research Institute of Catalysis aisbl, Messina/Italy and Brussels/Belgium*
** E-mail: centi@unime.it*

**Keywords:** green $H_2$, photoelectrocatalysis, plasma-assisted methane decomposition, LOHC, e-SMR

**Introduction**. "Green" hydrogen will play a crucial role in the future of a carbon-neutral society, with multiple applications from carbon-intensive industries to transport, power and buildings sectors [1]. Thus, it is surprising that the discussion is focused almost only on electrolysis, an energy-intensive process. This lecture will discuss examples of alternative $H_2$ production and novel possibilities for hydrogen vectors to explore new opportunities in hydrogen production and distribution [2].

**Discussion**. The lecture will discuss some examples of alternatives to electrolysis in producing green and even carbon-negative hydrogen. After introducing why it is necessary to go beyond electrolysis-only technologies, and briefly discussing the production of $H_2$ from waste [3], the concepts of i) $H_2$ from electrified SMR (steam methane reforming) and ii) green $H_2$ produced in a plasma-assisted process from bio$CH_4$ are presented. Both are just-started projects (EreTech and MECCA, respectively).

For hydrogen distribution ($H_2$ vectors), the catalytic hydrogenation of LOHC (Liquid organic hydrogen carriers) coupled with lignin derivatives oxidation to reduce LOHC production costs and links biowaste valorisation (biorefinery) to $H_2$ economy is introduced. This is also a just-started EU project (EPOCH). The final example regards the possibility of a PEC (photoelectrocatalytic) device integrating the chemical storage to allow a continuous (24h) production of green $H_2$. It is the first example of developing artificial trees for continuous or on-demand production of green $H_2$ in a distributed mode.

These examples highlight thus the many possibilities beyond the too-limited panorama of studies in the green $H_2$ arena. There is a need to accelerate innovative directions in green area production and distribution to address the challenge of a carbon-neutral society more effectively [1,2]. Catalysis and chemical engineering play a crucial role in realising this challenge [5,6].

# Unexpected formation of aromatics from ethylene conversion on non-zeolitic Ni catalysts

*M. Armbruster, U. Bentrup, H. Atia, D. Linke and U. Rodemerck**
*Leibniz Institute of Catalysis, 18059 Rostock, Germany, *uwe.rodemerck@catalysis.de*

**Introduction.** Ni on silica-alumina prepared by grafting converts ethylene mainly to propene and butenes as already described in the literature [1,2] whereas over $Ni/SiO_2$ aromatic compounds are formed. Nickel was doped on silica and silica-alumina by three methods to obtain $Ni^{2+}$ surface species with different vicinity and dispersion. The formation of aromatic compounds requires the interplay of metallic and acidic centres [3]. On the contrary to well-known metal-doped MFI zeolites, our new Ni-silica catalysts do not possess any Brønsted acidity which suggests a different reaction mechanism of aromatics formation.

**Experimental/methodology.** Commercial silica-alumina (Siral 70), $SiO_2$, MCM-41(MCM) and silicalite-1(S1) were used as supports for ca. 1-2 wt% Ni loading. The catalysts are prepared either by incipient wetness impregnation ($1Ni/SiO_2$_i, 1Ni/MCM_i), template-ion exchange (3Ni/MCM_t) or by grafting of $Ni(acac)_2$ (2Ni/MCM_g, $2Ni/SiO_2$_g, 1Ni/S1_g). Selected samples were characterized by various techniques and evaluated in ethylene conversion at atmospheric pressure and 375°C. The reaction was carried out in apparatus equipped with 15-parallel continuous flow fixed-bed reactors. The catalysts were screened consecutively, reactor by reactor. The products consisting of paraffins, isomers, olefins and aromatics were registered by gas chromatography. Ethylene conversion (X) and product selectivities ($S_i$) were calculated from the respective concentrations at inlet/outlet of reactor and for selectivity a coefficient equal to C-atoms in corresponding molecule was used. $S_{coke}$ was calculated as difference to 1.

**Results and discussion.** All Ni-silica catalysts possessed amorphous structure and diverse mesopores, but FTIR spectra of CO adsorption differ considerably: Ni impregnated samples show no CO adsorption on $Ni^{2+}$ surface species but only bands at 2157 and 2135 $cm^{-1}$ connected with CO adsorbed on OH groups of silica. This agrees with the absence of acidic Lewis sites on these catalysts as measured by pyridine adsorption. $2Ni/SiO_2$_g and 2Ni/MCM_g, prepared on different Si-supports by grafting of $Ni(acac)_2$, displayed an additional band in the IR spectrum at 2178-2180 $cm^{-1}$ that can be assigned to $Ni^{2+}$ species bound through OH groups linked to Si. On 1Ni/S1_g two additional bands were observed and assigned to diverse $Ni^{2+}$ species. XRD and TPR results confirmed as well that grafting method is much better suited to reach highly dispersed surface $Ni^{2+}$ sites than impregnation. Preparation method affects the anchoring of Ni species on the support and finally the interplay of Ni-support active sites. Hence, the reaction pathway ends up in different product distribution. Aromatics were observed on all-silica catalysts made by Ni grafting, where the highest selectivity of 25% was achieved on 2Ni/MCM_g, Fig.1. Ni ion-exchanged sample has shown low selectivity to aromatics while on catalysts prepared by simple impregnation no aromatics were observed at all. IR spectra of adsorbed pyridine and carbon monoxide recorded for impregnated $1Ni/SiO_2$_i and 1Ni/MCM_i showed neither Lewis acidic sites nor adsorbed CO on surface $Ni^{2+}$species. The formation of aromatics from ethylene occurs over catalysts with $Ni^{2+}$ surface species bound by O-bridges to silica. These sites do not involve any $H^+$-acidic sites. Such species have different electronic properties compared to those present in Ni/silica-alumina ($Ni^{2+}$-O-Al) as concluded from different wave number in IR spectrum of adsorbed CO (2180 *vs* 2195 $cm^{-1}$). The ability for aromatics formation and its selectivity depends on the kind of Ni species and its dispersion that can be controlled by the preparation method.

# Methane dehydroaromatization over $Mo/WO_3$-$ZrO_2$ catalysts

Jhonattan D. Manosalvas Mora[1], A.K.M. Kazi Aurnob[1], Ashraful Abedin[1], James J. Spivey[1*]

[1] *Louisiana State University and Agricultural and Mechanical College, Baton Rouge (LA), USA*

** jjspivey@lsu.edu*

**Introduction.** Methane dehydroaromatization (MDA) is widely reaction studied by a bifunctional Mo/H-ZSM-5 catalyst, to produce benzene from methane in a single step ($6CH_4 \rightarrow C_6H_6 + 9H_2$; $\Delta G^{\circ}$=432.5 kJ/mol). This chemical reaction has been classified as one of the most complex problems of catalysis [1] because of thermodynamic limitations and carbonaceous depositions which preclude steady state conditions and promote rapid deactivation. Here, we demonstrate the use of a novel $Mo/WO_3$-$ZrO_2$ (Mo/W-Z) catalyst, its characterization, and elucidate its advantages and/or disadvantages compared to literature. The 1%(wt.) Mo/W-Z catalyst showed the best stability at 600°C during TOS = 1000 min.

**Experimental/methodology.** The synthesis process involved two stages [2]. First, synthesis of the support, and second, impregnation of molybdenum oxide on to the support. In short, certain amount of ammonium metatungstate was impregnated into zirconium (IV) hydroxide using the dry impregnation method. Next, the $WO_3/ZrO_2$ (W-Z) catalytic support was dried, calcinated, and impregnated with ammonium heptamolybdate tetrahydrate [3], producing three loadings of 1% (wt.) Mo, 3% (wt.) Mo, and 6% (wt.) Mo,. The fresh, spent, and carburized samples were characterized by XRD, XPS, TEM-EDX elemental mapping, SEM-EDX elemental mapping, BET, $NH_3$-TPD, pyridine DRIFTS, H-NMR, EXAFS, and XANES. The catalyst tests were carried out using a PID Eng & Tech 9.1mm Hastelloy X tubular reactor (Serial: MA 12212MICROMERITICS) with TOS = 1000 min. Products were quantified downstream with an on-line Shimadzu GC-2014 and identified using a Shimadzu GCMS-QP2010 system. The reactions were completed in two stages [4]. The first stage consists of Mo carburization. The second stage involves MDA with $CH_4$ as the only reactant at temperature ranges from 600°C to 800°C at constant 1.013 $bar_{(a)}$ and 1500 mL/g·h.

**Results and discussion.** The main products of the reaction at each temperature were ethylene, ethane, propylene, and benzene. However, other aromatic products of higher molecular weight were not identified nor quantified. Furthermore, in figures from 1a to 1c, the results of the catalytic runs showed that samples with 6%(wt.) Mo loading at 700°C and 650°C produced the highest amounts of benzene within the first 100 min, but after this period deactivation made benzene not detectable after 300 minutes (at 700°C) and 850 minutes (at 650°C). However, the sample with 1%(wt.) Mo loading at 600°C exhibited highest stability and slowest deactivation. In fact, 1%(wt.) Mo at 600 °C reaction generated approximately 17 times more benzene than 6%(wt.) Mo at 700 °C (TOS = 300min), and 14 times more benzene than 6%(wt.) Mo at 650 °C (TOS = 900min). Figure 1d shows that samples have Bronsted (B) and Lewis (L) acid sites. B sites are essential, among other things [5], in ethylene oligomerization. In addition, there is no significant change in transmittance intensity which could mean that B and L sites were not affected by Mo impregnation. Finally, XRD patterns of all the tested samples show tetragonal (T) and monoclinic (M) zirconia phases, and crystalline $WO_3$ (W).

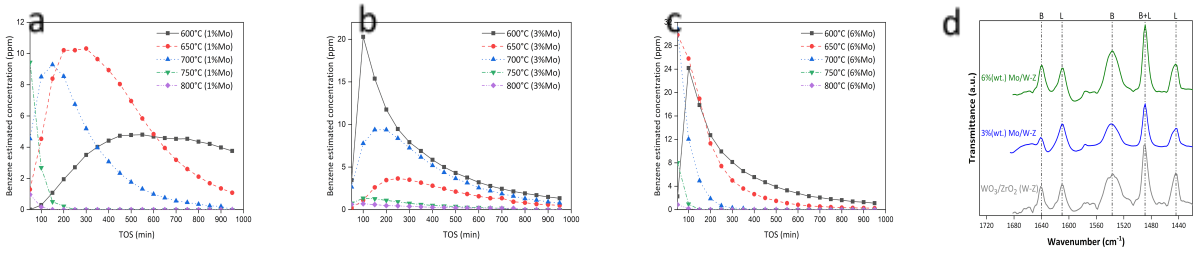

**Figure 1.** Benzene estimated concentration at different temperatures with a) 1% (wt.) Mo/W-Z, b) 3% (wt.) Mo/W-Z, c) 6% (wt.) Mo/W-Z, and d) Pyridine – DRIFTS at 100°C.

Catalytic cracking, zeolite USY, hydrothermal stabilization, phosphorus, rare earth

**Introduction.**

Fluidized Catalytic cracking (FCC), one of the main conversion processes in conventional refineries, employs a multicomponent catalyst with Y zeolite as the main source of activity and selectivity towards value added products.[1] In order to meet the severe requirements of the FCC unit, the hydrothermal stability of this large pore zeolite is traditionally improved by means of controlled hydrothermal treatment that could be coupled with acid washing cycles, by ion exchange with rare earth (RE) ions or by a combination of both.[2] Phosphorus has also been described as stabilization element, and although most of the studies are based on ZSM-5 zeolites, a new Y zeolite containing FCC catalyst based on the partial substitution of RE by P was developed, that allowed obtaining the same yield structure and activity as its conventional RE stabilized counterpart in vacuum gas oil (VGO) feed applications.[3]
Here, we present a systematic study where P- and La-free USYs with different dealumination degrees are compared with the corresponding USYs containing P or La alone or a combination of both.

**Experimental/methodology.**

Three ultrastable Y (USY) zeolites were prepared by pre-stabilization at different temperatures, 500, 600 and 700ºC (USY500, USY600 and USY700). La was introduced by ion exchange and P by wet impregnation. Comercial catalyst were tested for VGO cracking in a circulating riser unit. In-house prepared (P/La)-USYs were tested for VGO cracking in a MAT unit.

**Results and discussion.**

The results obtained confirmed that the properties of the starting USY zeolite carry a strong influence on the stabilization degree of elements such as P or La. Thus, for USYs obtained under milder pre-stabilization conditions, the presence of highly dispersed cationic EFAl species already exerts a stabilization function towards hydrothermal treatments at 750ºC. Only a strongly dealuminated USY such as USY700, does clearly benefit from the introduction of high REO loadings, thanks to the preservation of a larger amount of BAS. A similar trend was observed when adding P as single stabilization element, and only for the more dealuminated USY700, the addition of 1.0 wt% of P as H3PO4 or MAP resulted in a more active catalyst with similar liquid fuels and lower coke selectivity as compared to the reference P-free zeolite. However, it is possible to improve the catalytic behavior of a high UC size USY, with a low dealumination degree, to levels comparable to those given by a high REO La/USY by properly combining P and La as stabilization elements.

# The effect of the support pore structure on the oxidative desulphurization of dibenzothiophene

A. Nurwita*, M. Trejda

*Departement of Heterogeneous Catalysis, Faculty of Chemistry, Adam Mickiewicz Univerisity, Poznań, Poland, *ardnur@st.amu.edu.pl*

**Introduction.** Oxidative desulfurization (ODS) is one of the promising processes for desulfurization of fuels. Compared to conventional catalytic hydrodesulfurization, ODS can be carried out under mild reaction conditions and requires less energy. The success of the ODS process is determined by the catalyst efficiency in the oxidation, which strongly depends on the nature of the active centers and the type of support material. In this work two mesoporous silicas, i.e. SBA-15 and MCF, were applied as supports for Brønsted acid sites. The catalytic activities of the materials obtained were determined in oxidative desulphurization of the model compound, i.e. dibenzothiophene.

**Experimental/methodology.** SBA-15 and MCF supports were obtained by hydrothermal synthesis [1-2]. The organic template (Pluronic P123) was removed by calcination at 500°C. To generate Brønsted acidity, the supports were modified by 3-(trihydroxysilyl)-1-propanesulfonic acid (TPS) by grafting method keeping the Si/TPS molar ratio of 10 (in toluene at 100°C). The materials obtained were characterized by XRD, low temperature $N_2$ adsorption/desorption, elemental analysis and pyridine adsorption followed by FTIR measurements. Oxidative desulphurization of dibenzothiophene (DBT) was performed in EasyMax Workstation using $H_2O_2$ as an oxidant and different amounts of catalysts at various temperatures, $H_2O_2$/S ratios and reaction times.

**Results and discussion.** TPS containing catalysts based on SBA-15 and MCF were synthesized. Successful incorporation of TPS species on the surface of SBA-15 (0.70 mmol $g^{-1}$) and MCF (0.75 mmol $g^{-1}$) supports was confirmed by elemental analysis. The results were in agreement with the pyridine adsorption experiments combined with the FTIR spectroscopy. The results indicated that TPS/SBA-15 and TPS/MCF catalysts contained Brønsted acid sites (BAS). The concentration of BAS in MCF support was a little higher. The low-temperature $N_2$ adsorption/desorption experiments confirmed the mesoporous structure of the materials obtained. Incorporation of TPS species slightly decreased the surface area and pore diammeter, however, the samples maintained their mesoporous character. The catalytic tests performed with the participation of TPS/SBA-15 led to the aggregation of catalyst particles during the reaction, significantly limiting the activity in the ODS process (maximum 52% of conversion). On the other hand, TPS/MCF material appeared as an effective catalyst for ODS processes. Up to 99% DBT conversion was achieved at optimized reaction condition (Figure 1). Moreover, TPS/MCF maintained its catalytic activity over subsequent reaction cycles.

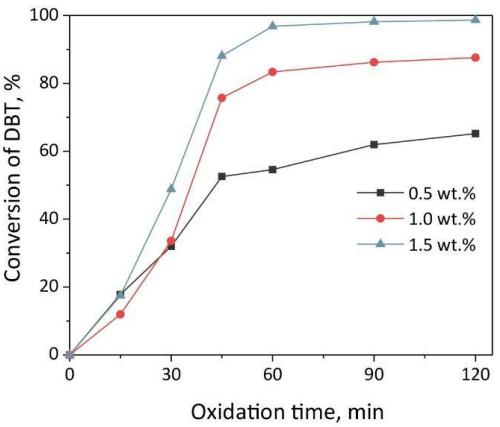

**Figure 1.** Catalytic activity of TPS/MCF (temp. 80°C; $H_2O_2$/S = 6:1, 1000 rpm)

# Investigation of induction period and oxygen species of chromium oxide catalyst for fluidized dehydrogenation of propane

H. Park, W.C. Choi, Y.K. Park, D.S. Park*

*Korea Research Institute of Chemical Technology, Daejeon, South Korea*
**dpark@krict.re.kr*

**Keywords:** Propane dehydrogenation (PDH), Chromium oxide, Induction period, Circulation fluidized bed

**Introduction.** The fluidized bed dehydrogenation has excellent advantages in terms of energy efficiency and low emissions of $NO_x$ and $CO_2$. However, it is challenging to develop a catalyst with high activity and propylene selectivity within a short residence time. Formation of propylene is delayed during a few seconds due to the formation of $CH_4$, CO and $CO_2$ over commercial Pt or Cr catalysts. To better understand this induction period, we figured out correlation between the initial selectivity to propylene and the formation of oxygen species on a chromium-alumina catalyst. We also introduce a catalyst-development strategy for fluidization process that reduces the induction period by control of oxygen species on catalyst and increases propylene selectivity within 3 s of the commencement of the reaction.

**Experimental/methodology.** The products were collected and analyzed on the second timescale reaction system. Analytical method (TPO) was carried out for distinguishing different oxygen species that develop over the $Cr/Al_2O_3$. A detailed correlation between the initial selectivity to propylene and the formation of oxygen species on a chromium-alumina catalyst was established by $O_2$-TPO and Raman analysis.

**Results and discussion.** Catalytic behavior at a very beginning of the reaction was related to diffrent oxygen species over the $Cr/Al_2O_3$ catalyst. Selective oxygen species in chromium oxide were rarely reduced or oxidized by $H_2$-TPR and $O_2$-TPO. Otherwise, non-selective oxygen species that are easily reduced of oxidized, were confirmed not highly dispersed, but are accumulated on the surface of the catalyst by the Raman analysis. The production of $CO_x$ in the early stage of the reaction was mainly caused by weakly bonded oxygen species on the surface of the catalyst, which favor the deep oxidation of propane. Furthermore, we suggest strategies to design catalyst for fast fluidized PDH process. One is increasing the amount of selective oxygen species by calcination method and the other is to selectively reducing non-selective oxygen species by pre-reduction with reductive gases which is applicable to fast-fluidized bed PDH process.

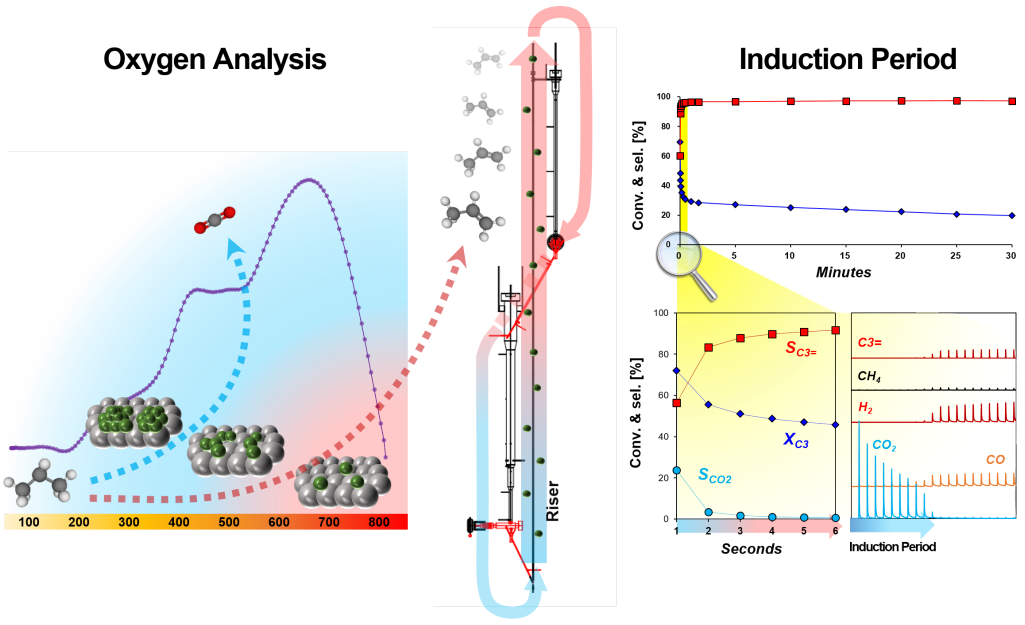

**Figure 1. Correlation between induction period and oxygen species of Cr catalyst for fluidized-PDH.**

**Keywords:** Oxidative coupling of methane, kinetic modeling, parameter estimation, effects of promoters

**Introduction.** Ethylene is mainly produced by steam cracking of ethane and naphtha. However, this method is the most energy-consuming process and is estimated to emit about 180 to 200 million tons of carbon dioxide [1-4]. For these reasons, many studies have been conducted on developing simpler, cheaper, and more sustainable ethylene production processes. Among them, the oxidative coupling of methane (OCM) is a potential solution for direct ethylene production utilizing natural gas as a substitute for petroleum resources. This study performed experiments over $Na_2WO_4$ catalyst on silica, where various promoters (Zn, Co, Ce, Cu, Cr, Ni) were adopted. Kinetic models were developed to evaluate the effects of those promoters on reaction pathways and catalytic activity.

**Experimental/methodology.** The metal-added $Na_2WO_4/SiO_2$ catalyst with different promoters was prepared with the impregnation method. The experiments were conducted at varying temperatures (725–800 °C), $CH_4/O_2$ ratio (2–4), inert nitrogen fraction (0.4–0.8), and gas hourly space velocity (10,000–20,000 $h^{-1}$). Kinetic parameters for lumped kinetic model were estimated by minimizing the objective function, which is the sum of the residuals of square errors of the objective elements. The estimation was performed using the "lsqcurvefit" subroutine in MATLAB (Mathworks, Inc.), where the Levenberg-Marquardt method was applied.

**Results and discussion.** Simplified reaction pathways were suggested for the OCM reaction. An active O site activates methane (reaction 1), and then ethane is produced by coupling methyl radicals (reaction 2). Produced ethane is converted to ethylene over the active site (reaction 3), and it could be decomposed to CHO radical by thermal or catalytic reaction (reaction 8). Meanwhile, part of the activated methyl radical is converted to CHO radicals (reaction 5) to produce CO (reaction 6) and $CO_2$ (reaction 7) as a byproduct. For simplified kinetics, pseudo-steady state assumptions were applied to the radicals, and the estimated activation energies for each promoter are as below.

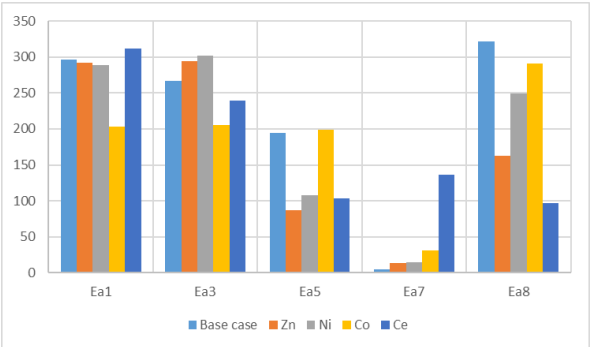

**Figure 1.** The comparison of activation energies for each promoter.

# Increased stability and activity of Mo/HZSM-5 for methane dehydroaromatization via Nb doping

Stefan Peters[1], Ana de Oliveira Guilherme Buzanich[2], Sebastian Wohlrab[1], Ali M. Abdel-Mageed*[1]

[1] Leibniz-Institut für Katalyse (LIKAT), Rostock, Germany
[2] Bundesanstalt für Materialforschung und -prüfung (BAM), Berlin, Germany
* ali.abdelmageed@catalysis.de

**Introduction:** Methane is the world's most abundant hydrocarbon, with large reserves proven as natural gas and methane hydrates (clathrates). High availability, low price and the possibility of renewable biogenic production makes it an attractive $C_1$ source.[1] The valorization of methane to C-C coupled products like alkenes and aromatics is a "dream reaction" in modern catalysis. Non-oxidative methane dehydroaromatization (MDA) is a promising pathway for the synthesis of benzenoids. Since its inception[2], highly dispersed Mo on porous zeolite materials (primarily HZSM-5) remain the most efficient catalysts for this reaction.[3] Due to the necessarily high reaction temperatures catalyst degradation by carbonaceous deposits ("coking") on active sites and inside pore systems is unavoidable. Improving catalyst stability and regenerability is therefore a pivotal subject for future applications of MDA, for which transition metal dopants have been investigated.[4] In this work we have systematically tested several transition metal dopants for their impact on the catalytic performance of Mo/HZSM-5 catalysts in the MDA reaction, focusing on conversion, product yields, stability on stream and catalyst regenerability.

**Experimental/methodology:** Studied catalysts were prepared by wet impregnation of $NH_4$-ZSM-5 supports with aqueous solutions of $(NH_4)_6Mo_7O_{24}{\cdot}4H_2O$ at 25 °C, aiming for 6 wt% Mo. Dopant transition metals (Fe, Co, Zn, Nb; 1 wt%) were introduced via co-impregnation with the respective metal nitrates (or oxalate for Nb). Prepared catalysts were dried and calcined in air at 550 °C for 6 h. Kinetic measurements were performed in a quartz tube reactor at 600-700 °C with a mixture of 90 % $CH_4$ / 10 % $N_2$. Reactants and products were quantified using a multichannel GC-MS with $N_2$ as the internal standard. Oxidative regeneration experiments were performed by *in situ* calcination in air at 450 °C. Catalysts were characterized before and after reaction and after regeneration steps using high-resoution STEM / EDS, XPS, XRD and other analyses. *In situ* XAS at the Mo K-edge was performed at BESSY II (*BAMline* beamline).

**Results and discussion:** Modification of 6Mo/HZSM-5 with 1 wt% Nb increased the benzene yield at similar methane conversions compared to the unmodified catalyst over 6 h of reaction, while 1Nb/HZSM-5 exhibited no intrinsic MDA activity. By variation of reaction temperature and residence time the positive effect of Nb was further explored: in comparison to 6Mo/HZSM-5, benzene and naphthalene yields for 6Mo1Nb/HZSM-5 were generally increased (by up to 10.4 % and 22.0 %, respectively, at 600 °C). Consecutive reaction / regeneration experiments with both catalysts revealed minor irreversible loss of activity, although superior stability was found for Nb-modified Mo/HZSM-5 in regards to conversion and benzene yield. Through high-resolution STEM coupled with EDS elemental mapping high dispersion and intimate mixing of Mo and Nb was observed in the fresh catalysts. Analysis of *ex situ* and *in situ* NAP XP spectra revealed partial reduction of $Mo^{6+}$ to $Mo^{4+}$ and $Mo^{2+}$. While $Nb^{5+}$ alone was not reducible under reaction conditions, it was converted to $Nb^{4+}$ and $Nb^{2+}$ species in the presence of Mo. Via *in situ* Mo K-edge XANES analysis in methane atmosphere a retardation of Mo reduction with Nb could be demonstrated, indicating intermetallic oxygen transfer. Further kinetic and analytical results from several characterization methods shall be discussed to explore the effect of Nb on performance and stability of Mo/HZSM-5 catalysts in the MDA reaction.

# Effect of Hydrocracked Vacuum Distillate Addition on FCC Yields

M. Pšenička[1*]

[1]ORLEN UniCRE, Revoluční 1521/84, 400 01 Ústí nad Labem, Czech Republic;
Martin.Psenicka@orlenunicre.cz

**Keywords:** FCC, HCVD, Alternative feedstock, coprocessing

**Introduction.** Fluid catalytic cracking units (FCC) are the heart of production within their refineries. Therefore, ways are constantly being sought to further increase the benefit of these cracking units for the future processing of alternative raw materials. Tests with alterative raw materials originating from pyrolysis oils from plastic depolymerization have already been carried out on the FCC simulation unit [1]. and the use of hydrocracked vacuum distillate (HCVD) in co-pyrolysis of Fisher-Tropsh wax vacuum residue [2]. The co-processing of hydrocracked residue on FCC units can bring more possibilities of its use.

**Experimental/methodology.** Additions of HCVD were chosen at 5, 10 and 20 wt%. It was tested using real raw material for the FCC unit and under real operating conditions on ACE laboratory unit. The resulting product composition is interpolated to constant conversion, constant C/O ratio and constant coke production.

**Results and discussion.** It was found that with the conversion to a constant production of coke (to maintain the heat balance of the operating unit) with increasing addition of HCVD, a higher total conversion of the raw material occurs and thus a higher production of desired products such as propylene, $C_4$ olefins and gasoline fraction. The reduction in production of LCO and slurry fraction is just another benefit. These fractions are not very desirable (LCO is mixed into diesel) and the slurry is rather recycled at the FCC unit. A comparison of total conversion as a function of C/O ratio and HCVD addition is shown in Figure 1.

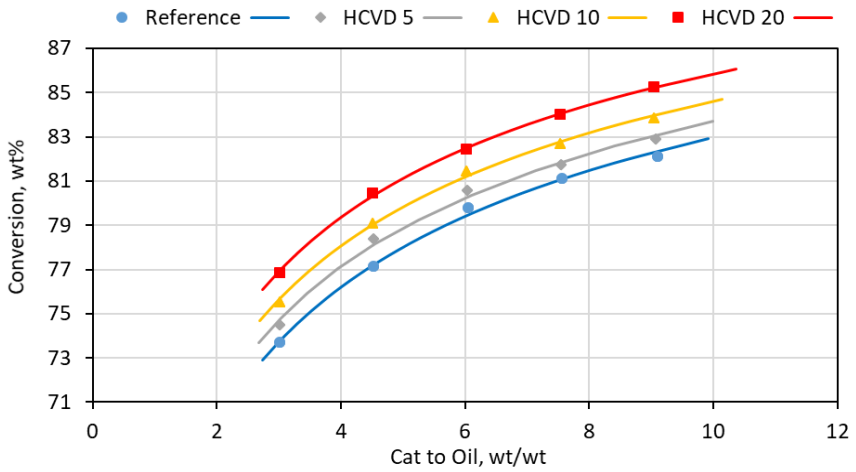

Figure 1 A comparison of the overall conversion

The processing of HCVD at the FCC unit shows only positive benefits and it is therefore at the discretion of the refinery whether it will continue to process HCVD at the FCC unit.

**Keywords:** oxidative dehydrogenation of ethane, Nb-doped nickel oxide catalysts, electrochemistry.

**Introduction.** The oxidative dehydrogenation of ethane (ODHE) could be a low demanding energy alternative to produce ethylene. One of the most promising catalytic systems for the ODH of ethane are NiO based catalysts, especially those doped with $Nb^{5+}$. ODHE on doped NiO catalysts proceeds through a redox mechanism. Therefore, the study of the electrochemical properties of these samples is highly interesting. However, there are just a couple of articles about NiO catalysts that have dealt with the conductivity of p-type semiconductors, and they have related this fact with the catalytic behavior in the ODHE [1, 2]. Then, the aim of this work is to undertake an electrochemical study of doped NiO catalysts to check if a correlation between electrochemical properties and catalytic performance does exist.

**Experimental/methodology. P**romoted nickel oxides catalysts (with a Ni/Me molar ratio of 9/1) were prepared through evaporation at 90 °C of aqueous solutions of nickel nitrate and metal salts (ammonium niobate (V) oxalate hydrate if Nb is the dopant) with different amount of oxalic acid in the synthesis gel. The solids were calcined in static air for 2 h at 350 or 500 °C. Catalysts were fully characterized by morphological, structural and physico-chemical techniques. Additionally a comprehensive electrochemical characterization using electrochemical impedance spectroscopy, Mott Shottky analysis and cyclic voltametries was carried out.

**Results and discussion.** According to the obtained results with Nb, the optimal catalysts present n-type semiconductivity, in spite of the fact that the composition (Ni/Nb ratio) is the same for all the catalysts studied. Interestingly, an inverse relationship between the density of non-stoichiometric oxygen and the selectivity towards ethylene has been clearly found in the catalysts presenting p-type semiconductivity. Additionally, the optimal catalysts present high total electrical resistance as a result of the removal of cationic vacancies and electrophilic O- species, which are selective towards the $CO_2$ formation (Figure 1).

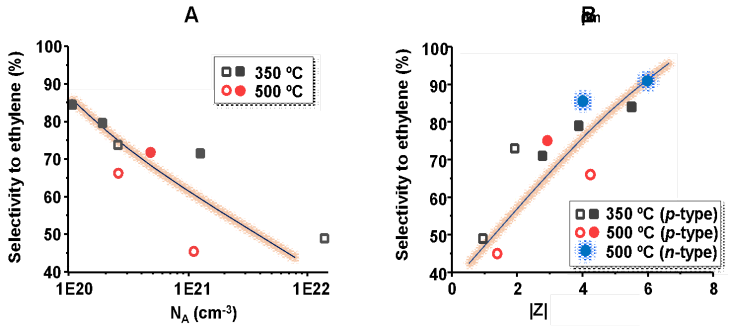

Figure 1. Relationship between the selectivity to ethylene and the acceptor density (A) or the total electrical resistance (B) for Nb-doped NiO catalysts calcined at 350 °C (■) or 500 °C (●,●).Nb-free NiO catalysts (○, □) are also shown. Selectivity to ethylene at isoconversion conditions (10% conversion) and 300 °C.

# A Self-Combustion-Depolymerization Approach to Activate Solid-Waste Coal Gangue Minerals for Fluid Catalytic Cracking Catalyst Synthesis

Ye Song, Ruoyu Wang, Xue Yang, Wei Lin*

*SINOPEC Research Institute of Petroleum Processing Co., Ltd., Beijing, China*
**linwei.ripp@sinopec.com*

**Keywords:** coal gangue, Y zeolite, solid waste, self-combustion-depolymerization, FCC catalyst.

**Introduction.**

Globally, explorating efficient utilization technologies for coal gangue, a notorious hazardous solid waste, is one of the most important issues among current sustainable development topics. Herein, a green and energy-efficient self-combustion-depolymerization (SCD) approach is proposed to activate coal gangue into highly reactive silica and alumina species for in-situ crystallization of fluid catalytic cracking (FCC) catalysts[1-3].

**Experimental/methodology.**

FCC catalysts (SCD-Y) bearing in-situ generated Y zeolites can be readily fabricated via hydrothermal synthesis. In addition to conventional analytical characterization techniques, temperature-distance profiles acquired by a lab-scale drop-tube furnace (DTF) was used to evaluate the self-combustion behavior and the obtained SCD-Y were analyzed by X-ray micro-computed tomography (μ-CT).

**Results and discussion.**

Taking advantage of the heat released by the self-combustion of coal residue, the SCD activation of kaolin-type CG can be achieved at a medium temperature much lower than that required by natural kaolinite. Using microspheres mainly composed of SCD-CG as zeolization precursors, FCC catalysts bearing in-situ generated Y zeolites (SCD-Y) have been synthesized under hydrothermal conditions, and the zeolite crystals are fully exposed on its external surface. The as-prepared SCD-Y has a high crystallinity of ca. 50 % and a well-developed intraparticle macro-, meso- and microporosity, as revealed by BET, Hg intrusion and μ-CT. A comprehensive dissolving-crystallization microscopic model corresponding to the SCD-Y zeolitization process is proposed on the basis of kinetic study. Significantly, SCD-Y exhibits superior catalytic performance for cracking and prominent anti-deactivation properties for heavy oil conversion, demonstrating a gasoline boosting effect while suppressing dry gas and coke formation. Remarkably, the overall energy consumption (Etot) using this SCD approach (1429.65 kgce/t product) is 33.5% lower than that of the conventional semi-synthesis route (2151.37 kgce/t product). The green synthesis of FCC catalyst can be successfully achieved following this proposed SCD approach, which opens a broad field for energy-saving and high-efficient ultilization of solid-waste coal gangue minerals.

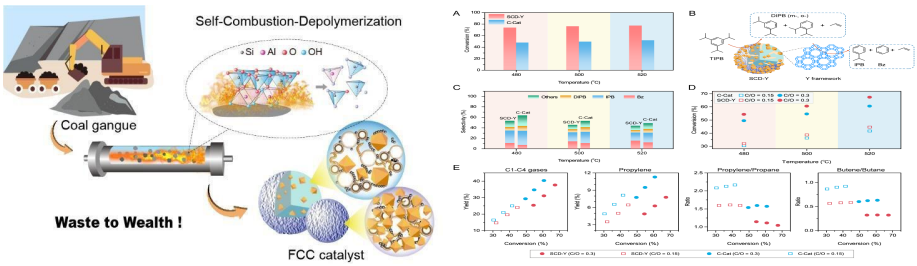

Fig.1 Schematic illustrations of the SCD approach proposed in this work using solid-waste coal gangue as the starting material. Fig.2 Catalytic cracking performances of SCD-Y and C-Cat

# Trail of Sulfur during the Desulfurization via Reactive Adsorption on Ni/ZnO

Ye Song, Bo Peng, Wei Lin*

*SINOPEC Research Institute of Petroleum Processing Co., Ltd., Beijing, China*
**linwei.ripp@sinopec.com*

**Keywords:** Desulfurization, Ni/ZnO; sulfur transfer, S Zorb; Mechanism.

**Introduction.**

With increasing number of motor vehicles, the harmful automotive exhaust becomes a major source of pollution in the urban environment all over the world and more stringent environmental legislations have been introduced all over the word. In Euro V and Tier III legislations, sulfur content in gasoline is required to be less than 10 ppm. The S Zorb process has been proved to be effective for the production of low-sulfur gasoline.The single step process is environmentally friendly and consumes significantly less hydrogen and energy, which makes a positive contribution to global carbon emission reduction.

**Experimental/methodology.**

The RADS mechanism of thiophene on Ni/ZnO sample was studied by a combination of DFT calculation and in-situ experiments. The detailed HYD and DDS pathways of thiophene over Ni (111) were simulated by DFT models. The phase transition during desulfurization process on Ni/ZnO was studied by in-situ XRD and STEM-EDS technology, in order to acquire direct evidence of S-transfer phenomenon between Ni and ZnO.

**Results and discussion.**

The desulfurization process of thiophene on Ni/ZnO was studied, and the desulfurization mechanism was elucidated. Thiophene molecule is preferentially adsorbed on metallic Ni as $\pi$-complexation mode. The desulfurization follows a DDS pathway. Namely, under the reaction conditions, the C-S bond is weakened and split with Ni-S bond formation, and $H_2$ is spontaneously split into H radicals, leading to the hydrogenation of C atom besides S. This is evidenced by DFT study. After twice of above C-S bond cleavage and following hydrogenation, the S-free C4 olefin is formed and can be further hydrogenated, while the sulfur is retained on the Ni surface, forming $Ni_3S_2$ phase. The resulted $Ni_3S_2$ phase after desulfurization, which is in close vicinity with ZnO phase in a typical S Zorb catalyst, undergoes a sulfur-transfer towards ZnO. As a consequence, the Ni active site is recovered and the sulfur moves towards ZnO, forming ZnS phase. Efficient sulfur-transfer is achieved at the interface of Ni/ZnO materials with the presence of $H_2$. This is demonstrated by a multi-technique characterization of in-situ XRD, STEM and EDS mapping. For the S Zorb process which has been widely applied in large scale, the current study is specifically meaningful, it provides convincing evidences of the essential materials transformation during practical operation.

**Keywords:** LOHCs, hydrogenation, noble metal catalysts

**Introduction.**

Liquid organic hydrogen carriers (LOHCs) are promising materials for hydrogen chemical storage, with similar properties than liquid fuels [1]. However, most of the proposed LOHCs are either pure compounds or model mixtures of aromatic compounds. The use of industrial oils enriched in aromatic compounds will be of key interest in these technologies. The hydrogenation of two carbochemical industrial oils containing large amounts of polyaromatics has been studied in this work, comparing the results with the obtained with a commercial aromatic fluid (Solvesso™ 200, Exxon Mobil). All of them contain naphthalenes and methylated derivatives, which are solid at ambient conditions, but easily solved for easier operation [2].

**Experimental/methodology.**

The reactions have been carried out in a stainless steel autoclave reactor of 50 mL total volume at temperatures of 150 and 250 °C. The volume used in all reactions was 30 mL. 5 % $Pt/Al_2O_3$ and $Pd/Al_2O_3$ reduced catalysts (Sigma-Aldrich), 1.5 g, were introduced into the reactor. After an evacuation in $N_2$, the media was pressurized until 50 bar and recorded its evolution for the 24 hours of reaction. Final products were analyzed in a gas chromatograph equipped with a mass spectrometry (Agilent Technologies 7890B).

**Results and discussion.**

Table 1 shows the content of the three oils, being included in methylnaphthalne derivates, 1-methylnaphthalene, 2-methylnaphthalene and their derivates. Likewise, Oil B presents quinoline in its composition. Oil A and Solvesso 200 are free of sulfur compounds, whereas Oil B presents a content < 0.7 %.

**Table 1**. Composition of the three considered aromatic oils.

| | Naphthalene | Methylnaphthalene derivates | Quinoline | Others |
|---|---|---|---|---|
| **Oil A** | 12.28 % | 32.92 % | - | 54.80 % |
| **Oil B** | 5.25 % | 56.29 % | 7.07 % | 31.39 % |
| **Solvesso 200** | 6.79 % | 72.18 % | - | 21.03 % |

Naphthalene and methylnaphthalenes do not hydrogenate at all, for any catalyst or temperature, in the case of Oil A and Oil B, whereas Solvesso 200, at 150 ºC, reaches a conversion around 20 % and, at 250 ºC, over 70 % for naphthalene and derivates for both catalysts, without observing substantial differences between the two oils. Quinoline of Oil B reacts easily to form tetrahydroquinoline, in fact, at 150 ºC for $Pt/Al_2O_3$ the conversion is already complete, and for the $Pd/Al_2O_3$, a value of 80 % is reached. These results suggest, add to the extraordinary reactivity for hydrogenation of quinoline, the possible interference in hydrogenation of heavy compounds, mainly of aromatic nature, which are present both in Oil A and Oil B, whereas Solvesso 200 is free of these heavy compounds. Our results suggests that that oils containing light aromatic (up to two fused cycles) and nitrogenated aromatic compounds are promising LOHCs, whereas the presence of larger polyaromatic compounds hinders this property.

**Keywords:** ethylene, propylene, AI-models, crude oil, cracking

**Introduction.** Demand for petrochemical feedstocks has been steadily increasing due to the growing demand of petrochemical intermediates that serves as raw materials in the production chain of many industries [1]. The light olefins, particularly ethylene and propylene are important part of these petrochemical feedstocks that have seen increasing demand in recent time [2]. Therefore, with careful optimization of crude oil feed and cracking conditions, the yield of light olefins can be maximized while lessening the yield of dry gas and coke. However, this approach involves handling large number of variables that are ordinarily difficult to process using simplified/physical models. The re-emergence of artificial intelligence (AI) in the early 21st century has made analysis, prediction and optimization of large number of variables in various academic and industrial application much easier and less laborious [3]. This study utilizes the application of four stand-alone AI techniques for modeling the yield of ethylene and propylene in the catalytic cracking of crude oil feeds using temperature, feed, conversion (%), total gas, dry gas and coke as the independent variables. Additionally, four Ensemble paradigms were developed to further improve the performance accuracy of the stand-alone paradigms.

**Experimental/methodology.** The catalytic cracking reaction was carried out according to the ASTM D-7964 method in an Advanced Catalytic Cracking (ACE) unit. The prediction of the MLs models was done on MATLAB (2017b). Correlation matrix and non-linear sensitivity analysis were conducted to filter the input combinations into three different classes (M1, M2 and C3) based on the dependent-independent variables relationship. Prediction performance was evaluated basaed on Co-efficient of determination (R2), Pearson correlation co-efficient (PCC), Mean squared error (MSE) and Root mean squared error (RMSE)

**Results and discussion.** Results of the stand-alone models at certain instances showed weak performance accuracy while the Ensemble paradigms depicts that these techniques can improve the performance of the single models up to 58% and 62% in the calibration and validation phases respectively as shown in figure 1.

# Chemical recycling of waste P-F resins and particle boards by fast catalytic pyrolysis towards value-added chemicals and fuels

S.M. Kavoukis[1], C. Pappa[1], S. Torofias[1], P. Soldatos[1], A. Margellou[1], K.S. Triantafyllidis[1,2,*]

**Keywords:** PF resins, waste particle boards, fast (catalytic) pyrolysis, chemical recycling

**Introduction**

Within the concept of circular (bio)economy, the chemical recycling and valorisation of organic wastes, such as plastics, polymers and related composite products, e.g. used furniture, etc., is a promising solution towards renewable fuels, chemicals and polymers. Thermochemical methods (combustion, gasification, pyrolysis) are proven to be efficient methods in recovering bio-energy and chemicals from waste biomass and plastics. Fast pyrolysis leads to enhanced production of liquid products (bio-oils) which however may contain oxygenated compounds (i.e. acids, furans, ketones, phenolics, etc.) in the case of lignocellulosic biomass wastes and related bio-based resins and wood-composite products [1,2]. These bio-oils can be either used to extract individual group of compounds, such as phenolics, to be utilized as monomers for the production of the original or other relevant adhesive resins or can be upgraded via deoxygenation and aromatization reactions over acidic catalysts to BTX aromatic compounds [3,4].

**Experimental/methodology**

In the present work we have investigated the fast (catalytic) pyrolysis of vine pruning (in the form of wood chips that are used to form the particle board), cured phenol-formaldehyde (PF) resin solids (used as adhesive in the particle board) and the particle board itself made from the PF resin and the vine pruning chips. The experiments were conducted on a lab-scale fixed bed pyrolysis reactor, using silica sand as the inert heat carrier at 400, 500 and 600$^{o}$C (for non-catalytic pyrolysis) or a ZSM-5 zeolite catalyst for in-situ upgrading of the pyrolysis vapors at 500 and 600$^{o}$C. Liquids, solids and gases were collected for analysis with GC-MS, GC-FID, NMR, etc. Additional fast pyrolysis experiments were performed on a Py/GC-MS system to investigate the relative composition of the pyrolysis vapors.

**Results and discussion**

The fast pyrolysis of vine pruning provided 30-50 wt.% bio-oil, 25-35 wt.% solids/char and 10-25 wt.% gases, depending on process temperature. The obtained bio-oil comprised mainly of alkoxy-phenols as well as carboxylic acids, esters and ketones. The pyrolysis products of the cured PF resin solids were 10-25 wt.% bio-oil, 60-80 wt.% solids and 2-10 wt.% gases, with bio-oil containing mainly phenol as well as some aromatic compounds. The respective particle board resulted in 30-55 wt.% bio-oil, 20-35 wt.% solids and 10-25 wt.% gases, with the bio-oil containing mainly alkyl-phenols, as well as alkoxy-phenols, carboxylic acids and esters. The above results indicate that the fast pyrolysis of particle boards is indeed a combination of the mechanisms/products that apply in the pyrolysis of the vine pruning chips (lignocellulosic biomass) and cured PF resin alone. Especially the PF resin derived oil can provide pure (alkyl)phenols that can be utilized back into the production of PF resins with the same or similar properties. With the use of the acidic zeolite catalyst, the obtained bio-oils were enriched in BTX mono-aromatics and naphthalenes, being also useful in the chemicals/polymer industry and refineries, via decarbonylation, decarboxylation, dehydration/ dehydroxylation, cracking, dealkylation and aromatization reactions of the intermediate oxygenated/ phenolic compounds formed by thermal pyrolysis.

**Keywords:** trickle bed reactor, hydrodenitrogenation, HDN, hydrodearomatization, HDA, adsorption

**Introduction.** One of the key processes to produce lubricant base oils is hydrotreatment over metal sulfide catalysts to remove the polyaromatic hydrocarbons and other compounds. The hydrotreating reactor is continuously operated producing different products from feedstocks of varying composition. Shifting between products (mode switch), can be impacted by memory effects of the catalyst which in turn affects the subsequent production [1,2]. Organic nitrogen compounds present in the feedstocks are considered to be partly responsible for this effect [3]. In this work, a dynamic mathematical model of a trickle bed reactor is developed to evaluate catalysts during a mode switch.

**Experimental/methodology.** Step response experiments were carried out in a microflow trickle bed reactor operated at 120 barg and between the temperatures 280 to 320 °C using sulfided NiMo catalysts. The model reaction was the hydrogenation of phenanthrene, a cata-condensed triaromatic hydrocarbon. The organic nitrogen compounds (carbazole and acridine, representing non-basic and basic nitrogen compounds, respectively) introduced in the step response. Tracer experiments were performed to estimate the residence time distribution (RTD) to differentiate the dispersion caused by the reactor, interaction with the catalyst, and tubing and gas-liquid separator. The RTD of the reactor itself was modelled using the Piston Dispersion Exchange (PDE) model and the tubing together with the gas-liquid separator was modelled using a combination of tank-in-series (TIS) and plug flow reactor (PFR) models.

**Results and discussion.** In Figure 1, two kinds of mode switches are presented: the introduction (deactivating mode switch) and the removal of (reactivating mode switch) of carbazole. When carbazole is introduced, the conversion of phenanthrene is lowered due to competitive adsorption of the hydrogenation sites. Moreover, during the reactivating mode switch, there is a time delay in the when the phenanthrene conversion is back at its initial value. This illustrates that the developed model system replicates the memory effect observed in full-scale hydrotreaters.

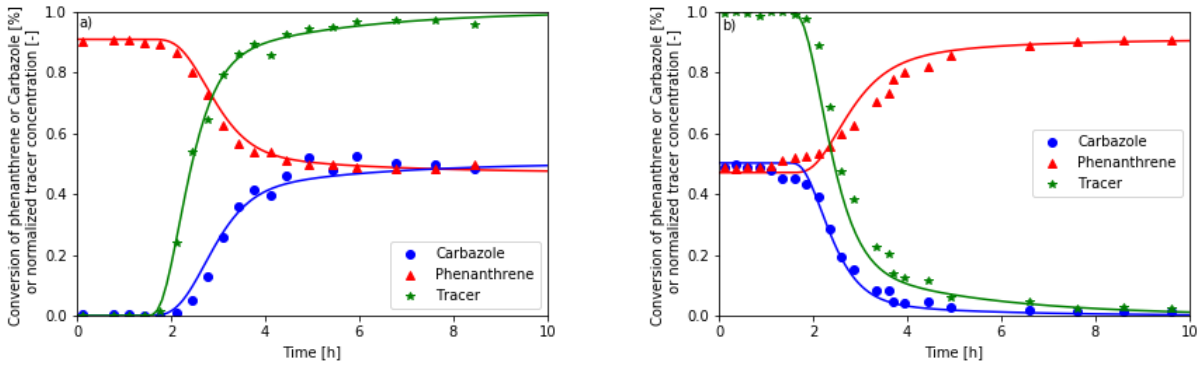

**Figure 1. Effect on the dynamic conversion of phenanthrene upon a mode switch with carbazole. The introduction(a) and the removal (b) elution profiles of carbazole, phenanthrene, and tracer(dodecane) as a function of time. The data points are the experimental observations while the lines represent the fitted model. Experimental conditions: 300 °C and 120 barg.**

# High Pressure Ring Opening using supported NiWMo catalysts

C. Gross[1], R. Khare[1], J.A. Lercher[1*]

[1]*Department of Chemistry and Catalysis Research Center, TU München, Garching 85748, Germany*
[*]*johannes.lercher@tum.de*

**Keywords:** high pressure, Ring opening, Decalin, mixed metal sulfides

**Introduction.** The interest in investigating the removal of polynuclear aromatics from fuel has steadily increased over the last few decades as an effort to decrease fossil fuel's environmental impact. Decreasing the fraction of naphthenic molecules with selective ring opening is also an important step to upgrade low-value crude oil and streams stemming from refineries. Commercially available catalysts for ring opening reactions usually contain hydrogenating agents based on one or more noble metals, supported on an acidic support. Common examples of such catalysts are iridium or platinum, supported on various aluminosilicates. Despite their decent ring opening capabilities, these catalysts are highly sensitive to sulfur in the feed, showing severe decrease or even complete halt of ring opening reactions at sulfur levels as low as 20 ppm.[1] In this work, we investigated supported metal sulfides, which show high selectivity towards ring opening without the need for noble metals and exhibit a high tolerance toward sulfur in the feed.[2]

**Experimental/methodology.** The influence of the metal composition, as well as pressure, temperature, and conversion, on the selectivity towards ring opening of decalin have been investigated. To achieve this, a series of $SiO_2$-supported mixed metal catalysts containing nickel, tungsten, and molybdenum were prepared by impregnating $SiO_2$ with an aqueous solution of their respective metal salts: $(Ni(NO_3)_2{\cdot}6\ H_2O$, $(NH_4)_6H_2W_{12}O_{40}{\cdot}x\ H_2O$, $(NH_4)_6Mo_7O_{24}{\cdot}4H_2O)$, followed by drying and calcining in a flow of synthetic air for 5 h at 773 K and a subsequent *in situ* sulfidation. The synthesized catalysts were characterized by AAS and IR spectroscopy. Ring opening was performed in a trickle bed reactor, pressurized to 160 bar. In a typical experiment, approximately 150 mg of catalysts were diluted with 350 mg SiC and loaded in the reactor. After an initial drying step in a flow of $H_2$, the catalysts were sulfided using a mixture of heptane and dimethyl disulfide (DMDS) with a total sulfur concentration of 3 wt.% in a flow of $H_2$. Following the sulfidation step, the liquid feed was changed to a mixture of decalin and DMDS with a total sulfur concentration of 0.1 wt.%.

**Results and discussion.** We report that the conversion, as well as the selectivity towards ring opened products, is influenced by the ratios of the respective metals. Based on the results of our experiments, the ideal ratio appears to be 10, 30, and 15 wt.% of Ni, W, and Mo respectively, and a deviation from these metal loadings led to a decrease in both conversion of decalin as well as selectivity towards ring opening. Our experiments also show, that for ring opening of decalin to occur, an initial (skeletal) isomerization step is necessary. Only after this primary isomerization, the secondary ring opening reaction can occur. Temperature and liquid hourly space velocity variations showed that an equilibrium of hydrogenation and isomerization reactions is achieved at a conversion of ~15%. Additionally, dehydrogenation towards tetralin (and subsequent naphthalene formation) occurs as a side reaction but can be minimized at elevated pressures above 150 bar. Our experiments also suggest that the ring opening of decalin is highly pressure dependent, as we observe a significant increase in the selectivity toward ring opening with increasing pressure, while we see a sharp drop in the formation of dehydrogenated products. The selectivity towards isomerized and cracking products stays virtually unchanged over the entire investigated pressure range.

[*]*Corresponding Author's E-mail address (ymchung@kunsan.ac.kr)*

**Keywords:** ethylene dimerization, ionic liquid, two-phase reaction

**Introduction.**

1-Butene is one of the important basic chemicals that belongs to the family of linear alpha olefins (LAO). While a number of technologies have been addressed for 1-butene production using different metal-complex catalysts, intensive separation processes are required to separate the 1-butene from other isomers and hydrocarbons with different chain length.

In this work, we report facile and recyclable ligand-free Cr-catalyzed ethylene dimerization in an ionic liquid-organic solvent biphasic system with 100% 1-butene selectivity. The unprecedented perfect α-olefin selectivity without polymer formation may offer promising opportunity for elucidation of highly efficient dimerization process without complicated and energy-intensive by-products separation processes.

**Experimental/methodology.**

A range of ionic liquids were synthesized by using two cations (1-octyl-3-methylimidazolium and 1-decyl-3-methylimidazolium) and three anions ($Tf_2N^-$, $BF_4^-$, and $PF_6^-$). Ethylene dimerization was performed in an IL-toluene biphasic system using a high-pressure reactor by using $Et_2AlCl$ or MMAO as an activator.

**Results and discussion.**

As shown in Table 1, with $Et_2AlCl$, catalytic activity and 1-butene selectivity were reached as high as 1405 g/gCr.h and 92.6 wt%, respectively (Entry 4). Furthermore, 100% 1-butene selectivity was obtained in the presence of MMAO (Entry 6). The uncontrollable polymerization proceeded (98% of PE) in the absence of IL (Entry 1) strongly implies the crucial role of IL in regulating the chain growth.

The extremely high 1-butene selectivity can be rationalized in terms of low solubility of hydrocarbons in IL [1]. It is assumed that the 1-butene formed by the first dimerization will no longer participate in the successive oligomerization, and transfer to organic phase immediately. This unique reaction environment is beneficial in maximizing 1-butene selectivity.

Table 1. Ethylene dimerization promoted by Cr catalyst under various reaction conditions

| Entry | M/L/A (mole ratio) | Activator | Ionic Liquid | TOF (g/gCr.h) | Selectivity (wt%) | | |

# SYNTHESIS OF HIGH-OCTANE GASOLINE ADDITIVES ON CATALYTIC "INTELLIGENT SYSTEMS"

*K. Kadirbekov, O. Yugay, A. Serebryanskaya, G. Abdiyusupov, S. Zholdybaev, Tusipkaliev E.*

[1] *JSC A.B. Bekturov Institute of Chemical Sciences, Almaty, Kazakhstan*
*E-mail: kkairati@mail.ru*

Methyl tert-butyl ether (MTBE) and ethanol were found the most widespread usage among oxygen-containing additives for gasoline. However foreign experience in the use of MTBE and ethanol in the composition of gasoline has revealed a number of problems. These include, for example, the harmfulness of MTBE and a possible ban on the production of gasoline containing this additive or the phase instability of gasoline-ethanol fuels. In recent years, the world's existing MTBE production facilities have been converted to the production of ethyl tert-butyl ether (ETBE) [1, 2].

Catalytic systems obtained by depositing polymer-metal complexes on solid inorganic supports are the most promising catalysts in alkylation reactions. The principle of operation of such catalysts is similar to the so-called "smart systems" (intelligent systems), where polymer ligands fix metal complexes on the surface, but at the same time retain relative structural mobility and have high catalytic activity.

In the ETBE synthesis reaction, the catalytic properties of a new "smart system" nanometal-polymer/natural zeolite were studied. In this communication, the features of the synthesis of ETBE by the interaction of bioethanol with isobutylene on the Mo-Polymer/HCL catalytic system are considered. HCL is acid-activated natural zeolite (Kazakhstan) with the mineral phase clinoptilolite. The polymer was applied on HCl in an amount of 0.5–1.0 wt%. The influence of the nature of the component of the composition of a catalytically intelligent system and process parameters on the yield of ETBE was investigated.

According to chromatographic analysis, the reaction mixture contains the main product ETBE, isobutylene, ethanol, methyl ethyl alcohol, 2-methoxy-2-methylpropane, ethyl propyl ether, 2,4,4-trimethyl-pentene-2, 2,3,4,5- tetramethylhexadiene and other hydrocarbons. A detailed review of all the by-products resulting from the alkylation of bioethanol with isobutylene showed that heavier and more branched compounds are obtained at elevated process temperatures. The maximum yield of ETBE was obtained at 70°C. An increase in the volume of the catalyst positively affects the increase in the yield of ETBE, at which the yield of the target product reaches 76%. This is due to the relatively long contact time of bioethanol and isobutylene vapors with the catalyst surface. The lowest ETBE yield is observed at a temperature of 50°C – 10% due to the fact that alcohol and gas vapors did not have time to reach the refrigerator, but began to condense even upon contact with the catalyst. With an increase in temperature to 90°C, a decrease in the yield of ETBE to 32% is observed due to the formation of heavier compounds. Thus, it can be concluded that maintaining the required temperature and stable contact of the vapors with the catalyst is an important factor in achieving a high yield of ETBE.

Compositions prepared from reaction mixtures with ETBE were added to A-80 commercial gasoline with the following initial octane data: RON (Research Octane Number) = 84.8; MON (Motor Octane Number) = 79.9 and AKI (Anti-Knock Index) = 82.3. Tests have shown that the highest octane number of 96.6 is observed when adding a composition with 8.33% ETBE, obtained at a temperature of 70°C. This indicates the technological and environmental efficiency of using compositions based on ETBE as a high-octane additive to gasoline.

**Keywords:** hydrocracking, aromatics, hydrogen excess, total pressure effect

**Introduction**

Hydrocracking of saturated hydrocarbons occurs on a bifunctional catalyst, containing metal and acid sites, via unsaturated intermediates [1]. In addition to (cyclo)alkanes, aromatic molecules represent a significant fraction in hydrocracking feeds, both in conventional ones as in renewable, bio-based ones. The reaction network of aromatic molecules over a bifunctional catalyst [2] includes hydrogenation to cycloalkanes and direct acid catalyzed reactions, which are clearly distinct from those for (cyclo)alkanes. This specific feature of aromatics may result, depending on operating conditions, in a more prominent admixture impact in contrast to cycloalkanes on alkane hydrocracking [3]. The goal of this work is to analyse this impact on *n*-alkane hydrocracking and suggest mitigation measures.

**Experimental**

The toluene admixture impact was experimentally assessed over 0.3 wt%Pt/HUSY (with $SiO_2/Al_2O_3$ molar ratio of 12), which was previously confirmed as a well-balanced catalyst for *n*-octane hydrocracking [4]. The experiments were carried out using the high-throughput kinetics setup for mechanistic investigations with pure *n*-octane and the feed containing 20 mol% toluene. The present work focuses on the interplay between toluene admixture effect, $H_2$-to-hydrocarbon ($H_2$/HC) molar ratio (6.5-200) and total pressure (10-20 bar), and consequently these parameters were primarily varied. Nitrogen was added as a diluent to keep *n*-octane partial pressure constant (0.1 bar). The catalyst stability was analyzed over more than 3 h time on stream.

**Results and discussion.**

The impact of toluene admixture and hydrogen excess on catalyst stability is shown in Figure 1. While at high $H_2$-to-hydrocarbon ratio, no impact of toluene on *n*-octane conversion was observed, toluene effect was obvious when $H_2$/HC ratio was decreased to 6.5. At high $H_2$ excess hydrogenation of toluene dominates over the reactions which lead to deactivation - only methylcyclohexane and its isomers are found as toluene products. On the other hand, a negative impact of toluene on the catalyst stability was observed at lowered $H_2$/HC ratio.

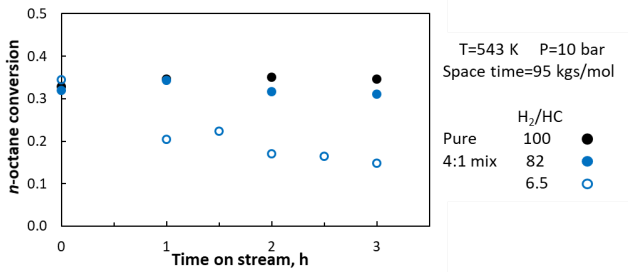

**Figure 1 *n*-Octane conversion when fed pure and in 4:1 n/n mixture with toluene as function of time on stream: impact of $H_2$/HC molar ratio**

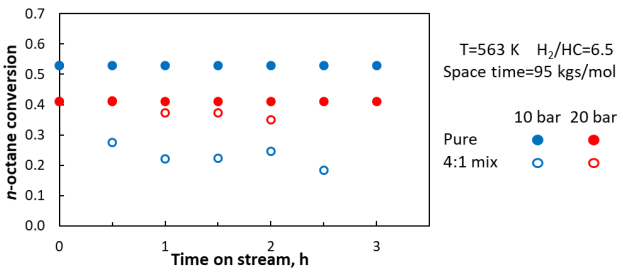

**Figure 2 *n*-Octane conversion when fed pure and in 4:1 n/n mixture with toluene as function of time on stream: impact of total pressure**

Figure 2 compares impact of toluene admixture at 6.5 mol$H_2$/molHC at two total pressures. The catalyst deactivation was more prominent at lower total pressure (and lower nitrogen dilution). At higher pressure and nitrogen dilution, bimolecular reactions of toluene on acid sites leading to coke precursors were less likely. In conclusion, the negative admixture impact of aromatics can be mitigated by increasing the hydrogen excess and/or total pressure.

# Supported Iron Nanoparticles as sustainable Catalysts for the selective Acetylene Hydrogenation under industrial Front-End Conditions

Hannah Lamers[1], M. Lucas[2], M. Rose[3*]

[1, 2, 3]*Technical University of Darmstadt, Darmstadt, Germany*
[*]marcus.rose@*tu-darmstadt.de*

**Keywords:** Heterogenous catalysis, acetylene hydrogenation, supported iron nanoparticles.

**Introduction.** Ethylene is one of the most important monomers for polymer production and is needed in high purity to guarantee reproducible product qualities in olefin-based polymers. Since multi unsaturated impurities, such as acetylene, coming from petroleum-based ethylene sources lead to catalyst poisoning in polymerization reactions, the generation of ethylene-rich streams with acetylene concentrations lower than 1 ppm are urgently necessary.[1,2] State of the art catalysts for the selective acetylene hydrogenation are alumina supported palladium silver alloyed nanoparticles.[3] Owing to high palladium prizes and low availability, innovative and sustainable catalyst systems are needed. Iron-based catalysts are highly promising substitutes due to the high natural occurrence, the non-toxicity and the known hydrogenation-activity.[2] In preliminary studies the suitability of zero-valent iron catalysts was proven by using unsupported α-Fe nanoparticles showing very high activity and selectivity in the semi-hydrogenation of acetylene.[2] To further enhance catalytic activity by modifying the particle size, the surface area and the metal dispersion, different alumina supported iron nanoparticles are currently investigated.

**Experimental/methodology.** The supported iron nanoparticles are synthesized via incipient wetness impregnation on alpha-alumina using different iron precursors as well as varying metal loadings. All catalyst precursors are calcinated and subsequently reduced to the zero-valent iron species before use. The supported iron catalysts are analyzed via X-ray diffraction (XRD), $N_2$-physisorption and X-ray fluorescence spectroscopy (XRF) as well as temperature programmed reduction (TPR). The catalytic testing of the supported iron nanoparticles is carried out in a continuous flow fixed-bed reactor with a modeled feedstock composition of industrial acetylene removal units under front-end conditions.[4,5] In a typical reaction sequence, 200 mg of catalyst are used, and the temperature is varied between 40 °C and 90 °C. The reaction is monitored via online GC resulting in high-resolution conversion- and selectivity-profiles.[5]

**Results and discussion.** Alpha-alumina supported catalysts with 1 %, 5 % and 10 % iron loading, respectively, were successfully synthesized, and the iron content was monitored via XRF. The reduction profiles of the supported iron catalysts were determined via TPR and indicate full reduction to $Fe^0$ at 900 °C. In a first attempt, the catalyst with 10 % iron loading is applied in the semi hydrogenation of acetylene. The temperature was varied between 40 °C and 90 °C in 10 °C intervals. At 90 °C the conversion is at 58.76 % and decreases with a decline in temperature. The produced amount of ethane is low at all temperatures intervals, indicating neither significant acetylene over hydrogenation nor ethylene hydrogenation. The results demonstrate that the alumina supported catalyst with 10 % iron loading shows excellent activity and very high selectivity at 90 °C as well as very good stability over time. These results underline the suitability of iron catalysts as very promising sustainable alternatives to conventional palladium-based materials. More investigations are needed to reveal the correlation between the metal loading and the catalysts activity. Moreover, the influence of carbon monoxide as selectivity directing agent and the influence of bimetallic compounds on the activity and selectivity needs to be determined to further improve the catalytic performance of alumina supported iron-based nanoparticles.

# Synergistic shape selectivity of H-Beta and H-ZSM-5 in heavy aromatics hydrocracking for xylene-rich BTX

Jinho Oh, Jung Kyoo Lee*

*Chemical Engineering (BK21 FOUR Graduate Program), Dong-A University, Busan 49315, South Korea*
**jklee88@dau.ac.kr*

**Introduction.**

Due to global climate change and environmental concerns caused by the increased carbon emissions from fossil fuels use, the demand for oil-derived fuels such as diesel and marine heavy fuel oil will decrease in the future. Hence, the disposal of polycyclic aromatics (PCA) by-products of diesel-boiling-range, being produced in large quantity from oil and petrochemical processes, would be a problematic issue. Therefore, the catalytic conversion of PCAs into high-value products is of great concern. One feasible option for upgrading the surplus PCAs is to produce high-value benzene/toluene/xylenes (BTX) by hydrocracking [1]. The hydrocracking of PCAs in principle gives BTX along with naphtha-range cracking products [2,3] which can be fed to naphtha cracker for light olefins or blended into gasoline pool.

**Experimental/methodology.**

Herein, we report a highly selective hydroconversion of PCAs obtained from a commercial aromatic complex, $C_{10}^{+}$ heavy aromatics, into BTX rich in xylenes. We tested two different processes, a direct HYC and selective hydrogenation (HYD) followed by HYC, by using a fixed-bed down-flow micro-reactor under a moderate pressure (40 bar). For the selective HYD of $C_{10}^{+}$ heavy aromatics, we employed a $Mo_2C/\gamma\text{-}Al_2O_3$ as the catalyst. For the HYC catalyst, various metals were supported on H-Beta (B) or hybrid zeolite mixture of H-Beta and H-ZSM-5 (Z) (BZ hereafter). We found that the two step process consisted of selective HYD followed by HYC can give much higher per-pass yield of BTX than the direct HYC. More importantly, it was found that the hybrid zeolite mixture, BZ in the HYC catalyst, can exhibit a synergistic shape selectivity in the hydrocracking of PCAs leading to a high per-pass yield of BTX rich in xylenes.

**Results and discussion.**

**Fig. 1a** shows that HYC catalyst containing BZ gave much higher yield of BTX than that containing B only, whereas ethylbenzene and $C_9$-$C_{10}$ aromatics yield was in opposite as shown in **Fig. 1b**. Over the HYC catalyst with BZ, xylenes were formed in the largest amount among BTX due to the transalkylation reactions described in **Fig. 1c**. More detail results and the synergistic shape selectivity brought by H-Beta and H-ZSM-5 will be discussed.

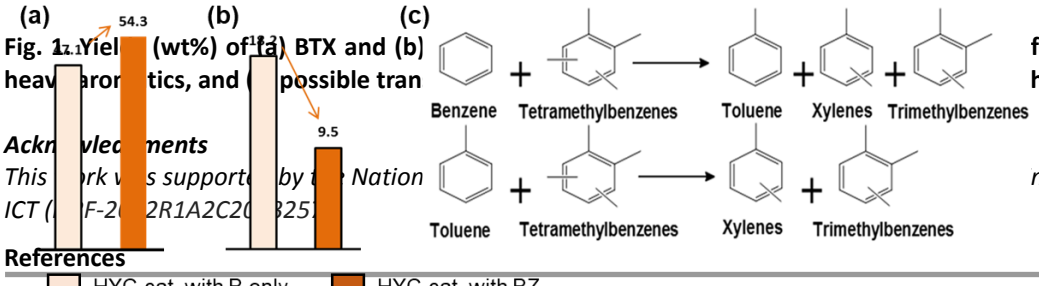

**Fig. 1. Yield (wt%) of (a) BTX and (b) heavy aromatics, and (c) possible transf pre-hydrogenated $C_{10}^{+}$ h xylenes selectivity.**

# The conversion of aliphatic hydrocarbons to aromatics over HZSM-5 zeolite catalysts

P. Lestinsky*, K. Klemencova, B. Grycova, A. Inayat

*Institute of Environmental Technology, CEET, VSB-TUO, Ostrava, Czech Republic*
**pavel.lestinsky@vsb.cz*

**Keywords:** zeolite, catalyst, catalytic cracking, aromatization

**Introduction.** Now a days, due to ever stricter environmental regulations on $CO_2$ emissions, alternative routes (other than involving coal and crude oil) for BTEX production are attracting the attention of researchers. At the same time, we are dealing with the problem of waste plastics, particularly polyolefins, a solution presents itself - aromatization of hydrocarbons from pyrolysis of waste polyolefins [1]. During the pyrolysis of waste polyolefins, a wide spectrum of gaseous ($C_1$-$C_4$) and liquid hydrocarbons ($C_5$-$C_{20}$) is produced. These compounds subsequently undergo aromatization over suitable catalysts. In this regard, in order to improve the aromatic yield and selectivity during catalytic treatment of waste polyolefins, it is important to gain enhanced understanding of cracking and the following aromatization processes. Therefore, the aim of the present work is to study cracking and aromatization of the most common hydrocarbons individually, which are produced as intermediates during the thermo-catalytic treatment of waste polyolefins.

**Experimental/methodology.** As feedstocks, both saturated ($C_5$-$C_{12}$: including straight, branched and cyclic) and unsaturated liquid aliphatic hydrocarbons were employed. As catalyst materials, HZSM-5 zeolites featuring different silica to alumina ratios and, consequently, having different acid site densities were used. The liquid hydrocarbons were continuously fed to the evaporation chamber and the resulting vapors were passed over a fixed bed of HZSM-5 zeolite catalyst at 500 °C. The products were passed through a cooling unit to separate liquid and gaseous fractions, which were then analyzed by GC-FID/TCE and GC-MS systems.

**Results and discussion.** The results obtained from preliminary tests showed that the liquid aliphatic hydrocarbons underwent both cracking and aromatization. Furthermore, it was observed that the chain length and type (straight, branched or cyclic) influenced both conversion and aromatization significantly. Moreover, in the case of branched chain hydrocarbons, no aromatization was detected, which can be attributed to their increased molecular size as compared to straight chain hydrocarbons of the same carbon number/molecular weight. For the conversion of such compounds, zeolites with additional mesoporosity might be interesting catalytic materials. A detailed and systematic study on the conversion of abovementioned hydrocarbons to aromatics over HZSM-5 zeolite catalysts will be presented.

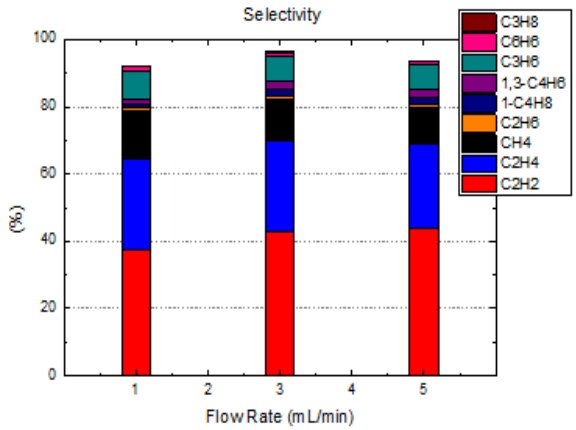
# Light olefins production with high and flexible selectivity by catalysis integrated electrified process

YN.Kim, CM.Jung and DH.Lee *

[1] *Korea Institute of Machinery and Materials, 156 Gajeongbuk-Ro Yuseong-Gu, Daejeon, Republic of Korea*
**dhlee@kimm.re.kr*

**Keywords:** Light olefins, arc plasma, plasma chemical process

**Introduction.**



Light olefins are significant raw materials in downstream chemical industry. Main process for light olefin production is thermal cracking of hydrocarbons such as light naphtha in the presence of steam. The thermal cracking process is the most energy intensive process in petrochemical industry and cause high amount of $CO_2$ emission. However, this half of century used industrial process is being asked to change due to the recent climate change and strong demand for $CO_2$ emission suppression. Here, we demonstrated an environmentally benign way for the light olefin production by using plasma. The plasma process can provide enough thermal conditions for conversion of feedstock to light olefin from renewable electricity. Also, several kinds of different compound having same carbon number were compared as feedstock for olefin production in order to reveal the effects of molecular structure. In results, this work shows that electrified plasma process can produce highly selective light olefins having flexible range depending on operation conditions and molecular structures.

**Experimental/methodology.**

The mixed gases for plasma discharge and the reaction are injected to the reactor having swirl flow. The feed for the olefin production is injected by syringe pump as a liquid phase. The converted products are pass through catalysis part. The feed and product gases are analysed by online GC-MS(5975C model, Agilent 19091P-K33 column, Agilent Technologies) and microGC(990 Micro GC, MS5A SS and PoraPLOT U FS columns, Agilent Technologies) using sample bag.

**Results and discussion.**

The figure shows the selecitivty of $C_1$-$C_4$ products under different flow rate of liquid hydrocarbons as feed.

The selectivity was calculated as following equations.

$$Selectivity_{C_xH_y}(\%) = \frac{x \times moles\ of\ C_xH_y\ produced}{6 \times moles\ of\ C_6\ converted} \times 100$$

In this graph, the ethylene selectivity is range from 20 – 30% depending on the flow rate conditions. Especially, the selectivity of propylene is alomost 10%. In results, more than 30% selectivity of $C_2$-$C_4$ olefin are produced. Moreover, ethylene selectivity can be increased about 40% by simple cataytic hydrogenation process of acetylene. As considerd light olefin selecitivty ($C_1$-$C_4$) of conventional thermal cracking process and previous researches, this potential selectivity for light olefins is extraordinary.

# Turquoise H2 and Carbon production through CH4 Cracking

A. Batistini[1], V. Cosentino[1*], G. Iaquaniello[1], E. Palo[1], B. De Caprariis[2], P. De Filippis[2]

[1]*NextChem Spa, Via di Vannina 88/94, 00156 Rome, Italy*
[2]*Department of Chemical Engineering, University La Sapienza di Roma, Via Eudossiana 18, 00184 Rome, Italy*
[*]*v.cosentino@nextchem.it*

**Keywords:** turquoise hydrogen; methane cracking; carbon; molten metal process; CO2 free process

**Introduction.** Up to 80% of hydrogen production is currently carried out through CO2 emission-intensive processes. The two main low-carbon production routes are Steam Methane Reforming coupled with CCUS (blue H2) and water electrolysis (green H2) [1]. NextChem has developed a new competitive process scheme based on methane cracking (turquoise H2) (Fig.1) [2], based on the use of a molten metal bubble reactor where the reaction, which leads to the production of only H2 and solid carbon without CO2 emissions, occurs. Experimental tests were carried out at the Industrial Chemistry laboratory, Department of Chemical Engineering University of La Sapienza in Rome [3]. From experimental tests, it was possible to obtain the data for the overall process scheme. A mathematical model was developped to predict CH4 conversion, solved for both lab-scale and industrial-scale reactors [3]. A techno-economic assessment of the industrial thermal cracking process was carried out for a capacity of 5'000Nm3/h of H2 (Fig.1).

**Experimental/methodology.** A tubular fixed-bed quartz reactor of different diameters was tested with a molten metal height up to 20cm. The reactor was heated by an electric furnace varying the temperature between 950°C-1070°C. The temperature was controlled by a K-type thermocouple. CH4 flow rate could be varied in a range 30-140ml/min. Differents molten metals (tin and tin alloys) were tested to evaluate both thermal and catalytic cracking.

**Results and discussion.** The main results, reported in Fig.2 for a CH4 flow rate of 45ml/min, show an almost equal behavior between pure Sn and the first Sn/Sb/Cu alloy in the whole temperature range. It seems that Sb and Cu do not have a catalytic behaviur on the system. Further experimental campaigns are on going with other percenatage of these elements and/or other alloys. The carbon structure, on the other hand, is affected by the presence of different metals, presenting a ordered structure in the case of Sn/Sb/Cu. Data for pure Sn were used to validate the developed mathematical model with a quite accurate final fit [3]. For the economic analysis, NextChem's innovative solution demonstrates a levelized cost of hydrogen (LCOH) of 1.75€/kg of H2 with a total energy consumption of about 1.2kWh/Nm3 of H2, proving to be competitive with benchmark solutions. It can be concluded that Methane Cracking on molten media represents a promising process for low-emission Hydrogen production.

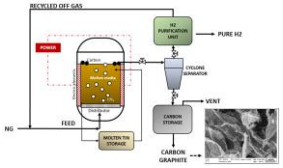

**Fig.1: NextChem methane cracking process scheme [2]**

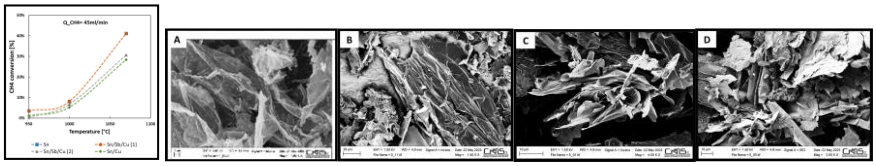

**Fig.2: CH4 conversion [%] vs. T [°C] with different molten metal and correspective carbon structure (A tin, B/C/D alloy)**

**Keywords:** photoemission electron microscopy, field emission microscopy, rhodium, hydrogen oxidation, reaction fronts, oscillations, single particle catalysis.

**Introduction.** Nanostructured metals are important functional materials for energy-relevant catalytic reactions. The oxidation of hydrogen to water by solid catalysts enables energy generation without combustion and without pollution, e.g., in fuel cells. For future developments of new green energy production technologies, it is important to monitor ongoing catalytic reactions by *in situ* microscopy of working catalyst surfaces. Two examples are presented, covering meso-scale planar Rhodium surfaces and a single Rh nanoparticle (*single particle catalysis*).

**Experimental/methodology.** Several different microscopic techniques (see below) were combined for *in situ* imaging of catalytic $H_2$ oxidation on the same structures of the same Rh sample, i.e., in a *correlative* approach preferentially operated in a single setup under truly identical reaction conditions.

**Results and discussion.** i) Using a correlative microscopy approach [1,2], $H_2$ oxidation on polycrystalline Rh foil was studied by scanning photoelectron microscopy (SPEM) and photoemission electron microscopy (PEEM), which allow local surface analysis and visualising the heterogeneity of ongoing reactions on a µm-scale. This revealed an anisotropy of surface oxidation, yielding an oxidation map, as well as the reaction mechanism involving subsurface oxygen. *In situ* PEEM imaging of ongoing $H_2$ oxidation directly compares the local reactivity of metallic and oxidised Rh, revealing a high transient activity of Rh surface oxide. Higher spatial resolution and chemical sensitivity were provided by low energy electron microscopy (LEEM) and XPEEM, revealing a new front propagation mechanism.

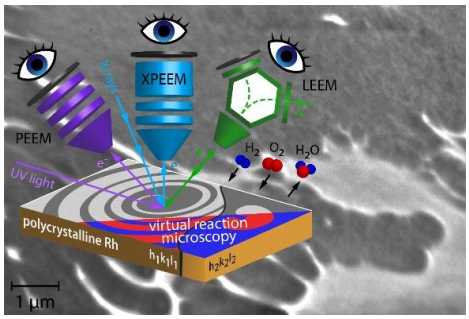

**Figure 1.** Concept of correlative microscopy and LEEM image of hydrogen oxidation on Rhodium [1].

ii) Using the apex of a Rh-nanotip as model structure, *single particle catalysis* [3,4] was studied on the nm-scale by field emission microscopy (FEM) as imaging tool. Novel effects were revealed, such as nanoscale multifrequential oscillations and limited interfacet coupling. Using ionized water as imaging species, the active sites on the metal nanotip were directly imaged by field ion microscopy (FIM).

The obtained insights may stimulate new ways of metal catalyst design and operation.

**Introduction.**

Pd based heterogeneous catalysts are used in a range of hydrogenation reactions.[1] In these reactions the surface of Pd will move from pure metal to full hydride as the hydrogen partial pressure is increased at a given temperature. As the level of hydrogen coverage will affect the reactivity of the surface, computer modelling should use an appropriate surface coverage when calculating the potential energy surface for hydrogenation reactions. In this contribution we use an *ab initio* thermodynamics approach to calculate an effective phase diagram for hydrogen adsorbed to Pd(111) and Pd(100) surfaces.

**Experimental/methodology.**

The energy of configurations was calculated using the full potential all-electron periodic DFT code, Fritz Haber Institute *ab initio* materials simulations (FHI-aims) package, with functionals linked from the LibXC density functional library. Calculations were controlled and analysed usingfunctionality of the Atomic Simulation Environment (ASE). The meta-generalised gradient approximation (MGGA) semi-local Bayesian error estimation (mBEEF) exchange-correlation functional is employed throughout this work.

For surface calculations, *p*(3×3) supercell slab models for Pd(111) and Pd(100) consisting of 5 atomic layers were constructed. During geometry optimisations the top 4 (Pd(111)) and top 3 (Pd100) layers are unconstrained. H atoms are added to the top most surface of the slabs interacting with unconstrained Pd atoms. Geometry optimisations were performed using a force convergence criterion of $1 \times 10^{-2}$ eV Å$^{-1}$.

**Results and discussion.**

Both slab models are supercells with 9 atoms in the surface layer. For one H atom the fcc and hcp hollow sites on Pd(111) and the hollow and bridge sites on Pd(100) have significantly lower calculated adsorption energies than any alternatives. To generate higher surface coverages H atoms are placed on the surface in these sites. The number of possible configurations rapidly increases up to 1 ML (9 H atoms) with 48,620 possibilities at 1 ML on Pd(111). A full set of calculations of all configurations up to 2 ML on Pd(111) would require 262,143 structural optimisations.

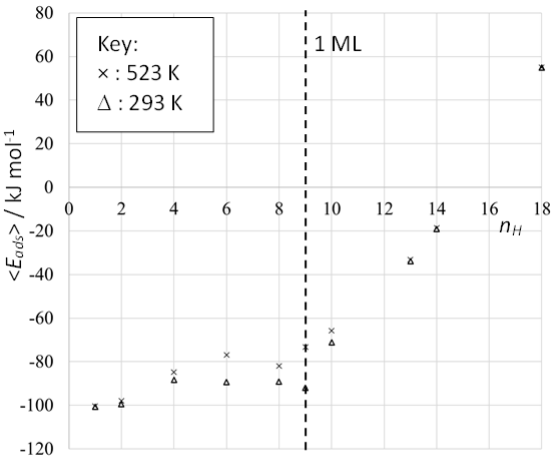

Figure 1: <$E_{ads}$> for $H_2$ adsorbed on Pd(111) *vs* num. H atoms, $n_H$. Temperatures in the key. 1 ML : 1 monolayer.

However, since the slab models are produced from supercell expansions of the primitive cell there is underlying symmetry. We have developed an algorithm to enumerate all configurations and identify the symmetry related configurations with the associated degeneracy. This makes direct DFT calculation of the configuration averaged adsorption energy tractable resulting in the temperature dependent averaged adsorption energy behaviour shown in Figure 1.

This data can be used to calculate the phase diagram for the Pd surfaces exposed to hydrogen at a range of partial pressures and temperatures and enables us to identify the conditions under which hydride formation with sub-surface hydrogen becomes significant.

**Keywords:** hydrogen diffusion, quasielastic neutron scattering, hydrogen capture, polar oxide surface, nanocatalyst

**Introduction.** Diffusion of hydrogen (H) on solid surfaces, such as metal oxides, at elevated temperature under gas phase hydrogen ($H_2$) plays a key role in a broad range of chemical processes, especially in energy storage, fuel cells, and catalysis. However, the dynamics of the H migration over the catalyst surfaces still remain unclear and extremely difficult to observe experimentally on atomic length scales. Thus, it is of importance to probe the diffusion of H over the catalyst surface using high-resolution equipment having the ability to detect the dynamics of such a light element under realistic conditions. Here, A key strength of quasielastic neutron scattering (QENS) is its extreme sensitivity to H motions due to a significantly larger incoherent cross-section of the H atom (80.26 barns, where 1 barn = $10^{-24}$ $cm^2$) compared to all other scattering cross-sections. This renders QENS to be one of the most powerful tools to study diffusion in which H is involved.

**Experimental/methodology.** Metal oxide-based materials including Ru/MgO(111) and Ru/MgO(110) investigated in this study were prepared by following the procedure previously reported by our group [1,2]. In situ QENS technique was used to study the H mobility on the Ru-based MgO catalyst surface, as a function of temperature and $H_2$ pressure. The QENS experiments were performed on the OSIRIS instrument, a high-flux backscattering, TOF spectrometer with an inverted geometry at the ISIS Pulsed Neutron and Muon Source, Rutherford Appleton Laboratory. Details of the in situ QENS experiments are given in [3].

**Results and discussion.** QENS results reveal an exceptional diffusion rate on the polar facet via a proton ($H^+$) hopping mechanism. The observable $H^+$ hopping occurs across the surface oxides ($O^{2-}$) of the MgO(111), with an average jump distance nearly equivalent to the distance between oxide anion sites. This degree of $H^+$ mobility is drastically less detectable when using the Ru/MgO(110) material, suggesting a key role of polar metal oxide surface in facilitating the fast $H^+$ transport. The $H^+$ diffusion coefficients are in between 1.41 ± 0.25 and 2.46 ± 0.72 × $10^{-5}$ $cm^2$ $s^{-1}$ under the temperature of 573–623 K and the $H_2$ pressure range of 1.0–5.0 bar. These values outperform those of $H^+$-conducting oxides, reaching to a similar magnitude to oxyhydride materials. The calculated activation energy for this $H^+$ hopping is ≈0.3 eV, also sensibly lower than $H^+$-conducting oxides in which $H^+$ is covalently bound to local $O^{2-}$ sites. This observation is attributed to the unique atomic arrangement of alternate layers of Mg cations and O anions of the polar MgO(111) where the strong electrostatic field of terminal oxygen anions facilitates protonic migration with a lower degree of local covalency. We envisage that this finding of using polar oxide facets will provide insights into the rational design of efficient catalysts for H diffusion-involved reactions.

**Keywords:** palladium, silver, single crystal, CO oxidation, hydrogen absorption, segregation, surface oxide

**Introduction.** *In situ* near-ambient pressure X-ray photoelectron spectroscopy (NAP-XPS) can elucidate the dynamics between segregation, surface or bulk oxide formation, and adsorption during reaction. We have compared $Pd_{75\%}Ag_{25\%}$ (100) [1] and (111) [2] single crystals to their pure Pd counterparts, with CO oxidation in excess oxygen as the test reaction. But ultrathin PdAg alloy membranes are also being commercialized for production of $H_2$ from natural gas with $CO_2$ capture and storage. We therefore study the adsorption, reactivity, and segregation of Pd-23wt%Ag polycrystalline films *in situ* under hydrogen permeation [3].

**Experimental/methodology.** A combination of in-house characterization and performance testing and near-ambient pressure X-ray photoelectron spectroscopy (NAP-XPS) at the MAXIV HIPPIE Beamline (Proposals 20180307, 20190540, 20190949) has been used. CO oxidation was studied at ~2 mbar and $O_2$/CO=10 during temperature cycling (up to 600 °C). Hydrogen adsorption-permeation was studied *in situ* at 1-5 mbar $H_2$ in a permeation cell designed for polycrystalline thin metal films, with comparison to ambient pressure exposures in permeation experiments without and with (up to 10%) CO or $CO_2$ present.

**Results and discussion.** Alloying significantly affects the reactivity of $Pd_{75\%}Ag_{25\%}$ relative to pure Pd (Fig. 1a) [1,2]. The segregation dynamics responds to exposure and temperature changes and can be followed through the relative amount of Pd bound to CO as well as the ($3d_{5/2}$) Pd/(Pd+Ag) ratio. The $CO_2$ formation is much lower on $Pd_{75\%}Ag_{25\%}$ (111) than on Pd(111) and there are no hysteresis effects. XPS confirms gas phase CO present near the surface, i.e., the commonly observed mass transfer limitations are circumvented by moderation of Pd(111) with Ag. In contrast to Pd(111), and albeit the (√6x√6) $Pd_5O_4$ surface oxide also forming on $Pd_{75\%}Ag_{25\%}$ (111) under pure $O_2$, this surface oxide is immediately lifted upon changing to $O_2$:CO=10 at 450 °C (Fig 1b). The impact of alloying also depends on the surface termination and is stronger for (111) than for (100) [2]. Segregation dynamics is also observed for the Pd-23wt%Ag polycrystalline thin films by NAP-XPS during hydrogen adsorption and dissolution [3].

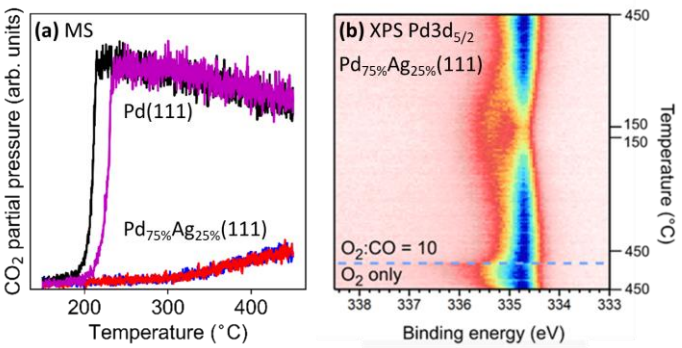

**Figure 1: (a) $CO_2$ formation mass spectrometry profiles for Pd(111) and $Pd_{75\%}Ag_{25\%}$(111) and (b) $Pd3d_{5/2}$ live spectra during initial surface oxidation followed by temperature cycling during CO oxidation for $Pd_{75\%}Ag_{25\%}$(111).**

**Keywords:** single-atom alloys, DFT, orbitals, atomic charges

**Introduction.** Embedding single atoms of transition metals into the surface of coinage metals (Cu, Ag and Au) has emerged as an effective atom-efficient approach to create active and selective catalysts. These so-called Single-Atom Alloys (SAAs) have proven to perform chemistries deemed as unattainable with pure transition metal catalysts [1]. This unique behaviour results from the SAAs' ability to escape decades-old models (d-band model, scaling relationships) that have successfully predicted the reactivity of more traditional metal catalysts [1]. With no predictive models, however, the design of new SAA catalysts is confined to trial-and-error approaches. Here we show that atomic charges and electron count rules are better suited for the identification of potentially active SAA catalysts.

**Experimental/methodology.** All Density Functional Theory (DFT) calculations have been performed using the optB86b-vdW functional and the Vienna *Ab Initio Simulation Package*. Further electronic analyses (orbital projection, overlap analyses) have been performed using the LOBSTER code (http://www.cohp.de).

**Results and discussion.**

To identify potential electronic descriptors for the reactivity of SAAs, two high throughput campaigns have been designed [2-3].

Following the (yet-scarce) experimental evidence of the existence of localised electrostatic charges on the dopant of SAAs [1], we have first determined the dopant charges of Cu, Ag and Au surfaces doped with Rh, Ni, Pd and Pt. Computed dopant charges show large differences among SAAs (-0.63e on PtCu vs +0.32e on NiAu) and could play a role in the binding of adsorbates [2]. To test this hypothesis, we have computed the binding energies of a large range of catalytically relevant adsorbates (H, CO, $CH_x$, $OH_y$, $NH_z$, $CH_3OH$). We have shown that the binding energies correlate with the dopant charges for a subset of adsorbates, namely electron rich Lewis bases such as $H_2O$, OH, and $NH_3$, suggesting that the binding energy can be decomposed into an electrostatic contribution (dominating in this subset) and a covalent contribution. By linearly combining the dopant charge (descriptor of the electrostatic term) and the binding energy for carbon (proxy for the covalent term), we reproduce the DFT data within 0.06 eV mean absolute error and 0.07 eV standard deviation. We also propose an adsorbate classification based on the relative importance of the two identified terms.

Although this classification already provides a very intuitive theoretical framework for the rationalisation of reactivity trends on SAA catalysts, the covalency descriptor only gives indirect information about the dopants and ignores their electronic structure [3]. In our attempt to identify an electronic descriptor for the covalent contribution, we have extended our high throughput approach to most of the d-block elements as potential dopants (3d, 4d and 5d). The obtained periodic trends reveal that the optimal binding energy is reached when the total number of valence electrons of both the dopant and the adsorbate reach 10. Further electronic structure analyses show that this corresponds to the saturation of the d-orbitals of the dopant. Finally, we illustrate how this 10-electron count rule can be used for the identification of promising SAA catalysts (in particular Mo, W and Re based SAAs) for the reduction of nitrogen to ammonia, a reaction of industrial significance.

# Thermodynamic and kinetic impacts of chlorine on Platinum single atoms supported on γ–$Al_2O_3$ during calcination and reduction

A. Hellier[1*], C. Chizallet[1], P. Raybaud[1,2]

[1]*IFP Energies nouvelles, Rond-point de l'échangeur de Solaize, 69360 Solaize, France*

[*]*adrien.hellier@ifpen.fr*

**Introduction.** Platinum based catalysts supported on γ-$Al_2O_3$ are used in a great variety of industrial chemical processes, including refining and biomass conversion. The activation steps (calcination and reduction) of these catalysts involve the transformation of oxidized platinum single atom (Pt SA) complexes into the reduced active phase containing both Pt clusters and Pt SA (Fig. 1.a))[1]. However, the exact nature of these intermediate species and the mechanisms of their transformation during activation remain unknown. By density functional theory (DFT) calculations, we propose to decipher the thermodynamic and kinetic features of these activation steps, and demonstrate the crucial role of chlorine on the mechanisms linking $Pt^{IV}$, $Pt^{II}$ and $Pt^0$ species, as well as on their mobility.

**Experimental/methodology.** DFT calculations have been carried out by using the PBE-dDsC and HSE06 functionals when needed[2] as implemented in VASP 5.4.1. Transition states and free activation energies were determined with the CI-NEB, Dimer method, intrinsic reaction coordinate and vibrational calculations. All supported complexes were modelled on the γ-$Al_2O_3$ (100) surface.

**Results and discussion.** During calcination, chlorine induces a strong dependence between the coordinative shell of Pt and the operating conditions. At high temperature (>500 K), $PtO_2$, $PtOCl_2$ (tetrahedral) and $PtCl_4$ (pentahedral) are predicted to exist, depending on P(HCl), used as a descriptor of the amount of chlorine in the system. At lower temperature, octahedral $PtCl_x(OH)_{4-x}(H_2O)$ species are expected. Our models were fruitfully compared to XAS experiments, in particular in terms of coordination numbers and Pt-X (X=O or Cl) bond lenghts. For reduction, we predict that chlorine increases the thermodynamic stability of $Pt^{II}$ species such as $PtCl_2$ by increasing the reduction temperature and by decreasing its affinity for $H_2$. Moreover, from a kinetic point of view, chlorine hardens Pt reduction by increasing the activation barrier up to 174 kJ/mol for $PtCl_2 \rightarrow Pt$ against 148 kJ/mol for $Pt(OH)_2 \rightarrow Pt$ (Fig. 1.b)). In addition, Cl also favours the migration of $PtCl_2$ (barriers of 14 kJ/mol) onto an alumina surface site where it cannot be reduced (Fig. 1.b)). $Pt(OH)_2$, conversely, is reluctant to migration (barriers of 144 kJ/mol) due to strong Pt-(OH)-Al bridges. This result might explain the higher proportion of SA observed experimentally in presence of chlorine[1] (Fig. 1.a)). Our study paves the way to a better control of the properties of Pt/γ-$Al_2O_3$ catalysts by tuning activation conditions.

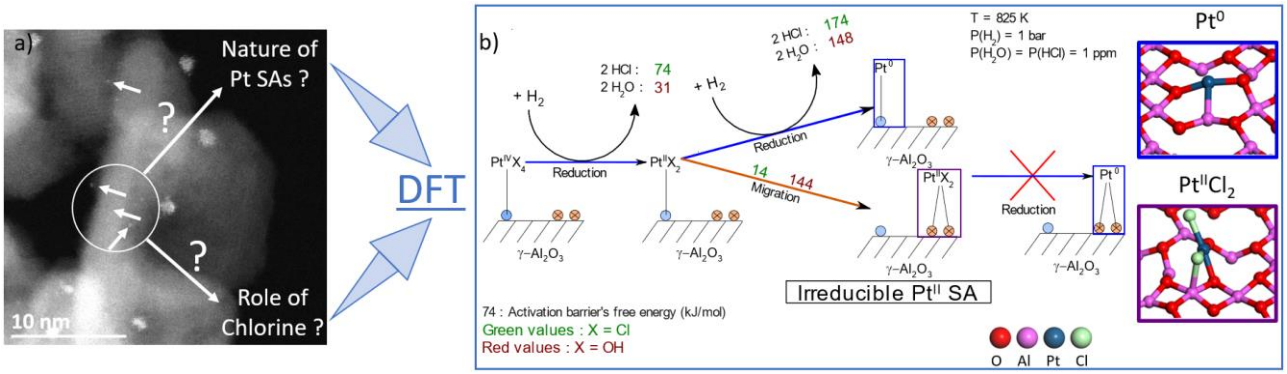

**Figure 1. a) HR-HAADF-STEM images of a reduced Pt/γ–$Al_2O_3$ catalyst [1]. White arrows exhibit Pt SAs. b) DFT scheme of the chlorine impact on the kinetics of platinum reduction and atomistic models of SA Pt/γ–$Al_2O_3$.**

# Computational Identification of True Active Sites in Electrocatalysis

Matthias Vandichel*
Matthias.Vandichel@ul.ie
*Department of Chemical Sciences and Bernal Institute, University of Limerick, Ireland*

**Keywords:** Electrocatalysis, DFT, OER, HER

**Introduction.** The transition of society to energy sustainability necessitates the production of fuels and chemicals via new renewable energy technologies such as electrolyzers. The development and understanding of cheap, durable and high-performance electrocatalyst systems will be necessary to reach sustainable development goals. Future hydrogen production from excess renewable power will rely on superior electrocatalysts for the oxygen evolution reaction (OER) and hydrogen evolution reaction (HER) taking place at anode and cathode, respectively. In this talk, recent computational results for various OER and HER catalysts and supporting experimental observations will be discussed.[1-12]

**Experimental/methodology.** Density functional Theory (DFT) calculations were performed with the Vienna Ab initio Simulation Package (VASP) and compared with experimental data.

**Results and discussion.** To identify what drives an electrocatalytic process, the true active sites need to be identified and molecular modelling can help to identify the dominant reaction pathways on various molecular model systems and assess their electrochemical stability. In case of OER, the usage of electrolyte solutions (*e.g.* KOH) containing trace amounts of Fe and Ni, can result in the creation of active material interfaces under relevant anode conditions, which cheap oxygen evolution catalysts at alkaline pH. Computationally, mixed (Fe, Ni, Co) metaloxy-hydroxides are stable under OER conditions, and their excellent OER-activity can be proven assuming a bifunctional mechanism.[1-2] In this regard, the beneficial effect of Fe-doping of other oxides ($PdO_x$, $MnO_x$) will also be discussed.[3-4] Furthermore, molecular metal-complexes are merely OER-'pre'catalysts, and case examples will be presented that point towards their decomposition;[5-7] for a vitamin B12 complex electrochemical leaching of Co is more likely to happen than the oxygen evolution reaction.[6-7] In case of HER, the hydrogen adsorption energy – typically used as activity descriptor – is determined to identify active sites.[8-9] We showed that carbon sites on a nanotube containing PtRh are more active for the hydrogen evolution reaction than other possible model systems,[8] and that cathodic hydrogen absorption results in metal-hydride formation, which changes the activity through strain and coordination.[9] Besides typical HER and OER process, I will present modelling results of various photo(electro)chemical processes taking place on material interfaces [11-12] and work in progress.[13] Summarizing, it should be clear that first-principles insights can transcend the viewpoint of the scientific community beyond the state-of-the-art and contribute to an enhanced understanding.

# Unrevealing Universal Water-Assisted Chemical Routes Towards the Oxygen Evolution Reaction at solid-liquid interfaces

F. Creazzo[1*], R. Ketkaew[1], S. Luber[1]

[1]*University of Zurich, Zurich, Switzerland*
[*]*fabrizio.creazzo@chem.uzh.ch*

**Introduction.** The biggest (or one of the biggest) issue that the world human population faces in this century is the urgent need for clean and renewable technologies. Herein, advanced enhanced sampling methods coupled with spin-polarized Density Functional Theory Molecular Dynamics (DFT-MD) simulations, which include in a realistic way finite-temperature and explicit-solvent effects, are applied to gain a global understanding of (100) $RuO_2$, (001) $WO_3$, (100) $WSe_2$ aqueous interfaces in catalyzing the Oxygen Evolution Reaction (OER), and hence possibly help in the design of novel catalysts in the context of photochemical water oxidation. Notwithstanding (100) $RuO_2$, (001) $WO_3$, (100) $WSe_2$ are gaining attention for active catalysts toward OER, a plethora of fundamental details on their catalytic properties are still elusive as well as the water interfacial organization, severely limiting their large-scale deployment.

**Experimental/methodology.** An atomistic understanding of structural, electronic and mechanical properties of bulk $RuO_2$, $WO_3$ and $WSe_2$ and explicit solvent effects on (110)-$RuO_2$, (001) $WO_3$, (100) $WSe_2$ facets are provided in the context of (photo)electrochemical conditions. We focus on the comprehension of the mechanistic interplay between surface wettability, interfacial water dynamics and surface chemical activity. Moreover, we provide a dependence of physical and chemical properties, such as surface electric field and work function in-and-out the presence of interfacial water with different degrees of surface wettability [1,2].

**Results and discussion.** Furthermore, we quantitatively assess the kinetics, thermodynamics and the involved energies behind the OER at (100) $RuO_2$, (001) $WO_3$, (100) $WSe_2$ catalyst surfaces revealing plausible pathways composing the reaction network of the $O_2$ evolution in both gas-phase and explicit solvent model [3,4]. Albeit a unique efficient pathway has been identified in the gas-phase OER, a lower-energy-requiring reaction route can be possible when facets are in contact with liquid water.

By estimating the free-energy surfaces associated to these processes, we reveal an unprecedented and universal water-assisted OER mechanism which involves a crucial proton-transfer-step assisted by the local water environment. These findings pave the way toward the systematic usage of those techniques for the fine assessment of the activity of catalysts.

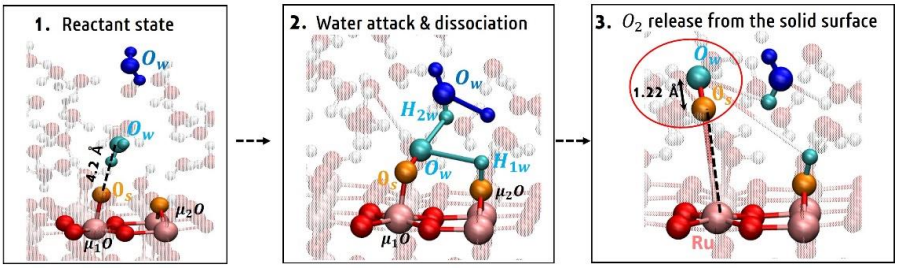

**Fig.** Water-assisted OER mechanism at the (110)-$RuO_2$ facet in explicit solvent model.

# Towards more realistic simulations of catalysis: supported metal nanoclusters on oxide surfaces

E. Strugovshchikov,[1*] A. Salom-Català,[1] J. Pan,[1] K. Kaźmierczak,[2] D. Curulla-Ferre,[2] J.J. Carbó[1] and J.M. Ricart[1]

[*]*evgenii.strugovshchikov@fundacio.urv.cat*

Supported sub-nanometric metal clusters are considered as a singular phase of matter exhibiting a number of interesting properties that can be used in the design and development of novel catalytic materials. For instance, metal sites on an oxide surface can exhibit high activity combined with enhanced selectivity, and decreased deactivation by undesired products.[1] However, their atomistic simulation requires the consideration of a complex variety of the possible active sites at the sub-nanometric level as well as the large number of the accessible atomic configurations at reaction temperatures.

The study of such a catalytic system, which is not easily accessible using Density Functional Theory, can be performed by implementing specific Reactive Force Fields capable of performing extensive simulations or identifying descriptors for the structure-activity relationship. Thus, we have adopted the ReaxFF method,[2,3] which employs the so-called bond order formalism, and is able to simulate bond formation/breakeage processes in systems of similar size to classical Molecular Dynamics simulations.

As a case study, we present a theoretical simulation of alumina-supported ($\gamma$-$Al_2O_3$) Pt and Pt-Sn sub-nanometric clusters for propane dehydrogenation (PDH) reaction.[4,5] To this end, we have developed a set of new parameters for the ReaxFF reactive force field. We will demonstrate that these ReaxFF parameters are capable to describe not only the productive PDH pathway but also deactivation routes involving deep dehydrogenation and C-C bond scission. Furthermore, our theoretical approach opens the way for the more efficient ensemble representation of nanocatalysts, bridging the gap between atomic-scale modelling and mesoscale experimental techniques, thus offering a possibility to design a more effective catalyst.

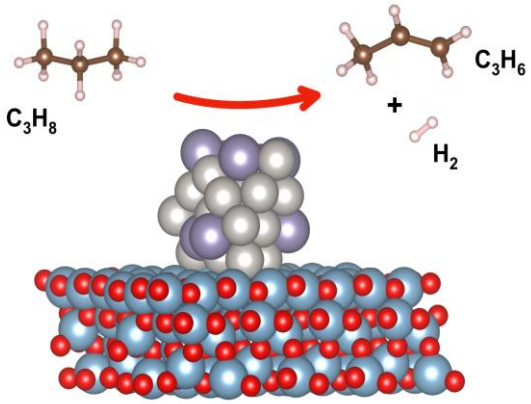

**Figure 1**. Pictorial representation of PtSn sub-nanometric clusters on $\gamma$-$Al_2O_3$, and propane dehydrogenation to hydrogen and propene. Pt – grey, Sn – violet, Al – blue, O – red, C – brown, H – whitish.

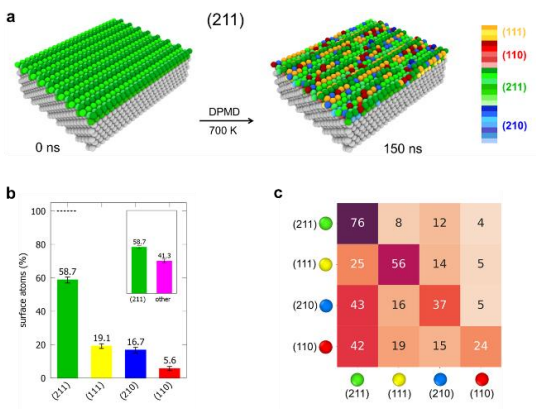
## Introduction

Solid's surfaces are known to become mobile due to thermal energy at temperatures well below the melting point. As pointed out by Spencer[1], many metals used in industrial catalytic processes work above the Hüttig temperature ($T_{Hüttig} \approx 1/3\ T_{melting}$), thus their surfaces should be mobile. Understanding how such surfaces move and reconstruct may be essential to determine their activity[2] e.g., establishing the number of active sites and their evolution in time. In this work we focused on copper (Cu) due to its relevance in several fields of catalysis such as methanol synthesis from $CO_2$[3]. An extensive campaign of DFT molecular dynamics (MD) simulations generated Cu surface data used to train a deep neural-network (NN) potential. This provided a dynamically accurate atomistic force field allowing to simulate various types of Cu FCC crystal facets above $T_{Hüttig}$ on relevant spatiotemporal scales. Smooth Overlap of Atomic Position (SOAP)[4] based analyses revealed the atomic environments that statistically populate Cu surfaces, including atomic environments typical of other types of Cu surfaces, which continuously emerge/resorb in equilibrium conditions. This allows estimating an "equivalent identity" for such metal surfaces on a statistical basis from the data emerging along the simulations.



## Methodology

A Cu NN-potential was built following the Deep Potential MD scheme[5]. The training data set was obtained from ab initio MD simulations of small Cu surfaces and bulk structures carried out in the NVT ensemble at 500-700 K. MD simulation of larger systems were performed and analyzed with the local environment descriptor SOAP. Environment similarity analyses were performed to characterize the atomic environments that statistically populate metal surfaces in equilibrium conditions. We created a dictionary of SOAP atomic environments by computing the SOAP spectra for all atoms in the optimized Cu FCC (111), (110), (211), and (210) surfaces.

## Results and discussion

Here we present the results obtained starting from an ideal Cu (211) surface simulated at 700 K. Figure 1a shows how the (211), ideally composed only of green native SOAP sites at 0 K (left), reconstructs local non-native domains, proper of (111), (110) and (210) ideal surfaces (right: yellow, red and blue respectively). Analyzing the population of atomic environments we notice that 40% of native domains disappear and reconstruct non-native domains (Figure 1b). The transition matrix of Figure 1c reports the normalized probabilities for atom transitions between native and non-native environments in the (211) surface (in $\Delta t$ = 300 ps). The diagonal entries show that only the native (green) and yellow (111) domains have a residence probability >50%, meaning that within these are persistent domains. In contrast, (210) and (110) atomic environments have persistence probabilities well <50%. Such domains are more dynamic, and the atoms composing them have higher probability to re-convert into native domains (red-to-green and blue-to-green transition probabilities 42-43%).

**Figure 1**. **a** Cu (211) at 0 ns and after 150 ns of MD at 700 K. **b** Equilibrium composition of (211) in terms of native (green) and non-native domains (yellow, blue, red, combined in pink in the inset). **c** Transition matrix showing probabilities for atomic transitions in (211) between native and non-native environments.

**Keywords:** Density Functional Theory, Artificial Neural Network, Dry Reforming Reaction of Methane

**Introduction.** This work demonstrated the improved algorithm based on first-principles and machine learning techniques: density functional theory (DFT) and artificial neural network (ANN). This algorithm is a two-step procedure that comprises catalyst identification and optimization. The Ratings concept was employed to identify the catalyst's reactivity and stability. Each catalyst is given a unique index based on its activation energy obtained from DFT on (1) reactants activation ($CH_4$ and $CO_2$) and (2) coke formation and removal benchmarking to the reference catalyst: Ni(111). These indexes on the reactivity and stability surface are used to predict DRM and coking rates at specified operating conditions. Also, the coking boundary proposed in the concept is used to determine the coke-resistant region during DRM. The next step is to generate the database for DRM and coke formation/removal rates of a chosen catalyst at different operating temperatures and $CO_2/CH_4$ feed ratios. This information is incorporated into the on-line optimization. Ultimately, the goal is to sustain the reaction rate of a given catalyst in the reactor and its coke-resistant property when changes in the condition of the reformer feed composition due to variations of fuel sources are present.

**Experimental/methodology.** Spin-polarized periodic density functional theory (DFT) calculations were employed via the Vienna ab initio simulation package (VASP). The Projector Augmented Wave pseudopotentials (PAW), plane-wave basis sets, and exchange-correlation functional described within the generalized gradient approximation (GGA) with the functional by Perdew, Burke, and Ernzerhof (PBE) were used for all systems. The Monkhorst-Pack Brillouin zone integration grid of $4\times4\times1$ with the first order Methfessel-Paxton smearing method of 0.2 eV smearing width was used. The convergence criteria are $10^{-4}$ and $10^{-3}$ eV for successive electronic and ionic steps. The climbing method nudged elastic band (CI-NEB) was employed to obtain each elementary step's activation energy (Ea). For the Ni oxide, the Hubbard-U correction was used with the GGA-PBE functional with $U_{eff}$ used at 5.4 eV. The assumptions and simplifications of the DRM mechanism were reported in our previous works[4], where the surface reaction is the rate-limiting step. The zero-point energy (ZPE), entropy (S), and internal energy (U) contributions were considered. The pseudo-steady-state hypothesis (PSSH) was applied to determine surface coverages, with no "most abundant reactive surface species" (mari). The $CO_{(g)}$ and $H_{2(g)}$ are assumed to be in the adsorption-desorption equilibrium. Reactivity and stability were illustrated via DRM rate and coke formation from CH and CO and coke removal via H and O, respectively, at a reaction condition of 1000 K with a unity $CO_2/CH_4$ feed ratio.

**Results and discussion.** It was demonstrated that the reaction would rapidly proceed on the carbide $Ni_3C(001)$ and the metallic Ni(111) surfaces but would be suppressed on the oxide surface of NiO(100) and the metallic Ni(100) due to the presence of high $E_a$. Hence, a reactive and stable DRM catalyst would need to be oxide-dominated on the (100) while being metallic-dominated on the (111) facet. On the DRM reactivity, all of the metallic, oxide, and carbide surfaces are active, except NiO(100). Hence, the surface composition that yields reactive and stable Ni-based DRM catalysts is proposed to have less than 10 % of carbide, and up to 75 % metallic is needed.

**Keywords:** Rochow-Müller, Copper, $CH_3Cl$, coke formation

**Introduction.** In the Rochow-Müller process chloromethyl silanes are made from silicon (s) and $CH_3Cl$ (g), producing $(CH_3)_2SiCl_2$ (M2) as the dominant product. A Cu-based catalyst is needed, which mixes with the silicon forming a Cu-Si alloy. η-$Cu_3Si$ is believed to be the predominant active phase for M2 formation [1]. The system suffers from deactivation and coke formation [2]. The coke formation may be associated with the presence of elemental copper, which is observed post reaction [3]. In this study we investigate the role of copper in the formation of coke precursors, i.e. $CH_2$, to aid the industrial challenge of hindering these unwanted reactions.

**Experimental/methodology.** Density functional theory is used to study the decomposition of $CH_3Cl$ and formation of possible coke precursors, $CH_2$ and CH, on various Cu surfaces, Cu(111), Cu(100), Cu(221) and Cu(410), in addition to Cu-rich Cu-Si models. The DFT calculations were performed using VASP [4], with the PBE functional [5] and an energy cutoff of 550 eV. Adsorption of $CH_3Cl$ and possible decomposition products down to atomic carbon were calculated. Nudged elastic band (NEB) [6] calculations were used to calculate the barriers for $CH_3Cl$ activation and subsequent reaction/decomposition processes.

**Results and discussion.** The formation of coke precursors (predominantly $CH_2$) formed in the decomposition of methyl chloride on the surface is compared with a pathway for the formation of the desired product M2. Figure 1 shows the potential energy diagram for the first decomposition step of methyl chloride on Cu surfaces with varying degree of coordination of the atoms in the top-most layer. The first decomposition step to adsorbed $CH_3$ and Cl is favored compared to C-H bond breaking. The former is a necessary step for the formation of M2 and the separation into paths leading to desired (M2) and undesired (coke precursors) products will be presented.

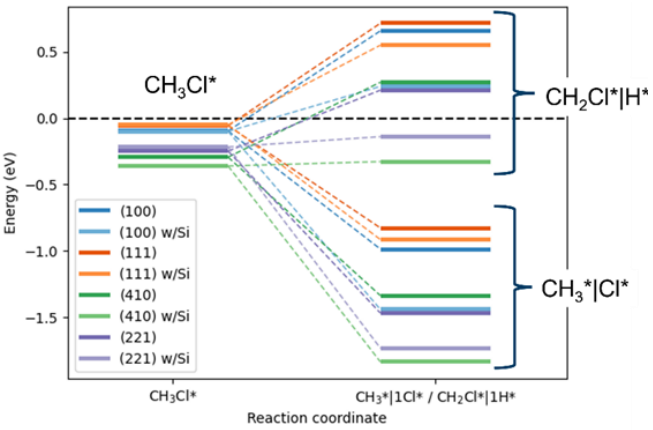

Figure 1. Energy diagram for the first decomposition step for CH3Cl on different Cu(Si) surfaces.

**Introduction.** $In_2O_3$-based catalysts have shown high activity and selectivity for $CO_2$ hydrogenation to methanol. The origin of this high performance is, however, still under debate.

**Experimental/methodology.** To improve the understanding of the surface chemistry of $In_2O_3$, we studied the reactivity of an $In_2O_3$(111) single-crystalline film [1] and investigated the adsorption of $CO_2$ on $In_2O_3$(111) in a combined X-ray photoelectron spectroscopy (XPS) and density-functional theory (DFT) study.

**Results and discussion.** Different surface terminations of $In_2O_3$(111) have been reported in the literature [2,3]. We have investigated the effect of these different surface terminations on the adsorption of $CO_2$ on the $In_2O_3$(111). The experiments show that the $CO_2$ adsorption is hindered on hydroxylated $In_2O_3$(111) compared to the stoichiometric and the reduced surface. This shows that the hydroxyl groups block the $CO_2$ adsorption. The $CO_2$ appears to adsorb as a carbonate on all surface terminations.

Additionally, we studied the effect of the pressure gap on this system (Figure 1). NAP-XPS measurements showed the formation of a new chemical species at 1 mbar $CO_2$ that might originate from HCOO. Furthermore, the addition CO to the $CO_2$ and $H_2$ gas mixture appears to cause the formation of O-$CH_3$ groups, indicating that CO in the syngas mixture might be crucial for $CO_2$ hydrogenation over $In_2O_3$ catalysts.

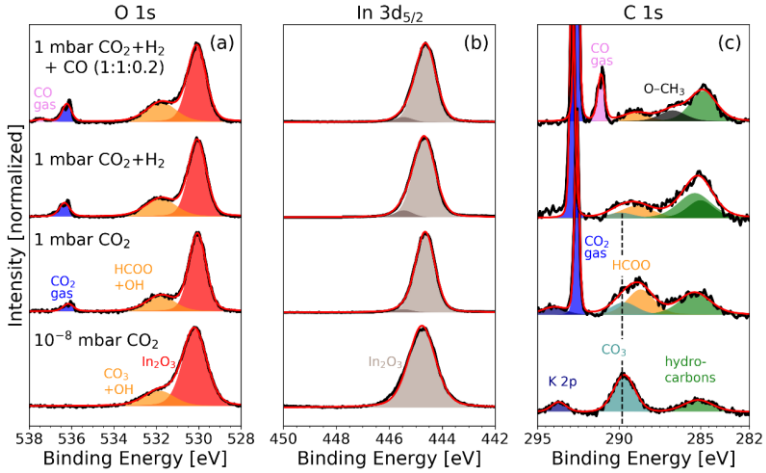

**Figure 1:** XPS and NAP-XPS measurements of $In_2O_3$(111) in different gas compositions.

**Keywords:** m-$ZrO_2$, DFT, $CO_2$ Adsorption, Oxygen vacancy, $CO_2$ Dissociation

**Introduction.** The performance stability of a Catalytic Dry Reforming of Methane (CDRM) catalyst is primarily determined by its ability to resist coke formation. This is possible through removal of carbon deposited on the hydrogen production sites of the catalyst by mobile surface oxygen formed via $CO_2$ dissociation. In this study, it is aimed to understand the role of oxygen vacancies in activation and dissociation of $CO_2$ molecule on m-$ZrO_2$, which has been widely studied as the support of CDRM catalysts.

**Computational.** All periodic DFT calculations in this study were carried out using (CASTEP). Exchange and correlation were included through the use of GGA-PBE functional. The plane-wave cut-off energy was determined to be 640 eV and 6 × 6 × 6 k-point mesh was chosen for the Brillouin Zone (BZ) sampling. m-$ZrO_2$($\bar{1}11$) surfaces were modeled as a four-layer slab with a vacuum layer of 12 Å along the z-direction. Oxygen vacancy formation on m-$ZrO_2$($\bar{1}11$) surface was investigated. Then, $CO_2$ adsorption onto both stoichiometric and nonstoichiometric m-$ZrO_2$($\bar{1}11$) surfaces were performed. The surface, adsorption and vacancy formation energies were calculated. Local density of states (LDOS) analysis was performed.

**Results and discussion.** The DFT calculations of oxygen vacancy formation showed that on the m-$ZrO_2$($\bar{1}11$) surface, the formation of 2-fold coordinated oxygen vacancy is favorable, indicated by its lower formation energy compared to others. Moreover, among 3-fold coordinated sites, removing the ones which are bonded to coordinatively unsaturated Zr atoms is easier compared to ones which are bonded to 7-fold coordinated Zr atom. The results of $CO_2$ adsorption on the stoichiometric m-$ZrO_2$($\bar{1}11$) surface revealed that even if strong adsorbate-metal oxide support interaction is present, dissociative adsorption of $CO_2$ is not observed. Instead, $CO_3^{2-}$ species were formed. On the other hand, spontaneous dissociation of $CO_2$ molecule was observed on the nonstoichiometric m-$ZrO_2$($\bar{1}11$) surface. In the final configuration, it was seen that the dissociated oxygen fills the vacancy and CO moiety approaches to either one of the NN cus Zr atom (Figure 1). The results showed that adsorption energies are significantly lower for the nonstoichiometric m-$ZrO_2$($\bar{1}11$) surface and $CO_2$ prefers the vacancy sites over other surface oxygen atoms. This implies that $CO_2$ adsorption on a surface with an oxygen vacancy is energetically more favorable than that on a clean, undefected surface.

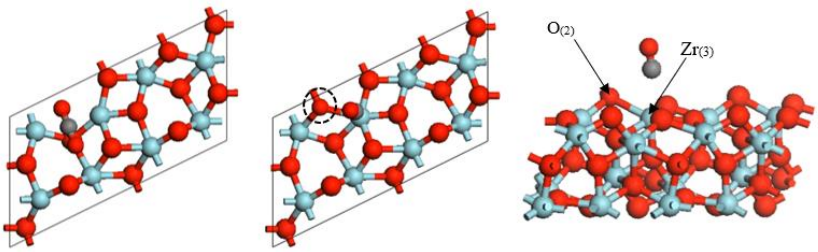

**Figure 1.** On the left-hand side initial configuration and on the right-hand side top view and side view of the final configuration of the $CO_2$ molecule on the nonstoichiometric m-$ZrO_2$ ($\bar{1}11$) surface with a 3-fold vacancy at $O_{(2)}$ location: Initially $CO_2$ on $O_{(L2)}$.

# $CO_2$ activation on Ni(111) model catalysts at ambient conditions

R. Ben David[1*], A. Ben Yaacov[1], B. Eren[1]

[1]*Weizmann Institute of Science, Rehovot, Israel*
[*]*Roey.ben-david@weizmann.ac.il*

**Keywords:** $CO_2$ activation, Dissociative adsorption, Ni(111) model catalyst, Infrared specroscopy.

**Introduction.**

The adsorption and activation of $CO_2$ on metal surfaces is an elementary step to consider for the rational design of catalytic systems for $CO_2$ conversion and utilization via heterogeneous catalysis [1-2]. Ni-based catalysts are considered to be efficient materials for several $CO_2$ conversion reactions such as dry methane reforming (DMR), $CO_2$ methanation, and $CO_2$ conversion to CO via the reverse water gas shift (RWGS) reaction. The interaction between $CO_2$ and Ni surfaces at ambient conditions have been recently studied with ambient pressure x-ray photoelectron spectroscopy (AP-XPS) [3-4]. Yet, the exact nature of the surface species and the chemical state of the surface are highly controversial.

**Experimental/methodology.**

We studied the interaction of $CO_2$ with metallic and oxidized Ni(111) model catalysts under 1 mbar $CO_2$ pressure in the temperature range of 25-300 °C using polarization modulation-infrared reflection-adsorption spectroscopy (PM-IRRAS) and Auger electron spectroscopy (AES). Our *in-situ* PM-IRRAS measurements provided information on the molecular surface species and their adsorption sites, whereas AES was used for *ex-situ* analysis of surface oxygen.

**Results and discussion.**

Our results suggest that $CO_2$ is dissociatively adsorbed on Ni(111) under ambient conditions. This dissociative adsorption produces CO and atomic oxygen; two strongly bound species which compete for the same preferred adsorption sites, namely the hollow sites. At 25 °C, the produced CO adsorbs mainly on hollow sites, and small fraction adsorbs on top sites. After heating to higher temperatures, the CO occupancy on top sites increases, as more atomic oxygen is produced and blocks the hollow sites. Overall, the surface temperature determines the site occupancy distribution of the CO product during $CO_2$ dissociation on Ni(111). On oxidized Ni(111) surface, $CO_2$ dissociation is rather inactive at 25 °C, however, heating the surface to higher temperatures (≥ 200 °C) reduces the oxide layer and exposes metallic Ni. Thus, both bare and oxide-covered Ni(111) surfaces have the same equilibrium chemical state and adsorbed species after heating to elevated temperatures. We attribute the reduction of the oxide layer to residual hydrogen impurities, which efficiently convert atomic oxygen into water vapor.

**Keywords:** Ir-clusters, Ir-support effect, sub-nanometric, hydrogen economy, heterogeneous catalysts.

**Introduction:** Stabilizing metal nanoparticles is vital for large scale implementations of supported metal catalysts, particularly for a sustainable transition to clean energy. Indeed, despite the intriguing properties of sub-nanometric metal clusters, one of the biggest challenges is still finding practical ways to stabilise them against migration and ripening phenomena.[1] Recent works indicated graphitic carbon nitride (GCN) as an ideal support for this purpose, due to its peculiar electronic structure and the N-rich framework composed of amine-bridged tri/heptazine moieties.[2] Herein, we report the synthesis of 1 wt% iridium sub-nanometric particles deposited on commercial graphite (Ir/graphite) and on graphitic carbon nitride (Ir/GCN) by a wet impregnation method. We have investigated the metal-support interaction during the hydrous hydrazine ($N_2H_4 \cdot H_2O$) decomposition reaction. $N_2H_4 \cdot H_2O$ is one of most promising hydrogen carriers, a carbon-free fuel with a hydrogen content of 8.0 wt%. It reported to decompose in two different routes: the complete reforming pathway, where $H_2$ and $N_2$ are produced, and the incomplete decomposition pathway, i.e., the thermodynamically favored process, producing $N_2$ and $NH_3$.[3]

**Experimental/methodology.** Liquid $N_2H_4{\cdot}H_2O$ decomposition was performed at a constant reaction temperature of 323 K, in a batch reactor connected to a pressure detection sensor, the *Man On the Moon X102 kit*. Fresh and used catalysts were characterized by HR-TEM and XPS in combination with computational techniques. These allowed deep understanding on the role of metal-support interactions on the particle activity and stability.

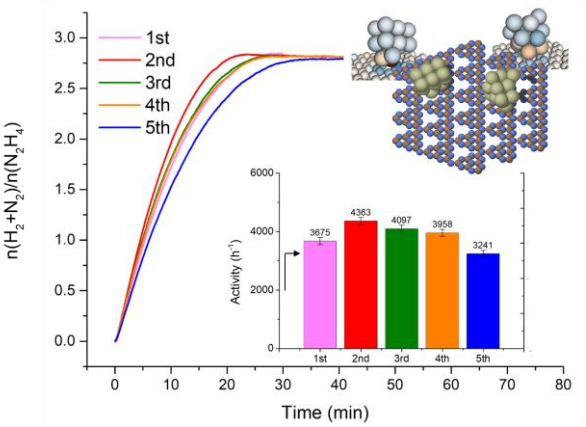

Figure 1 Hydrazine decomposition stability tests for 1%Ir/GCN. Inset is the charge transfer representation for Ir clusters deposited on the typical GCN sites.

**Results and discussion.** Both catalysts exhibited remarkable initial catalytic activities (3654 $h^{-1}$ and 4024 $h^{-1}$, respectively) in the hydrous hydrazine decomposition. Recycling tests evidenced an enhanced stability of the Ir/GCN samples upon repeated reaction cycles (Figure 1), without significant modification of the catalyst's structure compared to Ir/graphite, prone to leaching and agglomeration of the sub-nanometric clusters. The enhanced stability was rationalized at an atomic scale level through a combined TEM, XPS and DFT analysis. The combined experimental-computational approach allowed to precisely assign the GCN nitrogen anchoring sites as the main responsible for the sub-nanometric particles integrity and improved stability, and to rationalize the experimental reactivity and characterization results in terms of metal-support interaction. Overall, the enhanced charge transfer due to the N moieties allowed to better stabilise Ir nanoparticles, and in particular the sub-nanometric ones, ensuring high activity under operative conditions.

**Keywords:** Model Catalysis, Cobalt oxide, Thin Films, STM, LEED, Water interaction

**Introduction.**

Coxide-based based materials recently gained significant importance as efficient heterogeneous catalysts in a variety of reactive processes. In this study, ultrathin $CoO_x$ films were epitaxially grown on Pd(100) and Au(111) single crystals as proxies to powdered catalytic materials. The major focus of this study was on the dependence of the structural properties on the preparation parameters and film thickness.

**Experimental/methodology.**

The structural composition, termination and the stoichiometry of these films were investigated at the atomistic level by a combination of scanning tunneling microscopy (STM) and low energy electron diffraction (LEED) combined with the calibration via quartz microbalance.

**Results and discussion.**

Specifically at the lowest Co deposition, the two most prominent co-existing structural domains were identified as c(4x2)/CoO(100)/Pd(100) and bridging oxygen (BO)-$CoO_x$/Pd(100). With growing nominal Co coverage, the domain with the structural composition c(12x2)/CoO(111)/Pd(100) develops, while the amount of c(4x2)/CoO(100)/Pd(100)- and the BO-$CoO_x$/Pd(100) domains reduces. Further observed structures include Moiré-CoO(111)/Pd(100) and $Co_3O_4$(111)/Pd(100), which appear rather at higher Co coverages. Water interaction with two co-existing surfaces c(4x2)/CoO(100)/Pd(100) and BO-$CoO_x$/Pd(100) was investigated in a broad $H_2O$ coverage range. Specifically, we could show that water readily adsorbs and dissociates on BO-$CoO_x$/Pd(100) terminated surface, while c(4x2)/CoO(100)/Pd(100) is nearly inert with respect to $H_2O$ dissociation. Further characterization of the H2O-derived adsorbates on the BO-$CoO_x$/Pd(100)-structure enabled distinguishing three species: two of them could be assigned to OH groups on different adsorption sites – cobalt atoms and bridging oxygen rows. The third identified species can be most likely related to complexes containing non-dissociated water molecules.

# The time-resolved catalytic activity of 2D material-supported catalysts at the single active site level

**Keywords:** 2D materials; Platinum nanoparticles deposition; Single-molecule fluorescence microscopy; Reaction rate constant of the specific active site; Catalytic activity at the single-nanoparticle level

**Introduction.** Graphene and other 2D materials are receiving intense attention, driven by their unique chemical and physical properties. During the past decade, graphene, as a typical member of the 2D material family, has been widely investigated for catalysis. However, graphene could also be used as a 2D support for metal NPs [1]. These catalytic systems exhibit a significant increase in a catalytic activity and selectivity. The explanation of the increased activity and selectivity is usually reduced to the electronic properties of the 2D support and the specific interaction between NPs and the support [1]. To investigate these interactions and the support effect on a catalytic activity, it is necessary to obtain the same uniform pattern of metal NPs on different types of 2D supports. Electron Beam Lithography (EBL) enables to help with the precisely controlled nanofabrication of metal NPs. The advantage of this method is direct and target depositions on the selected 2D sheet features with the known size and spatial distribution. Due to a super-resolution, single-molecule fluorescence microscopy (SMFM) is used to determine a time-resolved catalytic activity at the single active site level using the localization of single molecules (reaction turnovers). SMFM has been demonstrated to be a powerful technique for the visualization of reaction behaviors and can be employed to record single reaction turnovers using fluorogenic molecules. Each turnover is represented by a single reaction track, from which catalytically active zones in the material can be reconstructed with a super-resolution. Because reaction events occur stochastically at the active catalyst sites, these tracks are spatially and temporally separated and can be resolved individually for each turnover [2]. These studies primarily focus on quantitative imaging of a time-resolved catalytic activity at a single active site level due to SMFM, which is eble to reveal the behavior of individual reaction turnovers.

**Experimental/methodology.** The platinum NPs deposited onto two types of 2D support materials by EBL were tested for a catalytic activity at a single active site level using a super-resolution fluorescence microscope. As a result, we acquired time-resolved image series that contained single-molecule reaction turnovers. Then, the microscopic activity map was produced by integrating images over the reaction time.

**Results and discussion.** In this study, we evaluated the time- and spatially-resolved microcatalytic activity of the same metal NPs on various supports and calculated an overall reaction rate constant for the specific active sites. We also determined the lifetimes of fluorescent (active) and non-fluorescent (dark) states for each active site. The comparison of kinetic characterization for two different supported catalysts demonstrated that the second catalyst had the longer lifetime of a dark state ($\tau_{off}$ = 5.72 × $10^{-2}$ s compared to $\tau_{off}$ = 4.05 × $10^{-2}$ s). This led to a decrease in the reaction rate constant (17.48 ± 0.22 $s^{-1}$ compared to 24.69 ± 0.22 $s^{-1}$) and, as a result, reduced the working quality of the catalyst. Therefore, this approach enabled us to understand how the catalytic activity of a specific active site can affect on the catalytic properties of 2D material-supported catalysts.

**Keywords:** metal nitrides; HDO; nanoparticles; spark discharge; carrier gas

**Introduction.** Ni-Mo catalysts are important in many different catalytic applications [1-3], such as hydrodesulfurization (HDS) [1,3] and hydrodeoxygenation (HDO) reactions [1]. To develop these catalysts further detailed knowledge about the properties of the material is needed. However, the active supported catalysts are complex and fundamental studies are challenging, due to the low concentration of the active phase. As such, model systems with a high concentration of the active phase are useful for elucidating the properties of catalytic systems.

In this study, we design a model system of well-defined nanoparticles generated by a spark discharge method. The spark discharge method offers the possibility of creating and depositing catalytically active nanoparticles of well-defined size, allowing for the construction of high-concentration model systems where the active phase can be studied in isolation. While this method has already been used to synthesize oxides [4] and hydrides [5], we can in this study also report, for the first time, of the synthesis of nitrides using this technique. Here, we present the successful spark-discharge synthesis and characterization of different phases of Ni-Mo nanoparticles.

**Experimental/methodology.**

Nanoparticles were generated using a previously-described spark discharge set-up and method [6]. Briefly, $Ni_{30}Mo_{70}$ electrodes with a separation of 1.5 mm were used as a material source, while 5 % $H_2$ in $N_2$ was used to prevent oxidation. Compaction was carried out at 1200 °C, and certain samples were size-filtered using a DMA. Oxidation of as-deposited nanoparticles was carried out in air at 400 and 510 °C.
Structural and compositional analysis was carried out using TEM, SAED, STEM-EDX, EELS and PXRD.
Further, synchrotron-based XPS studies following the $H_2$ reduction of the oxides were performed where the chemical compositions could be followed in situ.

**Results and discussion.** TEM and STEM-EDX imaging on as-deposited particles indicated the formation of Janus particles consisting of a pure Mo and a Ni/Mo phase, as illustrated in Figure 1. The presence of the oxides as well as nitride was further confirmed by TEM and STEM/EDX. The successful synthesis of NiMo nanoparticles opens up the possibility of in-detail mechanistic investigations of industrially important catalyst systems.

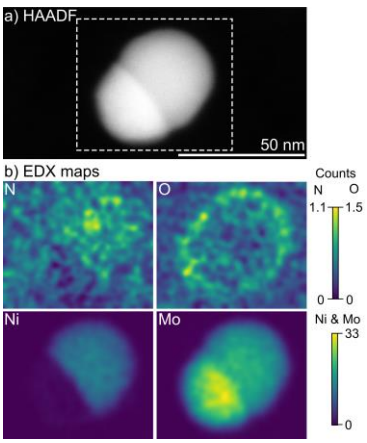

Figure 1: HAADF-STEM and STEM-EDX images of as-deposited Ni-Mo nanoparticles.

**felix.studt@kit.edu*

**Introduction.** An accurate description of adsorption process is of paramount importance for the understanding of heterogeneous catalytic process. However, the current approaches of adsorption free energies calculations either provide insufficient entropic contributions or are very complex and/or computationally expensive. The harmonic approximation (HA), the method that has been utilized most frequently thus far, is prone to significant deviations [1]. There is need in method that is able to recover the free energy contributed from a system's anharmonicity for a better description of free energy.

Herewith, we present a new approach, in which machine learned force field (MLFF) is used in place of DFT in the most time-consuming step of λ-path thermodynamic integration (MLFF-based λ-TI) in order to calculate the anharmonic contribution to free energies. This allows us to reach accurate free energies of adsorption processes, which could then provide more insight into the reaction mechanism of surface reactions.

**Results and discussion.** First, a model system of ethane ($C_2H_6$) was used to assess the applicability of the MLFF-based λ-TI method. Table 1 shows an excellent agreement in the free energy due to anharmonicity of the system resulted from MLFF-based λ-TI and from DFT-based λ-TI [2], in comparison with semi-analytical solution. An accuracy of mili-electronvolts makes it reasonable to apply the method for more realistic and complicated system of interest.

**Table 1 The anharmonic corrections ΔA0,q→1 (in meV) determined by MLFF-based TI compared with DFT-based TI and semi-analytical solutions (if available).**

| $\Delta A_{0,q\to1}$ | MLFF | DFT | Semi-analytic |
|---|---|---|---|
| $C_2H_6$ | -3.27 | -3.30 | -4.1 |
| OH@Pt(111) | -250.0 | - | - |

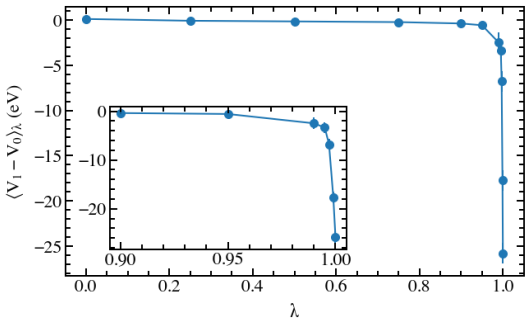

**Figure 1 Averaged energy differences obtained by MLFF-based MD runs at 400K**

Figure 1 provides the energy differences for TI of the OH@Pt(111) system obtained by MLFF-based MD simulations. As the behaviors of the system change rapidly when it comes closer to the fully interacting regime, more points were added (λ = 0.90, 0.95, 0.99, 0.995, 0.997, and 0.999) to smooth the curve, resulting in 11 λ points in total. The computed anharmonic correction for this system gives a significant value of -0.250 eV, which is as high as roughly 12.5% of the harmonically approximated adsorption free energy (-2.01 eV).

This method allows for fast and accurate calculations of adsorption and desorption free energies, which could pave the way for detailed and precise predictions of equilibrium and rate constants for surface reactions.

**Introduction.** Transition metal sulfides (TMS) are important commercial catalysts for hydrotreating processes like hydrodesulfurization, hydrodeoxygenation, hydrodearomatization. In this class of catalysts, molybdenum sulfide is the focus of more research than other catalysts due to its resistance to deactivation in comparison to other transition metals such as Pd, Pt, etc. In a move towards understanding catalyst performance, Lercher and co-workers presented the efficacy of $Mo_2S_4$ clusters finding that it differed from that of the traditional $MoS_2$ slabs [1, 2]. These catalysts were compared based on their reactivity and stability during ethylene hydrogenation to ethane. Due to the absence of Brønsted acid sites, the NaY zeolite support for $Mo_xS_y$ clusters was not active for ethylene hydrogenation. The comparison of ethane formation rate showed a stable reactivity for over 150 hours on molecular $Mo_2S_4$ clusters, much longer than on a $MoS_2$ slab. Therefore, there is a need for deep mechanistic understanding of $Mo_2S_4$ cluster stability and reactivity in NaY zeolites using ab initio calculations.

**Methodology.** Two NaY zeolite models are tested with different $Na^+$ ion positions as shown in Figure 1 while maintaining the experimental Si/Al ratio of ~2.5. For stable positions of $Mo_2S_4$ cluster in these zeolites, we compared two pathways for ethene hydrogenation over the cluster to decipher the role $Na^+$ ions on the reactivity using density functional theory. In addition, to obtain further insights into the role of $Na^+$, we carried out Bader charge analysis and analysed the dynamics of $Mo_2S_4$ clusters using ab initio molecular dynamics (AIMD). The ab initio calculations were carried out on Vienna ab intio simulation package (VASP).

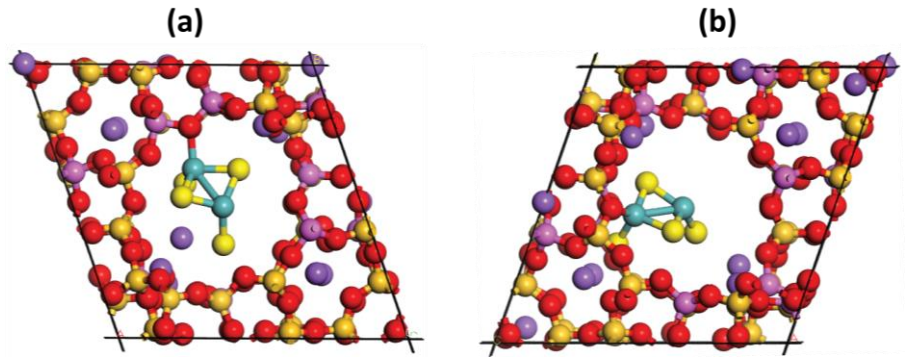

**Figure 1. Anchored $Mo_2S_4$ cluster in NaY zeolite supercage. The two models showcase different $Na^+$ positions– (a) $Na^+$ present, and (b) $Na^+$ absent in the supercage Here, spheres in cyan, yellow, red, orange, pink and majenta represent molybdenum, sulphur, oxygen, sulphur, aluminium, and sodium, respectively.**

**Results and discussion.** On analysing the activation barriers for ethene hydrogenation, we observed that with and without $Na^+$ in close vicinity to the $Mo_2S_4$ cluster, the 1$^{st}$ hydrogenation barrier changed by ~40 kJ/mol without altering the pathway. The Bader charge analysis showed that the charge transfer between $Na^+$ and $Mo_2S_4$ in the zeolite is not influenced by $Na^+$ position, thus suggesting that charge transfer does not affect the reactivity. The charge analysis showed a neutral $Mo_2S_4$ cluster and an average +1 charge on Mo atoms at different binding configurations. Therefore, we explored the dynamics of anchored $Mo_2S_4$ with different $Na^+$ positions. The AIMD simulations helped us to quantify that $Na^+$ plays an important role in cluster stability by providing a steric hinderance to their movement resulting in the change in hydrogenation barrier.

**Introduction.**

Cu/ZnO-based catalysts have been used to synthesize MeOH from syngas ($CO/CO_2/H_2$) for almost 60 years. Methanol production is a major industrial process, reaching 311 million tons per year in 2030 and growing. However, the mechanism of MeOH formation via $CO_2$ hydrogenation remains under discussion. Key areas of debate are the role of O defects/ vacancies on the ZnO surface, Cu-Zn synergism at the interface, the formation of Cu/Zn alloys, the role of ZnO (i.e. SMSI), etc.[1,2,3]

**Experimental/methodology.**

All periodic DFT calculations were performed using the software *VASP*. The electronic structure was calculated using PAW approximation for the core-valence interactions and $PBE_{Sol}$ as exchange-correlation functional. The plane wave cut-off was set at 450 eV and the gamma point was used as k-point. The system consists of 230 atoms in a 3D periodic slab model[4]. Bulk lattice parameters are a = 3.2518 Å, c =5.1969 Å, u = 0.3806. The system consists of 6 ZnO layers plus an 8 Cu atoms cluster. All Cu atoms and the top 3 ZnO layers are allowed to relax during structural optimisation until atomic forces converged to within 0.05 eV $Å^{-1}$. Other layers were fixed. The slabs are interleaved by an 18 Å vacuum.

**Results and discussion.**

Using computational resources, all relevant intermediates to the MeOH synthesis were investigated on a realistic model catalyst surface (a Cu cluster on a reconstructed polar ZnO surface).[4] We provide a detailed analysis of the different surface sites, stabilities, activation of the intermediates on the surface and activation barriers for relevant elementary processes. Our analysis explains that MeOH would be form following the path $CO_2$*→HCOO*→$H_2$COO*→$H_2$COOH*→$H_2$CO*→$H_3$CO*→MeOH on the interfacial Cu/Zn site of a Cu/ZnO catalyst.

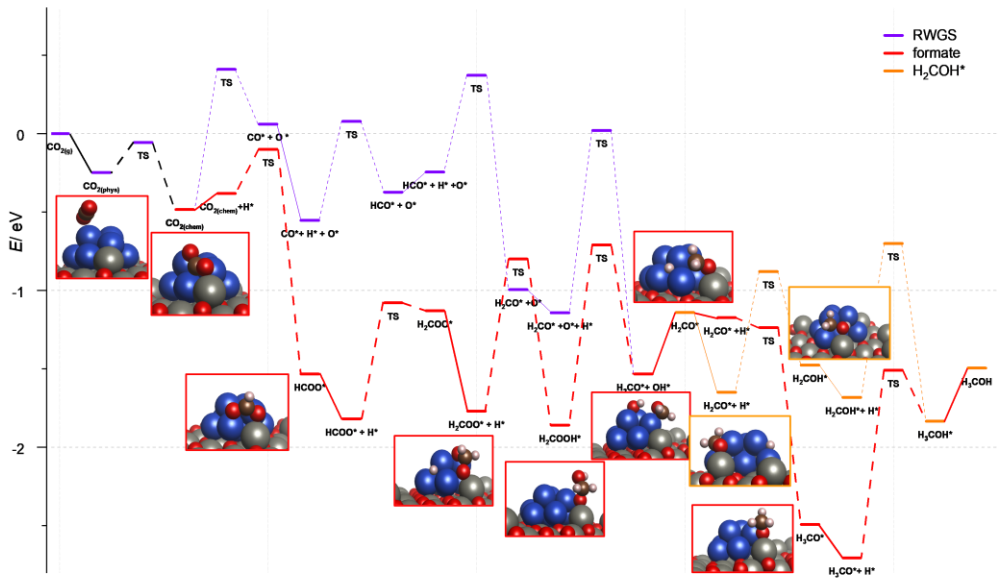

Figure 1: Energetic pathway of intermediates of the $CO_2$ hydrogenation via formate pathway and RWGS to form methanol on a model Cu/ZnO system. For the images red is reserved to O atoms, brown for C, blue for Cu, grey for Zn and white for H. Transition states (TS) are denoted with dashed lines.

**Keywords:** UHMWPE, fiber-reinforced composite, ethylene-vinylacetate, impact strength

**Introduction.**

Ultra-high molecular weight polyethylene(UHMWPE) fibers have excellent chemical resistance and impact resistance, and have low density, so they have excellent specific strength and specific modulus compared to other reinforced fibers. Due to these characteristics, it is widely used as a reinforcement material for high-performance polymer matrix composites, especially in the fields of hiking supplies, aerospace materials, and bulletproof materials.[1]

In order to prepare a fiber-reinforced composite using UHMWPE fiber, polyolefin elastomers(POE) with excellent ductility and low shore hardness were selected among thermoplastics elastomers. By borrowing the hot melt impregnation process, a prepreg was manufactured using a hot press machine, but impregnation was not properly performed at a temperature at which the fibers were not damaged.

In this study, ethylene-vinyl acetate(EVA) used as an adhesive was mixed with POE to increase the adhesion characteristics with fibers at low temperatures. The effect of EVA on the physical properties of UHMWPE fiber-reinforced composite was examined by analyzing the impact strength, peel strength, and morphology of composite materials applied with different composition ratios of POE and EVA.

**Experimental/methodology.**

Compound the content of EVA resin relative to POE at 0, 10, 20, 30, and 40 wt% at 120-180℃. The film according to EVA content is impregnated into the UHMWPE fabric by applying heat and pressure through a hot press machine to obtain prepreg. These prepregs are laminated at [0/90°] and then pressed to produce the final UHMWPE fiber-reinforced composite.

**Results and discussion.**

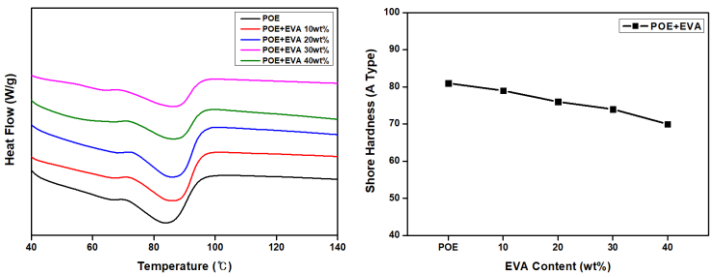

**Figure 1. DSC curves and shore hardness of POE films according to EVA content.**

When EVA is added to the amorphous POE resin, some crystallinity is given, and $T_m$ tends to increase slightly. However, the shore hardness of the film tends to decrease as the EVA content increases.

**Keywords:** Synchrotron-based XPS, Core level shifts, heterogeneous catalysis, density functional theory, oxides, methanol synthesis

**Introduction.** $In_2O_3$-based catalysts have shown to be highly selective, active, and stable methanol synthesis catalysts [1]. However, the nature of the active sites is still not fully understood. To advance understanding of the active sites and the effect of water on $CO_2$ hydrogenation to methanol, fundamental studies of single crystalline $In_2O_3$ surface in a controlled environment are required. We have employed both experiments and theory to investigate well-defined $In_2O_3$ surfaces with different surface treatments in order to elucidate the initial steps of the $CO_2$ hydrogenation reaction.

**Experimental/methodology.** X-ray Photoemission Spectroscopy (XPS) and Density Functional Theory (DFT) calculations were employed to study $CO_2$, $H_2O$, methanol and formic acid adsorption on $In_2O_3$(111) with different surface terminations, namely, pristine, hydroxylated, and reduced indium oxide[2]. Electronic structure and core-level shift calculations were calculated with the Vienna Ab initio Simulation Package using the Perdew-Buke-Ernzerhof (PBE) and the Heyd-Scuseria-Ernzerhof (HSE06) functionals.

**Results and discussion.** We were able to identify indium ad-atoms in the In 3d spectra on the reduced surface both with XPS and DFT calculated core-level shifts. On the hydroxylated surface OH-groups give characteristic peaks in the O 1s core level, and we report excellent agreement between the experimental and computed O 1s shifts. These fingerprints of the different surface terminations could be used in future studies at more realistic reaction conditions. In addition, comparison of the experimental C 1s spectra and the DFT calculated core-level shifts suggest that $CO_2$ adsorbs as a carbonate on all surface terminations. On the hydroxylated surface, we find that $CO_2$ adsorption is hindered by the presence of hydroxyl groups, which adsorb preferentially at the same site. This in turn could lead to a decrease in methanol synthesis activity, which is in agreement with a previously reported hindering effect of water on the reaction[1].

Stoichiometric $In_2O_3$(111)

# Molecular Model Catalysts of Atomically Dispersed Platinum on Silica

L. Kopietz[1*], K. Köhler[1]

[1]*Technical University of Munich, Munich, Germany*
[*]*lea.kopietz@tum.de*

**Keywords:** platinum, model catalyst, surface organometallic chemistry

**Introduction.** For a heterogeneous catalyst, it is still challenging to unravel the active site structure or to gain a deep understanding of the ongoing processes on a molecular level. [1] In academic research, different approaches focus on modeling the (proposed) active site. By that, one expects to get a deeper insight into the relation between structures and their reactivity (or a mechanism), which forms the basis for a more rational catalyst development. [2] Surface Organometallic Chemistry (SOMC) is one approach, which has been particularly successful in unraveling mechanisms due to defined, molecular sites on oxide materials (see Scheme 1). A key aspect thereof is a thorough investigation of the structure and the transfer of established elementary steps from homogeneous catalysis to a yet heterogeneous catalyst. [1]
This work focuses on the structure and reactivity of organometallic platinum complexes, which are immobilized on a pretreated silicon dioxide surface. In particular, changes in the molecular structure, which may be caused by temperature or atmosphere (e. g. CO), allow a deeper insight into the nature of such (potential) single-site catalysts, but also into their limitations (see Scheme 1).
**Experimental.** Dimethylbis(trimethylphosphine)platinum(II) is obtained in a two-stepped procedure, adapted from literature. [3] It is used afterwards for grafting on silicon dioxide, which has been partially dehydroxylated at 700 °C under high vacuum conditions. This procedure generates isolated, molecular platinum complexes on the silica surface.
**Results and discussion.** The platinum model catalyst was characterized by means of IR and solid-state NMR spectroscopy ($^{1}$H, $^{31}$P), as well as by elemental analysis. The methods support the successful synthesis and structure of the compound. Structural changes were evaluated as a function of the temperature in different gas atmospheres (helium, hydrogen, carbon monoxide).

**Scheme 1: Supported, molecular platinum(II) complex on silicon dioxide, which inserts CO into the Pt-C bond.**
For that purpose, CO chemisorption was performed as an *in-situ* IR experiment (1% CO in He, 20 mL min$^{-1}$, r. t.). Bands of linearly bound carbon monoxide on platinum (2094 cm$^{-1}$, 2071 cm$^{-1}$) are observed, as well as the band of an acyl species (1612 cm$^{-1}$). The latter one suggests the insertion of CO into the platinum-carbon bond and is illustrated in Scheme 1. [4] This reactivity is similar to molecular platinum complexes in solution and supports the molecular character of the platinum surface sites. [4] Ongoing investigations focus on structural changes under reducing conditions.

# Computational investigations into the direct synthesis of higher alcohols from syngas on copper–iron catalysts

Ville Korpelin[1*], Bhumi A. Baraiya[1], Hanan H. Ibrahim[1] ,Toni Kiljunen[1], Karoliina Honkala[1]

[1]*Department of Chemistry, Nanoscience Center, University of Jyväskylä, P.O. Box 35, 40014, Jyväskylä, Finland*

[*]*ville.p.korpelin@jyu.fi*

**Keywords:** alcohols, alloys, DFT, heterogeneous catalysis, syngas

**Introduction.** Higher alcohols (HA) are used as fuel additives, solvents and feedstocks in the production of pharmaceuticals, plasticizers and surfactants.[1] Currently, HA are mostly produced via fermentation (light alcohols) or from petroleum-derived hydrocarbons (heavy alcohols). The direct conversion of syngas to HA is a promising alternative for both environmental and economic reasons, enabling the application of bio-based feedstock in a one-step process. As the pathway involves CO activation, C–C coupling and hydrogenation, an optimal catalyst has to provide multiple functionalities. For this reason, mixtures such as Cu–Fe are among the most promising materials for the process.

**Experimental/methodology.** The Cu–Fe mixture is modeled as a well-mixed 1:1 alloy, representing the limit of maximum contact between the components. In order to describe typical active sites on a nanoparticle edge, the catalyst was modeled as a stepped CuFe(211) surface (see Figure 1). The DFT calculations were spin-polarized and vdW-corrected, and the transition states were located using the climbing image NEB method.

**Results and discussion.** The reaction network from CO and $H_2$ to the typical C1 and C2 hydrocarbons and alcohols ($CH_4$, $CH_3OH$, $C_2H_6$, $C_2H_5OH$) was simulated, along with selected chain-growth steps toward C3 intermediates. The activation of CO is most favorable at the step edge, as the 4-fold step site can strongly adsorb C and CH. For the C1 intermediates, the $CH_n$–$CH_n$ coupling, CO insertion and hydrogenation steps are competitive, with hydrogenation being the most favorable both kinetically and thermodynamically. This indicates that methanation is a major process on the alloy, though chain growth and alcohol formation can also occur. The results support the traditional HA synthesis concept of $C_nH_m$ chain growth followed by CO insertion and hydrogenation to primary alcohol; CO insertion is unlikely to be the main chain growth mechanism due to the high C–O cleavage barriers of the intermediates.

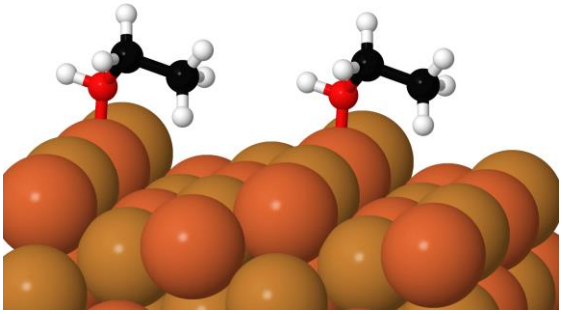

**Figure 1: Side view of well-mixed CuFe(211) with adsorbed ethanol.**

To clarify the roles of the metal components and the surface geometry, comparisons to alternative surface models are underway. According to the literature and our preliminary machine learning simulations, the surface layer of the binary CuFe mixture is preferably enriched in Cu, although adsorbates such as CO can induce the segregation of Fe to the surface.[2,3] These studies will complement the understanding gained on the perfectly mixed alloy and help identify the key properties of an effective HA synthesis catalyst.

# Electric Double Layer effect on outer-sphere benzyl halides electro-reduction mechanism

Aleksandr Kramarenko[1], Dmitry Sharapa[1], Evgeny Pidko[2], Felix Studt[1]

[1]*Karlsruhe Institute of Technology,Karlsruhe, Germany*

[2]*TU Delft, Delft, The Netherlands*

[*]*aleksandr.kramarenko@partner.kit.edu*

**Keywords:** Electrocatalysis, benzyl halides, DFT, Molecular dynamics

**Introduction.** Electrochemical $CO_2$ fixation is a perspective method of carbon dioxide conversion, which does not demand high temperatures and pressure[1]. Moreover, the fixation of $CO_2$ by electrochemicaly activated benzyl halides is and environmentally friendly and promising way for the synthesis of the important for pharmaceutical and fuel production carboxylic acids derivatives. Therefore, to improve the performance of electrode material and increase product yields, it is important to gain insight into the electrode-electrolyte interplay and the rate-determining reaction steps. The combination of first principles and molecular dynamics simulations gives us a good understanding at the molecular level of charged interface phenomena and allows us to study elementary chemical processes in detail, which sheds light on how to improve electrocatalytic reactivity.

**Computational methods.** In this study, we used complex approach for benzyl halide electroreduction process simulation. Therefore, we performed non-periodic density functional theory (DFT) calculations[2], in order to assess the standard reduction potentials of benzyl halides, and estimate the mechanism of electrochemical carboxylation reaction, together with the classical molecular dynamics[3] (CMD) to reveal the concentration distribution of the solution components in the EDL region.

**Results and discussion.** In this study, we have explored the electrochemical activation, and reduction mechanism of benzyl halides and their subsequent electrocarboxylation. Following our multi scale approach we first performed bulk electrolysis simulation in order to investigate the thermodynamic parameters of carboxylation steps in aprotic media. The standard reduction potentials (SRP) calculated for the three benzyl halides in MeCN are reported in Figure 1, and show a repeated shift to the less negative values in the following sequence BnCl < BnBr < BnI.

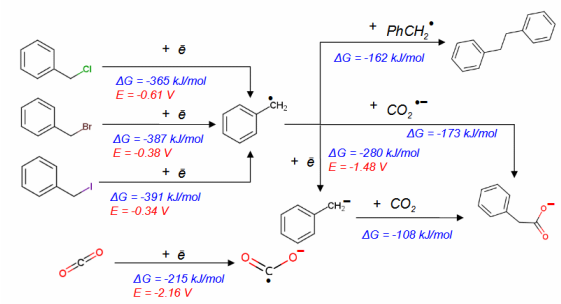

**Figure 1. Thermodynamic parameters for the proposed mechanism of electrochemical carboxylation of benzyl halides in acetonitrile solution. (Calculated using CPCM solvation model, the standard reduction potentials are shown with respect to the saturated calomel electrode).**

Moreover, experimental results of the electro-reduction process for the studied benzyl halides reveal the same qualitative tendency to our computational results[4]. Subsequent, electron transfer to the produced benzyl radicals has a higher energy barrier, therefore, it has more negative reduction potential. Hence, a simple thermochemical coupling of the benzyl radicals becomes more favorable.

**Keywords:** Plasma catalysis, methane conversion, density functional theory

**Introduction.** The selective activation and targeted conversion of methane into value-added chemicals is considered a holy grail in catalysis. Plasma technology is a promising approach to activate gas molecules by energetic electrons instead of heat, it can be operated at mild conditions and allows easy upscaling.[1] Our previous study revealed that plasma-catalytic direct oxidation of methane to methanol (DOMTM) could realize 81 % liquid oxygenates selectivity and 50 % $CH_3OH$ selectivity promoted by Ni-based catalysts, at low temperature and atmospheric pressure.[2] Recently, we found that one-step steam reforming of methane to methanol (OSRMTM) via a combination of $CH_4/H_2O/Ar$ plasma with copper-containing zeolite can further increase the $CH_3OH$ selectivity to 82 %, with 4.7 % $CH_4$ conversion.

**Experimental/methodology.** The plasma-catalytic OSRMTM setup was the same as in our previous study.[2] All the DFT calculations were carried out in CP2K 7.1 package with Quickstep module and PBE functional. [3]

**Results and discussion.** Catalyst characterization and plasma diagnostics reveal that the excellent reaction performance is attributed to Cu-O active sites confined by the pore of Cu-MOR zeolite. Furthermore, by dedicated experiments and DFT calculations, we demonstrate the existence of a redox process from $Cu^{2+}$ to $Cu^{+}$ on Cu-MOR, which plays an important role in plasma-catalytic OSRMTM in a continuous flow reactor (Scheme 1). This study provides a fundamental understanding of radical-involved processes taking place and the mutual interactions between plasma and zeolite-confined copper catalyst.

**Scheme 1.** Schematic of plasma-catalytic OSRMTM via $CH_4/H_2O/Ar$ plasma and Cu-MOR zeolites

# Carbonyl surface modification of $Al_2O_3$ to synthesize tailored noble metal catalytic sites: from single atoms to sub-nano clusters

Yu-Cheng Lin[1] and Jeremy S. Luterbacher[1*]

[1]*Laboratory of Sustainable and Catalytic Processing, Institute of Chemical Sciences and Engineering, École Polytechnique Fédérale de Lausanne (EPFL), CH-1015 Lausanne, Switzerland*

**Keywords:** Carbonyl group surface modification, single atom catalysis, size-controllable noble metal sites and CO oxidaiton

**Introduction.** Supported noble metals play an important role in heterogeneous catalysis due to their superior catalytic performance. Because of their scarcity, increasing the dispersion and maximizing the use of precious metals species on the catalyst surface have been extensively studied.[1] Recently, single-atom catalysts (SACs), with 100% atom efficiency and higher reactivity compared to their nanoparticle counterpart, have attracted much attention.[2] The conventional way to prepare supported metal catalysts is via the impregnation method. This tends to result in an uneven distribution of particle size with both metal nanoparticles and small clusters on catalyst surface, hindering the formation of single-atom sites.[2] To solve this issue, several methods have been proposed to increase the amount of isolated or highly dispersed metal atoms on the support.[3-4] For example, Christopher et al. synthesized stable Pt single atom sites on $TiO_2$ by strong electrostatic adsorption of a very low amount of Pt on $TiO_2$.[5] Lee et al. deposited single noble metal atoms on ceria nanoparticles which were anchored on $Al_2O_3$.[3] In another study, the doping of La into $Al_2O_3$ was found to stabilize isolated Pd atoms on the surface.[6] Pd SAC could also be achieved by a photochemical route.[7] However, a more general method to prepare different noble metal SACs as well as small clusters (<2nm) has not yet been proposed.

**Experimental/methodology.** Here we report a carbonyl surface modification method which helps to increase the dispersion of noble metal species on the $Al_2O_3$ surface. The surface OH groups of $Al_2O_3$ support were first changed to carbonyl groups with better ligand strength and affinity toward metal ions, confirmed by Fourier-transform infrared spectroscopy (FT-IR). The surface-modified $Al_2O_3$ was then used for preparing noble metal SACs (Pd and Pt) and characterized by aberration-corrected scanning transmission electron microscopy (AC-TEM), carbon monoxide diffuse reflectance infrared Fourier transform spectroscopy (CO-DRIFTS) and extended X-ray absorption fine structure (EXAFS). The CO oxidation reaction was used to test catalytic activity and the results were monitered by gas chromatography (GC).

**Results and discussion.** By AC-TEM, CO-DRIFTS and EXAFS, we confirmed that both Pd and Pt SACs can be achieved by this method. Moreover, Pd and Pt clusters with a diameter smaller than 1 nm can also be obtained by adjusting the experimental conditions. In a following CO oxidation test, Pd catalysts also showed the catalytic activity at 40°C, resulting from single Pd atoms as suggested by previous literature.[6] These results demonstrated that our carbonyl surface modification method can serve as a general tool to synthesize noble metal catalysts from single atom sites to sub-nano clusters.

# Metal Oxide-based Electrocatalyst for $CO_2$ Electroreduction – Investigating the Catalytic Surface via Pourbaix diagrams

Raju Lipin[1] , Matthias Vandichel[1*]
[1]*Department of Chemical Sciences and Bernal Institute, University of Limerick, Limerick V94 T9PX, Republic of Ireland*
[*]*Matthias.Vandichel@ul.ie*

**Keywords:** $CO_2$ Reduction, DFT, Pourbaix Diagram, $NiO_x$, $SnO_2$

**Introduction.** Electrocatalytic carbon dioxide reduction reactions ($CO_2$RR) have gained much attention in the recent years due to the significant role they play in creating clean energy.[1,2] The search for finding alternatives for the use of toxic and expensive transition metal based electrocatalysts is still an active focus in research. Recently, several studies have reported that metal oxide electrocatalysts show high $CO_2$RR performance.[2] In particular, $SnO_2$ is one of the most promising electrocatalysts for the generation of formate, however, due to the relative low intrinsic electrical conductivity its performance towards $CO_2$RR is far from satisfactory.[3] In this work, inspired by the experimental studies on a $NiO_x$:$SnO_2$ based electrocatalyst for $CO_2$ reduction to formate, a detailed molecular level understanding of the active surface of the earth abundant metal (eg. Ni) doped $SnO_2$ systems during the electrochemical conditions is investigated by ab initio thermodynamics employing DFT.

**Experimental/methodology.** Spin polarized Density functional Theory (DFT) calculations were performed with the plane wave package Vienna Ab initio Simulation Package (VASP).

**Results and discussion.** At electrochemical conditions, the catalytic surfaces on $SnO_2$ tends to get hydroxylated, and thereby altering the active terminations. Constructing surface Pourbaix diagram (SPD) based on molecular systems with various degrees of hydrogenation have aided in revealing the thermodynamically favourable terminations as a function of pH and potential.[4,5] (**Figure 1**)

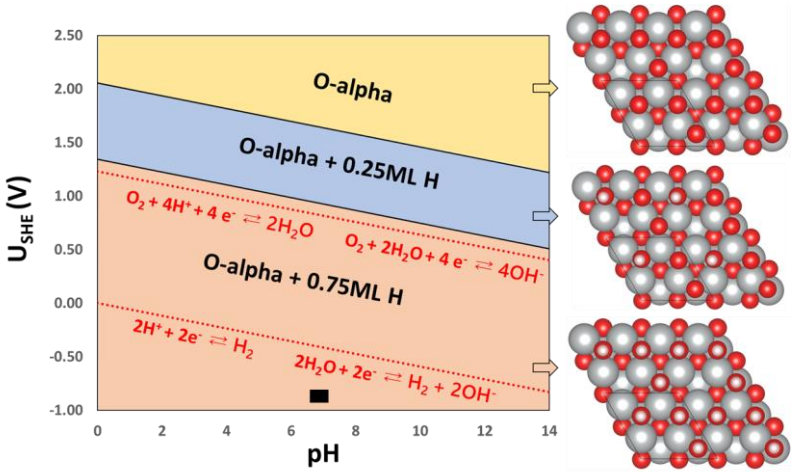

**Figure 1.** A representative Pourbaix diagram for a defective NiO(111) surface showing the stable terminations for a metal oxide-based electrocatalyst.[5]

# Water dynamics and p-cresol co-adsorption in (alumino)silicate CAN zeolite from machine learning potentials and DFT

D. Nováková [1*], A. Erlebach[1], L. Grajciar[1]

[1]*Charles University, Prague, Czech Republic*
[*]*denisa.novakova@natur.cuni.cz*

**Keywords:** Molecular dynamics, Machine learning, CAN, p-cresol

**Introduction:** Zeolites are traditionally used materials in the petrochemical and chemical industry that have recently drawn attention for their possible utilization in biomedicine as drug and gene carriers, materials in bone tissue engineering, or adsorbents for detoxifying human organisms.[1] Zeolites offer a possible solution for removing protein-binding uremic toxins, such as p-cresol, that are unremovable during classical hemodialysis.[2,3] This study focuses on analyzing the motion of water within zeolite with CAN framework topology using molecular dynamics (MD) simulations with neural network potentials (NNPs).[4] The obtained data is used to calculate the self-diffusion coefficients and analyze the effect of water loading, aluminum content, and the distribution of aluminum atoms on water diffusion and degree of deprotonation of Brønsted acid sites (BASs). In addition, the thoroughly tested water-loaded CAN models are used for evaluation of the interaction between the zeolite framework, water molecules and p-cresol.

**Experimental/methodology:** Models with CAN framework topology, various water content, Si/Al ratio and distribution of aluminium atoms were used in MD simulations performed for a time interval of 1 ns using the canonical NVT ensemble with the time step of 0.5 fs and constant temperature of 350 K. The NNPs utilized in MD simulations were constructed using the SchNetPack library. The training and testing of NNPs was accomplished by using the reference DFT data at the meta-GGA exchange-correlation functional level (SCAN+D3(BJ)). In addition, using DFT-only we studied the interaction of p-cresol and water with CAN models with different aluminum and water content.

**Results and discussion:** By calculating the water self-diffusion coefficients, it was ascertained that at low water loadings and low aluminum content, no diffusion is observed. At higher water loading, the molecules form clusters of two to three molecules capable of jumping a longer distance, e.g., to the neighboring BASs. At low Si/Al ratios, the water mobility is obstructed by BAS protons resulting in decreasing diffusion coefficients with higher aluminum content. Regarding BAS solvation dynamics, it was demonstrated that to completely deprotonate BAS, at least two to three protons are necessary. Also, we observed that proton solvation decreases with aluminum content and low water loading. During the simulations, almost in all systems we observed unusual *pinned* hydroxonium species[5] being formed over a 6-ring of ***can*** cage and connected to the framework oxygens by short hydrogen bonds. Lastly, the interaction between BAS and water was found to be clearly preferable over the one with p-cresol, although with higher water content, the difference between these interaction energies decreased regardless of the aluminum content. Importantly, all aluminosilicates appear to be better adsorbents of p-cresol than purely siliceous zeolite, even if p-cresol does not adsorb directly on BAS.

# A systematic computational exploration of bimetallicity and mechanical strain concepts for $N_2$ activation

Omer Elmutasim, and Kyriaki Polychronopoulou*

*Khalifa University of Science and Technology & Center for Catalysis and Separations, Abu Dhabi, United Arab Emirates;*

**Corresponding Author's E-mail address: kyriaki.polychrono@ku.ac.ae*

**Keywords:** nitrogen activation, ammonia production, mechanical strain, bimetallic alloys.

**Introduction.** The Haber-Bosch (HB) reaction is definitely one of the most important reaction of the 20th century with tremendous impact on significant, for mankind, sectors, such as fertilizers, chemical industry, medicine, bio-fuels and ammonia production [1]. It is now well accepted that the relative activity of metallic HB catalysts can be correlated to their binding energies with N-containing species in terms of a volcano-shaped relationship. Metals that bind nitrogen too strongly or too weakly are on either side of the volcano [2]. Thus, it is important to devise a *knowledge-based catalyst design* that could potentially replace the Haber-Bosch method, while achieving high efficiency and energy saving towards sustainable $NH_3$ production under ambient conditions. In this regard, herein density functional theory (DFT) calculations are used in order to screen the $N_2$ activation capacity and the accompanied electronic interactions for a portfolio of bimetallic alloys based on Mo, Ru and Fe metals, while using those metals *as reference ones*.

**Experimental/methodology.** Density functional theory (DFT) computations were carried out utilizing Quantum ESPRESSO package and projected augmented wave (PAW) method, using the Perdew–Burke–Ernzerhof (PBE) exchange–correlation functional based on the generalized gradient approximation (GGA). The DFT-D3 method was employed for Van der Waals dispersion corrections.

**Results and discussion.** In this work, DFT computations are performed for Mo(110), Fe(110) and stepped Ru(0001) surfaces alloyed with wide range of TM hetero-atoms (Ni, Co, Ru, Fe, Mo, Rh, Au, Ag, Pd, Pt, and Cu) to understand the $N_2$ activation and dissociation steps; the monometallic surfaces are also considered as references. To begin with, the energetic stability of binary metal alloy surfaces was investigated using the formation energy as major descriptor. Overall, TM-decorated Fe alloys exhibited relatively higher stability as compared to TM/Mo(110) and TM/st.Ru(0001) surfaces. Then, the adsorption of $N_2$ molecule on bare metal and bimetallic (alloy) surfaces was carefully investigated with the analysis of adsorption energetics. The results revealed that the most favorable N2 adsorption conformations on the three types of alloy systems are Ru/Mo(110), Mo/Fe(110) and Mo/st.Ru(0001). The analyses of electronic characteristics (PDOS and charge transfer) revealed that high $N_2$ activation on these bimetallic surfaces was mainly due to the hybridization between the host and TM solute orbitals. This hybridization gave rise to considerable charge transfer from the surface to the anti-bonding orbital of nitrogen, which further weakened the triple bond and thereby promoted $N_2$ decoupling. The dissociation barrier for $N_2$ on monometallic and bimetallic substrates was also computed. It was found that all Mo-alloys, except for TM/Mo(110) (TM=Ru and Fe) surfaces, presented energy barriers lower than that of the bare Mo(110) surface. Interestingly, apart from Mo, the favorability of N2 dissociation increased while moving from the Fe(110) substrate alloying with early to late transition metal series. The origin of difference in activity of the considered Fe-based alloys can be attributed to the electronegativity difference between Fe and TM, which in turn play a pivotal role in fluctuating d-band center belong to the surface atoms. Notably, the promotion of st.Ru(0001) with TM atoms has appreciably affected the thermodynamics of dissociation process rather than the reaction kinetics. For most of the alloy surfaces studied, apart from Mo/Fe(110) one, the N2 binding energy on the previously mentioned surfaces vary as a linear function of the applied strain. This work not only introduces efficient catalysts for nitrogen activation but also provides valuable insights on the rational design of bimetallic catalysts to enhance the performance of Haber-Bosch process for $NH_3$ production.

**Keywords:** Density Functional Theory, Artificial Neural Network, Dry Reforming Reaction of Methane

**Introduction.** This work demonstrated the improved algorithm based on first-principles and machine learning techniques: density functional theory (DFT) and artificial neural network (ANN). This algorithm is a two-step procedure that comprises catalyst identification and optimization. The Ratings concept was employed to identify the catalyst's reactivity and stability. Each catalyst is given a unique index based on its activation energy obtained from DFT on (1) reactants activation ($CH_4$ and $CO_2$) and (2) coke formation and removal benchmarking to the reference catalyst: Ni(111). These indexes on the reactivity and stability surface are used to predict DRM and coking rates at specified operating conditions. Also, the coking boundary proposed in the concept is used to determine the coke-resistant region during DRM. The next step is to generate the database for DRM and coke formation/removal rates of a chosen catalyst at different operating temperatures and $CO_2/CH_4$ feed ratios. This information is incorporated into the on-line optimization. Ultimately, the goal is to sustain the reaction rate of a given catalyst in the reactor and its coke-resistant property when changes in the condition of the reformer feed composition due to variations of fuel sources are present.

**Experimental/methodology.** Spin-polarized periodic density functional theory (DFT) calculations were employed via the Vienna ab initio simulation package (VASP). The Projector Augmented Wave pseudopotentials (PAW), plane-wave basis sets, and exchange-correlation functional described within the generalized gradient approximation (GGA) with the functional by Perdew, Burke, and Ernzerhof (PBE) were used for all systems. The Monkhorst-Pack Brillouin zone integration grid of $4\times4\times1$ with the first order Methfessel-Paxton smearing method of 0.2 eV smearing width was used. The convergence criteria are $10^{-4}$ and $10^{-3}$ eV for successive electronic and ionic steps. The climbing method nudged elastic band (CI-NEB) was employed to obtain each elementary step's activation energy (Ea). For the Ni oxide, the Hubbard-U correction was used with the GGA-PBE functional with $U_{eff}$ used at 5.4 eV. The assumptions and simplifications of the DRM mechanism were reported in our previous works[4], where the surface reaction is the rate-limiting step. The zero-point energy (ZPE), entropy (S), and internal energy (U) contributions were considered. The pseudo-steady-state hypothesis (PSSH) was applied to determine surface coverages, with no "most abundant reactive surface species" (mari). The $CO_{(g)}$ and $H_{2(g)}$ are assumed to be in the adsorption-desorption equilibrium. Reactivity and stability were illustrated via DRM rate and coke formation from CH and CO and coke removal via H and O, respectively, at a reaction condition of 1000 K with a unity $CO_2/CH_4$ feed ratio.

**Results and discussion.** It was demonstrated that the reaction would rapidly proceed on the carbide $Ni_3C(001)$ and the metallic Ni(111) surfaces but would be suppressed on the oxide surface of NiO(100) and the metallic Ni(100) due to the presence of high $E_a$. Hence, a reactive and stable DRM catalyst would need to be oxide-dominated on the (100) while being metallic-dominated on the (111) facet. On the DRM reactivity, all of the metallic, oxide, and carbide surfaces are active, except NiO(100). Hence, the surface composition that yields reactive and stable Ni-based DRM catalysts is proposed to have less than 10 % of carbide, and up to 75 % metallic is needed.

# Mechanistic insights on the catalytic hydrogenation of furfural derivatives on Pd and Ru surfaces

M. Quayle,[1] M. Pera-Titus,[1] A. Roldan[1,*]

[1]*Cardiff Catalysis Institute, School of Chemistry, Cardiff University, Main Building, Park Place, Cardiff, CF10 3AT*
[*] *roldanmartineza@cardiff.ac.uk*

**Keywords:** Hydrogenation, furfural derivates, heterogeneous catalysis, biomass, DFT.

**Introduction.** As industry moves towards a circular economy of chemicals, it is imperative that green catalytic processes are developed to reduce humanity's reliance on unrenewable feedstocks. Furfural and its derivates are furanic aldehydes that can be cheaply extracted from food waste,[1,2] and have shown promise as renewable reagents in organic synthesis.[3,4] With the proper use of heterogeneous catalysts, furfural derivatives can undergo hydrogenation to provide synthetic chemists with a wide variety of useful precursors.[5,6]

**Methodology.** The mechanism behind the catalytic hydrogenation of furfural derivatives on Pd(111) and Ru(0001) was investigated by constructing spin-polarized density functional theory (DFT) periodic models for each of the possible hydrogenation sites. The exchange-correlation contributions were calculated within the constraints of the generalized gradient approximation (GGA) using the revised Perdew-Burke-Ernzerhof (RPBE) functional.[7] Transition states were modelled using improved dimer methods and confirmed by a single imaginary vibrational mode along the reaction coordinate.[8–10]

**Results and discussion.** Herein, we report novel insights into how furfural-based unsaturated ketones bind to these metal catalysts through their ring systems and carbonyl groups. In agreement with experiment,[4] hydrogenation of α,β-double bonds on the carbon chain (Figure 1) is energetically preferred over hydrogenating the ring system on both Pd and Ru, but Pd hydrogenation proved to be more selective. On Pd, the substrate favored strong interactions with the furan ring, whereas Ru catalysis was dominated by the oxophilicity of the surface, prioritizing interactions with the carbonyl and ring oxygens. We also highlight the role that C=C conjugation plays in stabilizing ring hydrogenation intermediates.

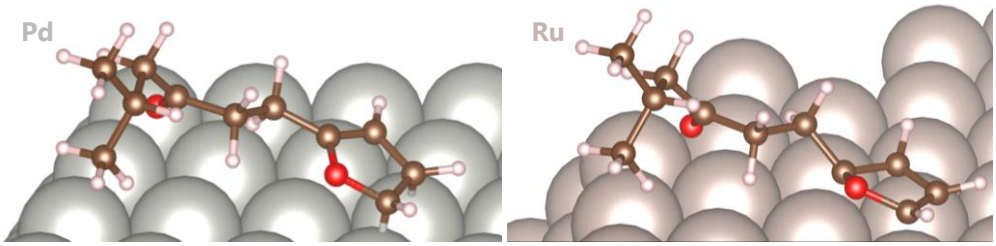

**Figure 1.** Furfural derivatives on Pd(111) (left) and Ru(0001) (right) after the hydrogenation of the α,β-double bond.

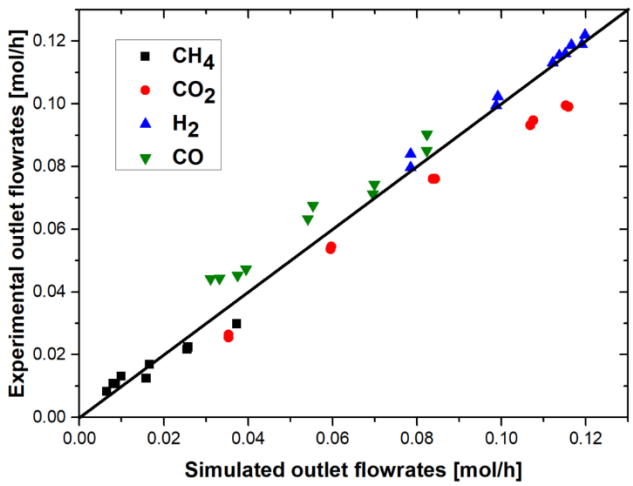
# Rate Determining Steps and Development of Rate Equation for Oxidative Dry Reforming of Methane over Supported Ni Catalyst

A. S. Russel[1], Satyam Gupta[1], Goutam Deo[1,2*]
[1]*Department of Chemical Engineering, Indian Institute of Technology, Kanpur, India*
[2]*Department of Sustainable Energy Engineering, Indian Institute of Technology, Kanpur, India*
[*]*goutam@iitk.ac.in*



**Keywords:** Microkinetic modelling, oxidative dry reforming, rate-determining step

**Introduction:**
Dry reforming of methane (DRM), utilising $CO_2$ and $CH_4$, is increasingly being considered as an alternative to produce $H_2$ and syngas (a mixture of $H_2$ and CO). The DRM with $O_2$ co-feed reaction, also called oxidative dry reforming of methane (ODRM), produces more $H_2$ at milder than the DRM reaction conditions. One way to represent ODRM is given in reaction 1. In analysing reaction kinetics involving complex reaction mechanisms, the evaluation of the rate-determining step (RDS) has proven to be very useful. However, there is a lack of agreement regarding the RDS of DRM, which is necessary for the understanding of the ODRM reaction. Furthermore, the RDS can assist in developing an appropriate rate equation. Microkinetic models (mkm) play a crucial role in addressing these knowledge gaps.[1]

$$CH_4 + CO_2 + 0.5O_2 \rightarrow 3CO + 4H_2 \quad (1)$$

**Experimental/methodology:**
In this study we use various $O_2$ feed rates to conduct the ODRM reaction over a freshly prepared alumina-supported Ni catalyst. The incipient wet impregnation approach was used to synthesised the 15% w/w Ni supported on $Al_2O_3$ catalyst. The steady state concentration of all the surface species is calculated by mkm, where a set of differential equations and site balance are solved. The rates are incorporated into the continuity and species balance equations and solved to determine the molar flow rates of the gaseous species along the axial distance of the reactor. An existing general reforming reaction mechanism for ODRM over an alumina-supported Ni catalyst is used for developing the mkm.[2] Validation is achieved by comparing experimental and mkm-calculated outlet flow rates at different feed rates of $O_2$ and two contact times.

**Results and discussion:**

The mkm using the existing 52 steps reaction mechanism is successfully validated as shown in Figure 1. We then proceed to identify the RDS(s) through a hierarchical strategy using sensitivity analysis for the varying amounts of $O_2$ co-feed.[3] After identifying the RDS(s), we derive an overall rate equation that effectively simulates the DRM reaction with different $O_2$ co-feed amounts. We then examine the effect of $O_2$ co-feed amounts on the hydrogen yield and ascertained the presence of a maximum in hydrogen yield. Thus, mkm proves very helpful in developing suitable rate equations and analysing the ODRM reaction.

**Keywords:** H-ZSM-5, zeolite, Brønsted acid sites, DFT

**Introduction.** H-ZSM-5 is a widely studied zeolite catalyst used commonly in the metanol-to-hydrocarbons (MTH) reaction. Its topology is characterized by a 3D cross-linked pore system, formed by sinusoidal (along the *a* direction) and straight (along the *b* direction) channels. One of the main limitations of this zeolite is the loss of catalytic performance when nonreactive species *i.e.*, coke, accumulates.[1] In a recent study, the structural distortions of H-ZSM-5 zeolite have been monitored by *operando* time-resolved synchrotron X-ray diffraction.[2] It was observed that the presence of coke species affects the architecture of the straight channel, distorting it to an elliptical-like shape. Xiong *et al.* also reported the same behavior in a study of ZSM-5 with benzene as probe molecule using in situ STEM.[3]

In the present work we explore the sensitivity of the zeolite to adsorbed species at a detailed atomistic level. Particular attention is given to the effect of Brønsted acid (BA) site position and the type of coke molecules on the local (represented by the deformation of pore shape) and global (described with previously introduced "a-b" parameter) structural changes. This work will shed light on the fundamental properties of zeolites and their deactivation behavior, while aiding in the interpretation of experimental results.

**Experimental/methodology.** Periodic density functional theory using the plane wave basis set and Gaussian ortbital scheme method is applied to model the influence of different hydrocarbon guest species and the effect of Al position on global and local structural distortion in H-ZSM-5. The calculations are executed with PBE exchange correlation functional and a plane-wave auxilary basis set cutoff at 660 Ry.

The investigated MFI zeolite structure model has Si/Al ratio of 31. Three different active sites are investigated and hydrocarbons are placed in either the intersection, straight or sinusoidal channel. The guest species are placed in the zeolite pores in a stepwise manner – up to 4 molecules per cell, and the system relaxation is performed.

**Results and discussion.** Our calculations revealed that all examined hydrocarbons prefered the easily available channel intersection. This is in agreement with the previously reported work.[4] To quantify the pore distortion, we measured the distance between two opposite T-atoms of the straight channel and calculated the aspect ratio using the longest and shortest distances.

We observe that independent of the type of coke species, there exists a relationship between the BA site position and the local structural distortion, i.e. when guest species has low accessibility to the proton, the pore shape changes are the most noticeable. Furthermore, depending on the type of adsorbed molecule we can recognize two types of behavior. Upon one-by-one aromatic hydrocarbon insertion, the unit cell shrinks in the *a* direction, resulting in the decrease of the "a-b" parameter. The size of the cell along *b* and *c* directions are not affected by these compounds. The second type of behavior can be linked to methylated benzenes. Regardless of proton siting, coke occupation of the pores leads to cell expansion in the *b* direction and moderate contraction in the *a* direction, resulting in "a-b" parameter reaching values close to zero. This study presents a non-indentical structural behavior of H-ZSM-5 depending on the active site location and type of coke compound.

**Keywords:** MOF, HKUST-1, computational catalysis, multireference, adsorption, CO-oxidation

**Introduction.** HKUST-1 is one of the first synthsised MOFs, as well as one of rare MOFs with coordinatively unsaturated metal centers, it is also relatively robust, has high porosity and crystalinity. This braught a lot of attention to this material over years, yet, there is many puzzles to be solved. Here we would like to focus on three different aspects of paddle-wheel (PW) copper center: adsorption on the ideal PW, catalytic oxidation on defective PW and water-induced colour change of HKUST-1. All three studies are complicated by multireference nature of studied objects.

**Methodology.**
**"Adsorption" project:**
PBE, B3LYP, M06–L, BEEF–vdW, as well as CASSCF, NEVPT2, DLPNO-MR-CCSD with 2x2 active space.
**"Catalysis" project:**
M06 + CASSCF/NEVPT2 with 5x4 active space
**"Spectroscopic" project:**
CIS, TDA and TD-DFT with different functionals, CASSCF, NEVPT2, SORCI and MRDDCI3

**Results and discussion.**

"Adsorption". Although DFT approaches are not properly accounting multiconfigurational nature of ground state of PW, they appears to be able to describe adsorption relatively good. We showed out that CASSCF strongly underestimate and NEVPT2 overestimate binding energies. These drawbacks are properly accounted in DLPNO-MR-CCSD that is extremely accurate, but its ultimative cost strongly hinder its application.[1]

"Catalysis". We showed out that pristine PW cannot catalyse CO-oxidation, and the process take place on "linker-missing" defects, where Langmuir-Hinshelwood reaction between CO and $O_2$ results in formation of an intermediate that is then broken by second CO molecule. While mechanism can be built with DFT-approaches, found barrier would not allow process to take place under low-temperature conditions. Reason of it lies in multireference nature of Transition State (TS) that unify two single-referent intermediates. Proper treatment of this TS results in a barriers that are in excellent agreament with experimental conditions. Defect-driven mechanism suggested by computations was confirmed experimentally.[2]

"Spectroscopy". Hunt on mysterious colour change of HKUST-1 drove us to the system, excitations of which (despite looking very simple) can't be reliably described by typical approaches. Approaches of outstanding cost and complexity were used for nailing down the peaks.

**Keywords:** Ammonia synthesis, DFT calculations, Ru nanoparticles

**Introduction.** Ammonia has a big impact on our lives since it is mostly used for the production of fertilizers, which are necessary to grow crops. Ammonia is produced via the Haber–Bosch (HB) process, which is more than 100 year old but still most commonly used for ammonia production.[1] Due to major drawbacks of the HB process, such as a high energy consumption (more than 2 % of global energy is used only for ammonia production) and $CO_2$ emissions, new ways of ammonia synthesis are investigated, where different types of catalysis would be used. [1,2] A lot of effort is being put into the catalyst design using experimental as well as theoretical approaches. First principles calculations and microkinetic modelling are used to predict the catalyst shape and structure, investigate reaction mechanism, computational fluid dynamics are used for reactor design. [3]

**Experimental/methodology.** Using DFT calculations, we are modelling a Ru catalyst for ammonia synthesis. For the purpose of our symulations, we used the GPAW software where the wave functions were described with plane waves (PW) with a cut-off energy of 450 eV and a 2x2x1 k-point mesh. The dispersion correction DFT-D3 and dipole correction were applied to our calculations. NEB calculations with the climbing image approach were used to find transition states and activation barriers. The DFT results were used in microkinetic modelling.

**Results and discussion.** First-principles calculations allowed us to calculate favourable adsorption sites for the single atom as well as the molecular adsorption over Ru(0001) slab. We studied 6 possible adsorption sites for $N_2$ adsorprtion. Lattice size manipulation allowed us to model entire dissociative mechanism for ammonia production and to create relations between the activation barrier and adsorption energies for further Ru nanoparticles modelling. We have modelled simple Ru nanoparticles and researched different edges, planes and vertices in order to find the most favourable Ru shape for ammonia production.

**Figure 11: Ammonia synthesis mechanism over Ru (0001).**

# Predicting Adsorption Energies on Bimetallic Cu-based Catalysts via ML

A. Usuga[1*], A. Comas-Vives[1,2]

[1]*Department of Chemistry, Universitat Autònoma de Barcelona, 08193 Cerdanyola del Vallès, Catalonia, Spain.*

**Keywords:** DFT, Machine Learning, bimetallic alloys, adsorption energy.

**Introduction.** Increasing the performance of heterogeneous catalysts is challenging. To predict better materials for tailored reactions, it is a fundamental step to relate the nature of catalysts and their catalytic activity. Theoretical studies allow screening at a lower cost compared to experiments. Adsorption energies of reactive intermediates are a key catalytic descriptor, as one can relate them to the catalytic activity. Nevertheless, the calculation of adsorption energies is costly and increases with the number of reaction intermediates, facets and the complexity of the evaluated materials. For instance, in the case of bimetallic alloys, the adsorption energies of catalytic intermediates are not easily predictable since they do not follow a linear trend among adsorbates of the same family. Thus, machine learning (ML) algorithms have arisen as an alternative to predict adsorption energies on monometallic surfaces [1]. Still, they must be redesigned to predict the adsorption energies of bimetallic alloys.

**Experimental/methodology.** The present work focuses on built-up a workflow to generate a database; this database will be used to train an ML-based model to predict the adsorption energy on bimetallic alloys. We first design a workflow to generate the database for different facets of Cu-based alloys: the generation of each bulk structure, the bulk optimization to get its lattice parameter used to build the slab, the relaxation of the clean alloy surface, and adding the adsorbate on it, and finally, reoptimize the resulting structure to obtain its adsorption energy. Currently, we are working on aspects related to the parameters of the ML-based model; we are developing and testing features of both the clean surface and the adsorbate.

**Results and discussion.** With the development workflow to generate the database, we got several surface models using FCC bulk structures. Some effects were included in the ML model to increase their robustness; the following list contains the studied aspects: the facet, possible slab termination, chemical composition, and type of adsorption site. Additionally, we use features that only require calculating properties for the clean surface and insulated adsorbate, such as Bader charges, occupancies, electronegativities, and coordination numbers. With the current model based on the XGBoost ML algorithm, we obtain a model with an MSE of 0.012 and 0.307 eV for the train and test sets, respectively. The current ML model shows that it is possible to predict the adsorption energy in complex systems such as bimetallic alloys.

**Keywords:** m-$ZrO_2$, FTIR-DRIFTS, DFT, XPS, $CO_2$ adsorption, O migration

**Introduction.** Stable CDRM performance of a catalyst is dominantly determined by its ability to dissociate $CO_2$ to produce and utilize surface oxygen at rates high enough to clean surface carbon formed on its active sites. The current study is an attempt to understand the nature of $CO_2$ activation on a commercial $ZrO_2$, which is a widely used CDRM support responsible for $CO_2$ dissociation and surface O mobility, via combined evaluation of computational and experimental findings.

**Experimental.** Calcined and reduced $ZrO_2$ (from Alfa Aesar), ground to 45-60 mesh size, was characterized by using a XRD and XPS. The FTIR-DRIFTS analysis was performed on a Bruker Vertex 70V equipped with an MCT detector, and DRIFTS cell with ZnSe window. The spectra were collected at a resolution of 4 $cm^{-1}$ and 128 scans. The samples prepared in powder form were blended with KBr in 1 to 5 ratio. $CO_2$ adsorption tests were carried out with 10% $CO_2$-He mixture at RT, 373 K and 573 K for 30 min and the mixture was flushed with pure He flow for 30 min afterwards.

**Computational.** Spin-polarized DFT calculations were performed for repeated slab geometry, by using the program package CASTEP in Materials Studio. Exchange and correlation were included through the use of GGA-PBE functional. m-$ZrO_2(\bar{1}11)$ surfaces were modeled as a two-layer slab with 14 Å vacuum thickness. Adsorption of $CO_2$, CO and O was studied on (1x1) surface unit cell. Adsorption energies were calculated. Local density of states (LDOS) analysis was performed. The energy barrier for an oxygen atom moving from one stable site to another was calculated by the CASTEP Transition State Search Task.

**Results and discussion.** The XRD spectrum showed peaks corresponding to characteristic reflection planes of monoclinic zirconia (JCPDS 86-1449). FTIR-DRIFTS analyses of $CO_2$ adsorption on m-$ZrO_2$ samples at different temperatures confirmed $CO_2$ activation and $ZrO_2$-$CO_2$ interaction via detection of surface bicarbonate, carbonate, formate and OH species as well as bridged CO (Figure 1). It was also shown that the extent of the interaction is very much related to temperature; reversible formate formation pathway is found to dominate at 573 K. XPS analysis results revealed the existence of oxygen vacancies and defect sites. DFT simulations of $CO_2$ adsorption revealed that bidentate and tridentate carbonates are formed while dissociative $CO_2$ adsorption does not take place on m-$ZrO_2(\bar{1}11)$ surface. The lower energy barrier for oxygen mobility between sites A, B, C and D which is below ca. 1.0 eV enables higher oxygen mobility on these sites (Figure 2). High oxygen mobility on $ZrO_2$ surface allows O migration from $ZrO_2$ support to the catalyst active metal sites suffering from surface carbon deposition. Combined evaluation of experimental and computational results hints that O-defect on m-$ZrO_2$ are necessary for $CO_2$ siplitting.

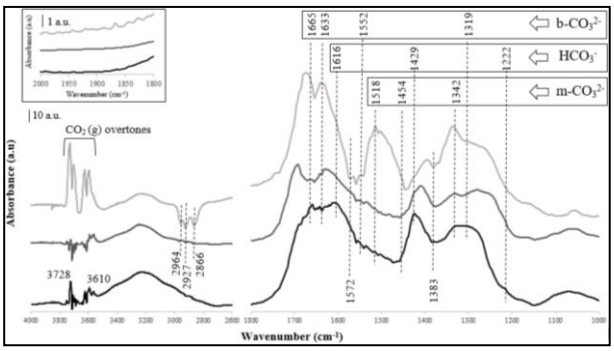

**Figure 1.** FTIR-DRIFT spectra obtained on $ZrO_2$ after He flush of 10% $CO_2$ adsorption at RT(bottom), 373 K and 573 K (top).

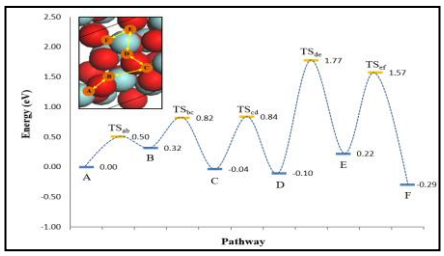

**Figure 2.** Potential energy profile for oxygen mobility pathway on m-r$O_2(\bar{1}11)$ surface.

# Elucidation of Structure–Activity Relations in Electrocatalytic Hydrogen Evolution Reaction at Pd Hydride Surfaces: Theoretical Insight

A. Ngoipala, R. Lipin, R. L. Arevalo, M. Vandichel*

*Department of Chemical Sciences and Bernal Institute, University of Limerick, Limerick, V94 T9PX, Ireland*
**matthias.vandichel@ul.ie*

**Keywords:** density functional theory, palladium, hydride formation, strain effect, hydrogen evolution reaction

**Introduction.** The structure–activity relationship is a cornerstone topic in catalysis, which lays the foundation for the design and functionalization of catalytic materials. Of particular interest is the catalysis of the hydrogen evolution reaction (HER) by palladium (Pd), which is envisioned to play a major role in realizing a hydrogen-based economy. Interestingly, experimentalists observed excess heat generation in such systems, which became known as the debated "cold fusion" phenomenon.[1-3] Despite the considerable attention on this report, more fundamental knowledge, such as the impact of the hydride formation on the stability of Pd hydride structures and HER activity, remains largely unexplored.

**Experimental/methodology.** In this work, first-principles density functional theory calculations were carried out to characterize the adsorption and absorption behaviors of hydrogen on Pd surfaces, directing a particular focus on the stability and HER activity of model Pd hydride surfaces.

**Results and discussion.** Our computational results reveal that among the low-indexed surface planes for an fcc Pd, the (111) surface is not only expected to be the most dominant surface in a Pd nanostructure, but also the most preferred surface for hydrogen adsorption. The calculated surface energies indicate the greater stability of the surfaces containing hydrogen subsurfaces over the corresponding clean ones (Table 1). Under electrochemical conditions, the calculated Pourbaix diagrams show that below the equilibrium potential and pH region at which HER can take place, Pd surfaces are already covered by hydrogen adatoms. In addition, the thermodynamically most stable systems contain more and more Pd hydride subsurface layers when decreasing electrode potential. Interestingly, the formation of subsurface hydride results in a compressive strain, which lowers the H adsorption free energy on (111), (110), (100), and (211) facets, thereby increasing the HER activities. In the presence of strain, the HER activities in the model surfaces were in the decreasing order of (211) > (111) > (110) > (100), in agreement with the experimental results.[4] These findings provide significant insights into the role of subsurface hydride formation on the structure–activity relations toward the design of efficient Pd-based nanocatalysts for the HER.

**Table 1. Calculated surface energy of Pd(111), (100), (110), and (211) surfaces containing different numbers of PdH sublayers.**

| Number of PdH sublayers | Surface energy ($\gamma$)*, eV/Å$^2$ | | | |
|---|---|---|---|---|
| | Pd(111) | Pd(100) | Pd(110) | Pd(211) |
| 0 | 0.132 | 0.145 | 0.150 | 0.147 |
| 1 | 0.092 | 0.112 | 0.124 | 0.103 |
| 2 | 0.056 | 0.075 | 0.101 | 0.066 |
| 3 | 0.031 | 0.047 | 0.079 | 0.033 |
| 4 | 0.005 | 0.018 | 0.058 | 0.004 |

* $\gamma = \gamma_{H^*_{sub}/Pd} - \gamma_{Pd,clean}$ where $\gamma_{H^*_{sub}/Pd} = \frac{1}{A}\left(E_{Pd,slab+H^*_{sub}} - \frac{N_H}{2}E_{H_2} - N_{Pd}E_{Pd_1,bulk}\right)$; $\gamma_{Pd,clean} = \frac{1}{2A}\left(E_{Pd,slab} - N_{Pd}E_{Pd_1,bulk}\right)$
